THE CARDIAC OUTPUT IN MAN: STUDIES WITH THE LOW FREQUENCY, CRITICALLY-DAMPED BALLISTOCARDIOGRAPH, AND THE METHOD OF RIGHT ATRIAL CATHETERIZATION [1]

By J. L. NICKERSON, J. V. WARREN, and E. S. BRANNON

(From the Department of Physiology, College of Physicians and Surgeons, Columbia University, New York, and the Medical Service of the Grady Hospital and the Department of Medicine, Emory University School of Medicine, Atlanta)

(Received for publication November 13, 1945)

Although the determination of cardiac output from the ballistic recoil of the body with each heart beat has been used repeatedly during the past 40 years, it has not been entirely satisfactory for general clinical use. Recently a survey of the problem has been made by Nickerson and Curtis (1), and as a result of this investigation they have recommended certain conditions to be satisfied in the construction of the ballistic system. Since a simple and reliable clinical method for the determination of cardiac output is of considerable importance, we have undertaken to test the type of ballistocardiograph described by Nickerson and Curtis. Studies have been made measuring the cardiac output by the ballistocardiograph, and by the method of right atrial catheterization utilizing the Fick principle.

APPARATUS

The ballistocardiograph used in this study differs from the instrument described by Starr *et al.* (2) in two main respects: (*1*) the undamped natural frequency of the bed is low; (*2*) the system is critically damped. The frequency of our bed is 1.5 cycles per second, whereas that of Starr was much more rapid. The bed described here is damped so that when it is deflected from its resting position, it returns to the original position with a minimum of overshooting. This is "critical damping" in the terminology of the physicists.

The apparatus used in this study differs from that of Nickerson and Curtis (1) only in that it was constructed for mounting on the fluoroscopic table upon which the right atrial catheterizations were performed. This arrangement permitted the almost simultaneous determination of the cardiac output by the technique of right atrial catheterization and by the ballistic method.

The ballistic bed consisted of a flat wooden table-top mounted on 4 flat strips of spring steel (Figure 1), so that movement in the longitudinal direction only was possible. The weight of the moving parts of the bed was about 75 pounds; the actual amount was not at all important, since variations in it were accounted for in the calibration to be described. Observations of the effect of increasing the weight of the moving part of the bed have led us to believe that it is more important that the bed be rigid than that it be of light weight. The effective length of the 4 springs upon which the bed was mounted was adjustable by means of clamps (Figure 1), so that the undamped frequency of the ballistic system could be brought to the same value (1.5 cycles per second) whatever load was placed on the bed. (The same result could be attained by keeping the spring lengths constant and supplementing the patient's weight by dead weights, thus maintaining the total load and hence the undamped frequency constant.) It should be noted that when calibrating the bed to its proper frequency for various loads, the damping bellows, emptied of oil, should be connected in the system so as to contribute its part to the restoring forces determining the movement of the bed. It is also important that the sylphon bellows be as flexible as possible in order to add but little to the restoring forces. The most satisfactory bellows requires a force of not more than 0.5 pound to compress it about 0.100 inch. The proper position of the clamps for each load was marked on a scale graduated in steps of 5 kgm., so that once calibrated, the setting of the ballistic bed to the nearest 5 kgm. for a subject of any weight was a rapid and simple procedure.

After the frequency calibration had been completed, the damper bellows, tube and reservoir (Figure 1) were filled with oil, care being taken to exclude air bubbles from the system. The position of the damping rod to produce critical damping for each load was then determined. The condition of critical damping can be practically considered as that situation where the bed on release from a displaced position moves back to its resting place with a minimum detectable overshoot. The calibration was made for a wide range of bed loads and over an oil temperature range corresponding to the room temperatures customarily found. When these calibrations were completed it was sufficient to know the oil temperature and the patient's weight in order to set the damping rod at the proper value.

The movements of the bed were recorded optically on

[1] The work described in this paper was done under contracts, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Columbia University and also between the Office of Scientific Research and Development and Emory University School of Medicine.

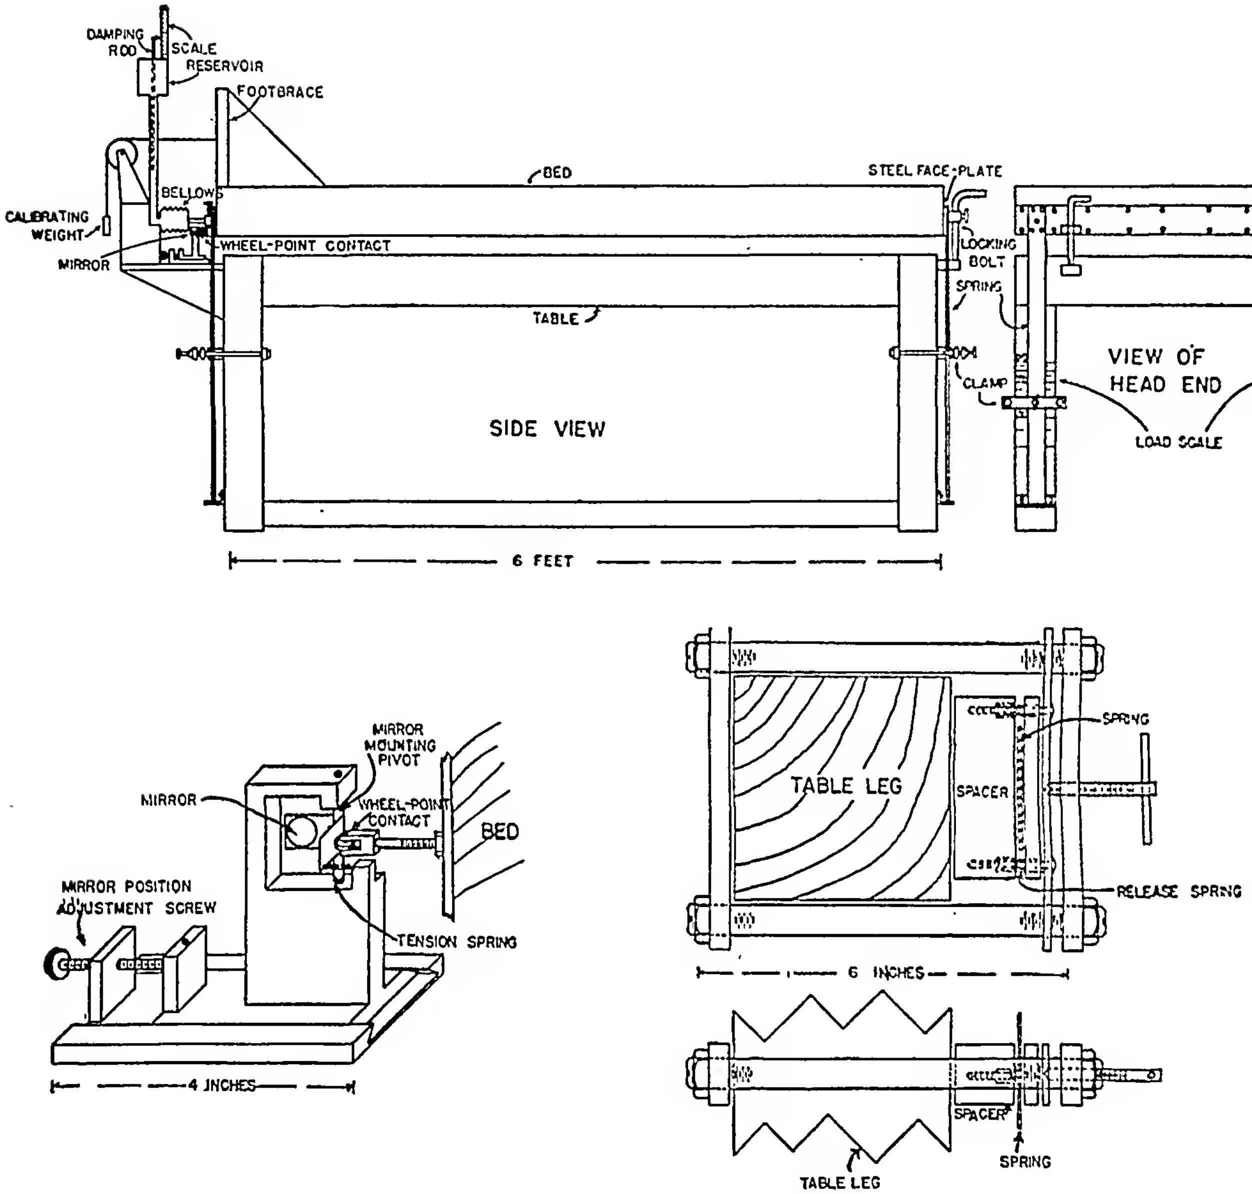

FIG. 1. DETAILS OF THE CONSTRUCTION OF THE BALLISTIC BED AS MOUNTED ON A TABLE

The figure shows the flat springs on which the bed is supported, the spring clamps, the locking bolt damping system, the pickup mirror mounting, and wheel-point contact. The spring clamp and mirror sy are shown in considerable detail.

photographic paper. A light beam was reflected from a small pivoted concave mirror, which was held by means of a small spring against a frictionless wheel point moving with the ballistic bed (Figure 1). The movements of the reflected light were recorded by a camera similar to that used in an electrocardiographic apparatus.

METHOD

The subject was placed on his back on the ballistocardiograph with the soles of the feet tight against the upright foot-board, and the breath held in mid-position while the tracing was being taken. Figure 2 shows a typical tracing, with the headward deflections recorded in the upward direction, and the footward deflections in the downward direction. The initial major footward tion (I) resulting from the recoil due largely to tion of blood by the heart, and the initial maj

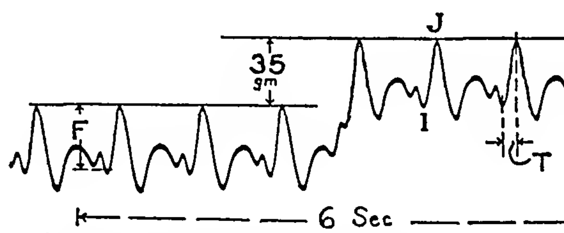

FIG. 2. A CHARACTERISTIC BALLISTOCARDIOGRAPH

This figure demonstrates the method of calibrat indicates the measurements to be taken from the

ward deflection (J), resulting in the main from the slowing of blood in its headward course and from its turning around the aortic arch, are the most important landmarks in the tracing. A force of 35 grams was applied to the system during a portion of the tracing by weights attached to the foot of the ballistic bed and hanging over a light frictionless pulley. This offered a means of calibrating the bed while it was under the actual conditions of use, by showing how far the base line was displaced by a standard force. Knowing the displacement caused by the standard force, the displacement of the major deflection can be converted to the force involved (F) by measuring the distance between the peak of the first major footward deflection (I) and the peak of the first major headward deflection (J) and making a simple proportionality calculation. Two other measurements were required from the tracing: (*1*) the heart rate, and (*2*) the time interval in seconds (T) between the peak of the first major footward movement (I) and the peak of the first major headward movement (J).

The formula used for computing the cardiac output is slightly modified from the basic equations discussed in an earlier paper (3). The stroke volume is given by:

$$SV = \frac{5.02\, F\, P}{T\, L}\ \text{ml.},$$

and the cardiac output equals the stroke volume multiplied by the heart rate, where F and T have been defined above and, along with the heart rate, are obtained from the ballistic record. The quantity L is the height of the subject in centimeters, and 5.02 is a constant determined to adjust the ballistic results to a best fit with the catheter data. The factor P over most of the range of blood pressures, equals the square root of the arithmetic mean of the systolic and the diastolic pressures. However, at low pressures the results computed using $\sqrt{P_a}$ in the formula were somewhat too large, since with the correspondingly small stroke volumes, the momentum of the center of gravity of the heart muscle provided an appreciable part of the impact. For this reason, a table of P values (Table I) has been provided which gives a better fit for the data on normal subjects. As seen in Table I, the values of P differed only from $\sqrt{P_a}$ at low pressures.

The methods used in the cardiac output determination by the catheter technique have been described elsewhere (4). Samples of mixed venous blood were obtained by passing a flexible radiopaque catheter through the venous system into the right side of the heart. Arterial blood was obtained from an inlying needle in the femoral artery. Oxygen consumption was measured by collecting a 2- or 3-minute sample of expired air and analyzing its contents. From these data, utilizing the Fick principle, the cardiac output was calculated as follows:

$$\text{cardiac output} = \frac{\text{oxygen consumption}}{\text{arteriovenous difference}}.$$

Because the output of the heart varies with body size, we have facilitated comparison between individuals by expressing the output in terms of cardiac index. This is the cardiac output in liters per minute per square meter of body surface.

96	9.8	9.8			
98	9.9	9.9			

In obtaining the data reported here, all subjects, except the patients in shock, were studied in the morning 15 hours after the last meal. The catheter was passed and the arterial needle inserted. After a variable period of time, during which the subject was able to relax and reach a relatively stable state, the observations were made. At first, ballistic tracings were obtained both before and after the samples were taken for the Fick output. Later, because these tracings varied so little, they were obtained only either immediately before or after the Fick output determinations.

RESULTS

Eighty-one cardiac output determinations by the catheter technique and almost simultaneous ballistic tracings were made on 58 individuals. The data obtained on the first 50 of these determinations on subjects without heart disease or myxedema were used to evaluate empirically the constants in the stroke volume equation. The stroke volume constant 5.02, and the values of the pressure factor P given in Table I are the results of these determinations. Once determined, these constants, which gave the best fit of the ballistic and

the catheter data, were used throughout this study. This method of computing the cardiac output from the ballistic records does not invalidate a comparative study of the results of the 2 methods. Actually, it tests the success of the formula in fitting the ballistic data to that obtained by the application of the Fick principle. It should be remembered, however, that because of the empirical adjustment, the cardiac output by the ballistic method is dependent on the values obtained by the

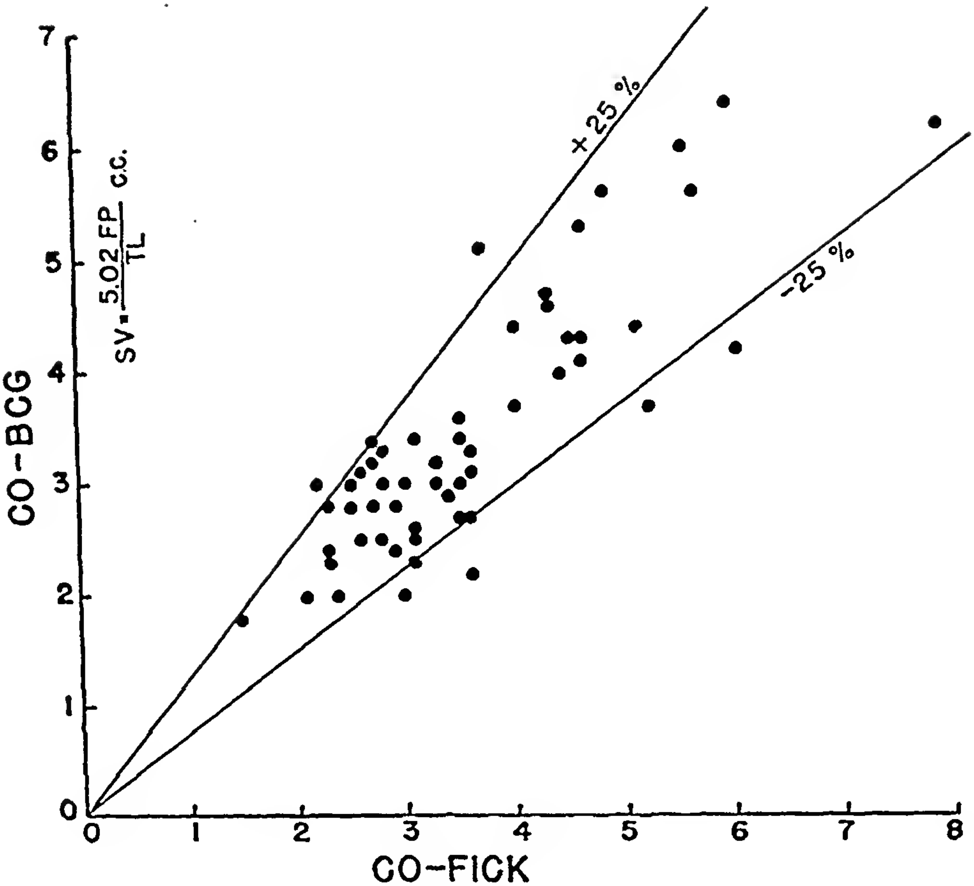

FIG. 3. CARDIAC INDICES COMPUTED FROM THE BALLISTIC TRACING PLOTTED AGAINST THE VALUES DETERMINED FROM THE CATHETER METHOD FOR PATIENTS IN WHOM THERE IS NO CLINICAL EVIDENCE OF CARDIAC DISEASE

The limits of ± 25 per cent deviation from the catheter values are shown.

catheter technique and is subject, therefore, to any fundamental errors in that method.

Fifty-four of the observations reported here were made on 32 subjects without clinical evidence of heart disease. The data on this group are given in Table II. These subjects represent a cross-section of the hospital population. They include members of the staff, convalescent patients, patients with anemia, thyrotoxicosis and shock, and normal subjects given albumin and saline intravenously. If the subjects were cooperative, and if the technical procedures were satisfactory, the data were used, regardless of whether or not the subject showed evidence of anxiety or apprehension. We are primarily interested in determining the relation of the ballistic tracings to the cardiac output as measured by the catheter technique under a variety of conditions, rather than in establishing basal values for the cardiac output. The comparison of the cardiac indices as measured by the 2 methods is shown for this group of subjects in Figure 3. Eighty-seven per cent of the values obtained by the ballistic method fall within 25 per cent of those by the catheter method. The correlation coefficient relating the data from the 2 methods has a value of 0.83.

Twenty-seven almost simultaneous measurements were made on a group of 26 patients with heart disease or myxedema. The data on these patients, with diagnosis, are given in Table III. The cardiac output as measured by the 2 methods did not agree as closely in this group as in the group without heart disease. Excepting those patients having aortic insufficiency, 60 per cent of the ballistic values of the patients in this group fell within 25 per cent of the catheter values (Figure

4). As one might expect on theoretical grounds, the patients with aortic insufficiency failed to show good correlation between the 2 methods. While the ballistic outputs were large, the catheter outputs were small, the difference between the ballistic and the catheter results giving some indication of the quantity of blood regurgitated during each cardiac cycle.

With the exception of those patients with aortic insufficiency, the cardiac output as calculated from the ballistic record fell within 25 per cent of that obtained by the catheter method in 80 per cent of the cases for the entire group studied.

Serial measurements were made at various stages in the treatment of 5 patients in shock (Figure 5). In Figure 6 portions of 4 successive ballistic records taken on one such patient are shown. All patients had distinct clinical evidence of shock. Two (W.T. and M.Z.) were patients with hemorrhagic shock from superficial stab wounds, one (L.A.) with a penetrating stab wound of the chest, one (E.J.) following an operative procedure for tuberculous infection of the kidney, and one (S.M.) with shock resulting from hemorrhage after drainage of a periurethral abscess. All, except one whose arterial pressure was 103/59, had systolic blood pressures below 100 mm. Hg at the time the initial measurements were made. The increase in cardiac output after treatment with saline and albumin was shown by both methods of measurement, and the agreement between the methods was good. In fact it appears that changes

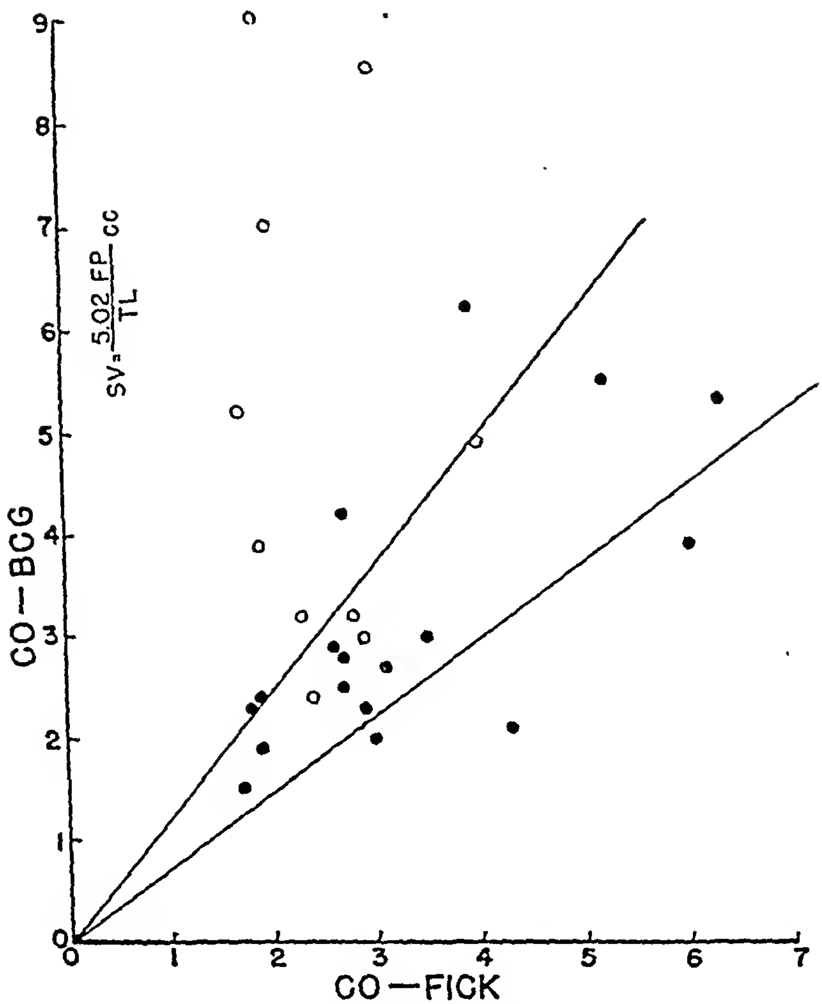

FIG. 4. THE CARDIAC INDICES FROM THE BALLISTIC TRACINGS PLOTTED AGAINST THE CATHETER VALUES FOR ALL SUBJECTS DIAGNOSED AS HAVING CARDIAC DISEASE OR MYXEDEMA

Those patients having aortic insufficiency are specifically designated by open circles. The limits of ± 25 per cent deviation from the catheter values are shown.

in cardiac output for any individual subject were measured with considerable accuracy by the ballistocardiograph.

Variations in arterial pressure, heart rate and age appear to cause no significant variation in the relationship between the cardiac index as measured by the ballistic method and as determined by the catheter method. This is demonstrated in Figure 7 where the ratios of the ballistocardiograph values to the catheter values are plotted against blood pressure, heart rate, and age. This figure includes the patients without heart disease (solid dots) and the patients with heart disease (open dots), except those patients having aortic insufficiency.

DISCUSSION

In comparing the ballistocardiographic determinations of the cardiac output with the method which involves right atrial catheterization and the application of the Fick principle, it must be remembered that the latter method is a procedure subject to considerable error. Although it does not afford an ideal standard for comparative studies, it does, however, appear to offer the best means available. Its limitations have been evaluated in other

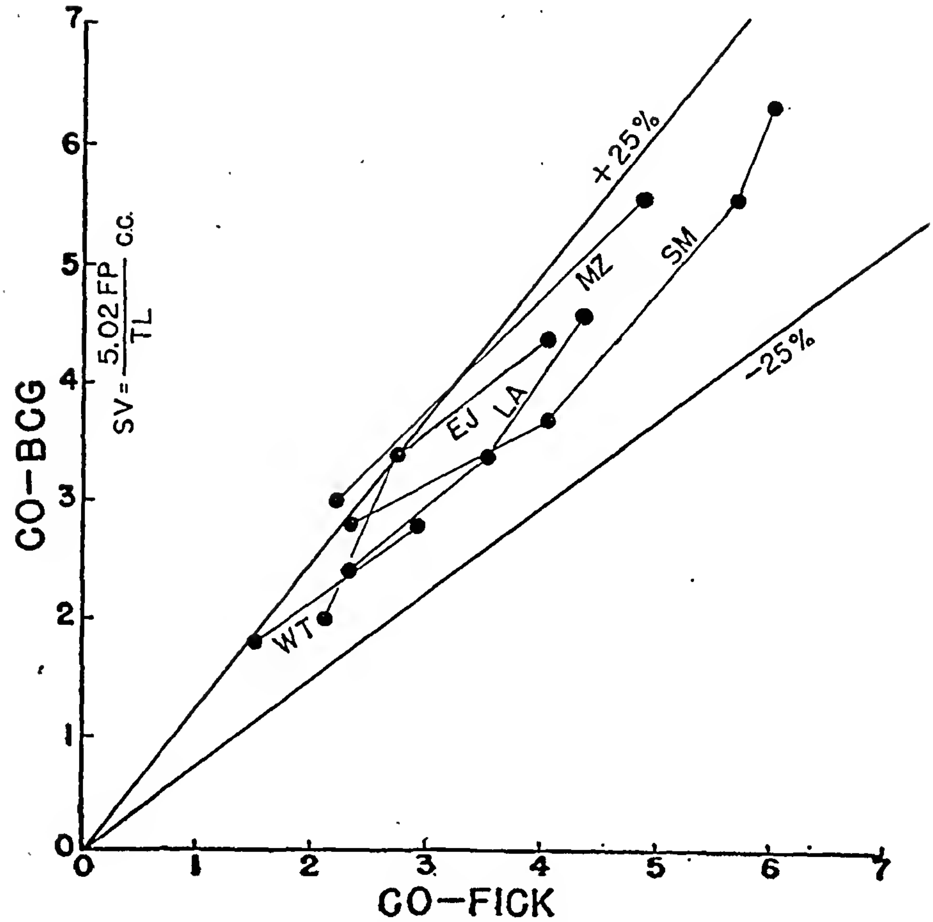

FIG. 5. SERIAL CARDIAC INDEX OBSERVATIONS ON 5 PATIENTS IN SHOCK AND WITH TREATMENT

The limits of ± 25 per cent deviation from the catheter values are shown.

communications from this laboratory (4, 5). Such factors as technical variations in the chemical determinations, inadequate sampling of mixed blood due to the streaming of the blood within the heart, and minute to minute variations of the cardiac output account for unavoidable errors, which may at times rise as high as ± 25 per cent. Moreover, since the computation of the cardiac output depends on the arteriovenous difference, the effect of errors will be larger when this difference is small. These factors should be considered in evaluating this comparative study; and because of these factors even a perfect ballistocardiographic method would fail to give excellent correlation.

The only other reported study comparing the ballistocardiographic method to the catheter technique of cardiac output determination is that of Cournand *et al.* (6). These authors used a high frequency, undamped ballistocardiograph, and found good correlation in relatively normal subjects. We believe that since our patients represent a wider variety of disease conditions, a wider variance of the data is to be expected. In a later publication (7) these authors reported that they were led to discard the high frequency ballistocardiograph for the patients in, or recovering from, shock. This objection to the use of the ballistocardiograph in the study of shock was not found to be applicable to the instrument described in the present paper.

The low frequency, critically-damped ballistocardiograph offers a remarkably simple and rapid method of determining the output of the heart. Rapid changes in output may be followed with ease, thus permitting studies to be made which are not possible by any other method. It is of particular value in following the output changes in an individual subject such as the studies of patients in shock recorded here. The ballistocardiograph, however, is not without disadvantages. As was anticipated, our data demonstrate that the

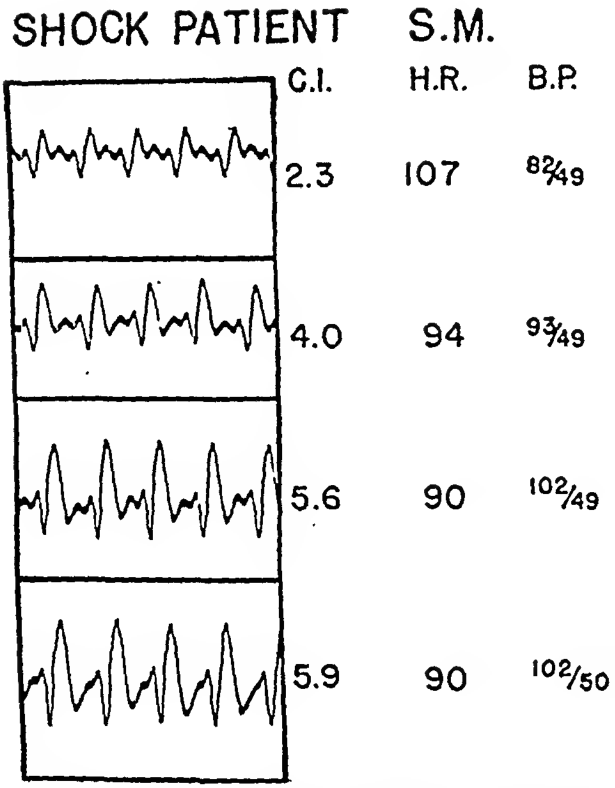

Fig. 6. Portions of the Successive Ballistic Tracings and Some of the Measurements on the Shock Patient S. M. of Figure 5

findings in aortic insufficiency are unrelated to the effective output of the heart. Good results are difficult or impossible to obtain in patients with marked respiratory distress, or those unable to hold their breath for even a few seconds. Extremely irregular heart rhythms and marked tremors might also be mentioned as factors leading to results that are unsatisfactory. Finally, in some patients, particularly those with myocardial disease, we have seen patterns of unusual shape that are quite difficult to interpret.

CONCLUSIONS

The details of the construction of a low frequency, critically-damped ballistocardiograph are presented in this paper, and the procedures for its adjustment to definite physical conditions described. The adjustments enable the reproduction of this type of ballistocardiograph to be made easily, and permit, without the necessity of further calibration by the catheter method, the use of the stroke volume equation tested in this study.

Eighty-one determinations of the cardiac output by the method of right heart catheterization and by almost simultaneous ballistic records with the low frequency, critically-damped ballistocardiograph have been made on a group of 58 normal subjects and hospital patients under a variety of conditions. From the first 50 of these observations on subjects without heart disease, constants were derived for use in determining the cardiac output from the ballistic record. Applying these constants to the entire group of subjects (except patients with aortic insufficiency) the cardiac output computed by the ballistic method fell within 25 per cent of that obtained by the catheter method in 80 per cent of the cases.

Fifty-four of these determinations were made on subjects without evidence of heart disease, but with a variety of other illnesses. Eighty-seven per cent of the results by the ballistic method lay within 25 per cent of the values by the catheter technique. The other twenty-seven patients studied had clinical evidence of heart disease or myxedema. For 17 patients in this group, *i.e.*, excepting those with aortic insufficiency, the cardiac output by the ballistic method was within 25 per cent of that by the catheter technique in 60 per cent of the cases. Patients with aortic insufficiency showed marked discrepancies between the results from the ballistocardiograph and from the catheter method. As might be expected, the ballistic method gave output results which were considerably higher than those by the other method.

Serial measurements on patients in shock and during recovery showed a good correlation between the cardiac output measurements by the 2 methods. These results suggest that changes in cardiac output in any individual subject may be measured with considerable accuracy by the ballistocardiograph.

It is concluded that the low frequency, critically-damped ballistocardiograph provides a useful and reasonably accurate method of determining cardiac output in normal subjects, and in patients with a variety of disease conditions.

We wish to thank Mr. Herman Just of the Department of Physiology, Columbia University College of Physicians and Surgeons, for his precise work in the construction of the ballistic bed, especially the clamps for adjusting the spring lengths. Mrs. Jane Bailey, Miss Eloise Cavin, Miss Maurine Giese and Miss Lois Jackson gave valuable technical assistance.

INTUBATION STUDIES OF THE HUMAN SMALL INTESTINE. XXV. THE ABSORPTION OF GALACTOSE FROM THE INTESTINE OF NORMAL INDIVIDUALS AND THYROTOXIC PATIENTS

By VINCE MOSELEY and FRANCIS W. CHORNOCK

(From the Gastro-Intestinal Section, Kinsey-Thomas Foundation, of the Medical Clinic, Hospital of the University of Pennsylvania, Philadelphia)

(Received for publication December 10, 1945)

The concentration of galactose in the blood stream at determined intervals after its ingestion has been proposed as a clinical test of intestinal absorption (1). It is said not only to indicate the rate at which galactose is absorbed from the intestine, but also to be a means of measuring the ability with which and the rate at which the intestinal mucosa absorbs various substances by the mechanism of phosphorylation (1 to 4). Some workers, finding by this procedure that the thyrotoxic patient shows a higher galactose curve than does the normal subject, have attributed this result to a specific accelerating action on intestinal absorption by the thyroid hormone (2 to 5).

The blood concentration of a substance following its ingestion, however, is not dependent solely on the capacity of the intestinal mucosa to absorb it. First of all, and most important, it is necessary to know whether or not, and to what extent, the material reaches the absorbing surface, and so is available for absorption. The hexoses are absorbed chiefly from the duodenum and jejunum (6 to 9), and from the stomach only when in hypertonic solution (10, 9). Consequently, alterations in gastric and intestinal motility, whether due to organic or functional disturbances, may profoundly affect the availability of the ingested galactose in the absorbing area (6, 29b, 29c). In spite of the experimental evidence that glucose and galactose orally administered are absorbed at a constant rate and independent of their concentration (11, 12, 8), this holds true only within certain limits (13, 6). When widely varying concentrations of a sugar are introduced directly into the intestine the absorption rate is proportional to the concentration (15, 29d, 31, 32, 36).

Secondly, it has been demonstrated in animals that irrespective of the actual rate of hexose absorption, the concentration in the blood is chiefly dependent on metabolic factors (11, 12). In this respect the liver is the principal, though not the sole, organ involved (14, 15, 19b, 24, 35). Hepatic dysfunction especially has been held responsible by some authors for the hypergalactemia found after the ingestion of that sugar in the thyrotoxic patient (29a). Furthermore, in such a condition, as well as in cases with various nutritional, endocrine, and urinary tract disturbances, the renal output of the sugar is often altered (16 to 24, 14, 15). Thus the rate of its excretion constitutes a third factor that influences the concentration of galactose in the blood (24, 29e).

Finally, it has been claimed, as we shall show, that the blood concentration of galactose is in some way affected by the coincident concentration of glucose (15, 16, 20, 21, 25).

In an attempt to obviate some of these disturbing factors, we have employed the absorption technique devised by Nicholson and Chornock (26), which makes possible over a fixed period of time the presence of a known quantity of the galactose in a predetermined area of the intestinal tract. Thus it measures accurately the availability of the galactose for absorption and the actual quantity absorbed, and so eliminates the chief factors that previously, for the human subject, had not been controlled. The other factors, metabolic disturbances and excretion through the kidneys, have been controlled insofar as possible by the selection of the subjects for the experiments.

SUBJECTS AND METHODS

For this study, 6 normal persons and 5 patients with thyrotoxicosis were employed. The normals were paid subjects found to be in good health by history, physical examination, and clinical laboratory studies. Radiological examinations of the gastro-intestinal tract and the basal metabolic rates were within normal limits. The hyperthyroid subjects exhibited clear-cut clinical pictures of thyrotoxicosis, and were patients from the medical wards awaiting thyroid surgery.

The details of the technique developed by Nicholson and Chornock need not be repeated. It involves the injection of the test solution into the mid-duodenum through one lumen of the Miller-Abbott tube (27) and the removal of the residue from the jejuno-ileal area, 90 cm. lower in the tract, through the other lumen.

The subjects fasted 12 hours (overnight) and on the morning of the test day, after getting the apparatus into its proper position, which usually required 2 to 3 hours, the absorption study was undertaken. The absorption period varied from 30 to 90 minutes, and the exact procedure was as follows: A 10 per cent solution of galactose was allowed to drip into the mid-duodenum via the first lumen at a rate of 10 ml. per minute. It was introduced by means of a flask with a Murphy drip attachment at a hydrostatic pressure of 75 cm. The rate of drip was regulated by means of a Hoffman clamp. This concentration of galactose and the rate of its administration were selected after preliminary experiments indicated that they gave the most consistent results.

As soon as the galactose began to flow into the duodenum, aspiration of the succus from the jejunum was begun. All of the material aspirated during the experimental period was collected in flask No. 1 and subsequently analyzed quantitatively for its galactose content. By subtracting this unabsorbed quantity, plus the quantities obtained in flasks 2, 3, 4 and 5 (the details of collection of which are outlined below), from the amount administered, a calculation of the amount absorbed was derived.

After administering the desired quantity of galactose, the absorption period was abruptly terminated by discontinuing the galactose drip, removing flask No. 1 and injecting 30 ml. of a 33 per cent solution of magnesium sulfate into the duodenum. In each experiment, in order to check on the abruptness with which the absorbing period was ended, a 30-minute period of washing the bowel with tap water was carried out. Aspiration was continued using flasks Nos. 2, 3 and 4 for the collection at 10-, 20- and 30-minute periods. Each of the specimens obtained during this wash period was analyzed for galactose. The tap water wash was performed in the same manner as the galactose was administered.

As can be seen by reference to Table I, except in specimen No. 2, which immediately followed the magnesium sulfate injection, only traces of galactose were present after the experimental period, thus indicating that the peristaltic rush induced by the magnesium sulfate solution was highly effective in abruptly terminating the absorption period. The intensity of this peristaltic rush, and the completeness with which it cleared the intestinal lumen, were confirmed in a few experiments by adding vital red in known concentration to the magnesium sulfate solution and determining its time of appearance; this was from 1 to 3 minutes. Furthermore, it was demonstrated that most of the dye and the sugar contained in specimen

* Thyrotoxic patient.

No. 2 appeared within the first 5 minutes of the 10-minute period of aspiration.

As a further check in every experiment, a fifth specimen (No. 5) was collected and analyzed. This consisted of the material that could be aspirated from the duodenum and stomach during the time the tube was being withdrawn. When any considerable amount of galactose was detected in this specimen, the experiment was discarded.

The absorption studies were conducted in the beginning over periods of 30, 60 and 90 minutes. As these revealed the rate of absorption to be fairly constant, a 30-minute period was chosen as satisfactory for the experiments comparing the results in normal and thyrotoxic patients (Tables I and II).

In addition to comparing the rate of galactose absorption in normal and hyperthyroid patients by this method, blood specimens were drawn at ½-, 1- and 2-hour periods after beginning the galactose administration, to determine the concentration of galactose in the blood stream (Tables III and IV). Thus a comparison of the blood galactose values of normal and of hyperthyroid individuals was accomplished simultaneously with the measurement of the amount of galactose absorbed from the intestine.

In a small group of experiments, a solution of glucose was administered ½ hour prior to the administration of the galactose solution, using the same technique of administration as was employed for the galactose. This modification of the experiment was employed in order to determine what effect this previous administration of glucose would have on the absorption of the galactose from the intestine, and on the concentration of galactose in the blood (Table V).

In every instance the chemical determinations on the blood and succus entericus specimens were conducted promptly after their collection.

Determination of blood galactose.

The blood specimens were collected in thymolfluoride tubes. Haden's methods for protein precipitation and for

‡ Thyrotoxic patient.

the preparation of whole blood filtrates were employed. The filtrates were then freed of glucose by means of yeast fermentation, by the method of Somogyi. Control tubes of glucose and of yeast suspension were simultaneously incubated with the blood filtrates. After adequate fermentation, the filtrates were centrifuged and filtered. The concentration of galactose was then determined in the filtrate by the method of Benedict, using a Klett-Summerson Photoelectric Colorimeter.

Determination of galactose in succus entericus.

The volume of each sample was measured. To 2 ml. of each sample were added 17 ml. of H_2O, 0.5 ml. of 10 per cent $ZnSO_4$, and 0.5 ml. of 0.5 N NaOH. This was shaken and filtered. The excess zinc was removed by adding a pinch of anhydrous Na_2CO_3, shaking well and filtering. In most instances the first 2 samples were diluted further, so that the final dilution was 1 to 100. Two ml. of each of the diluted samples were then analyzed for galactose.

RESULTS AND DISCUSSION

This method of studying the absorption of sugar from the duodeno-jejunal area was highly satisfactory in that it allowed control of the amount, concentration and time during which the sugar was delivered to a selected area of the intestine. The absorbing or experimental period, furthermore, could be abruptly terminated, an accomplishment not satisfactorily attained by other methods employable in the human subject (Table I).

Galactose, when given in 10 per cent solution, was found to be absorbed at a fairly constant rate in the same subject in repeated tests extending over intervals of 30, 60 and 90 minutes (Tables I and II) and varied between 13.4 and 25.6 grams per ½ hour for the different subjects. Calculating the grams absorbed on the basis of body surface area per ½ hour gave a closer correlation to serve as a basis for comparison in the different individuals (29d). The rates calculated on this basis were found to range from 8.7 to 15.7 grams per square metre of body surface per ½ hour, with an average value of 11.2 grams (Tables II and III).

No differences were observed between the rates at which the galactose was absorbed in 6 healthy and in 5 thyrotoxic patients, nor was there any notable difference in the blood galactose concentration of the 2 groups (Tables III and IV).

Furthermore, as can be seen by reference to Table III, there was no direct correlation between the blood galactose concentration and the amount of that sugar absorbed during a ½ hour period of its administration. When the administration was continued for a full hour, the second or 1-hour blood specimen, showed a somewhat higher galactose concentration than when the galactose was instilled for only ½ hour. The blood galactose concentrations obtained during the longer period of administration tended to resemble those after the oral administration of the sugar (Tables IV and V). This provides experimental proof that a variation in gastric motility, by increasing or decreasing the amount of galactose available for absorption, materially alters its concentration in the blood, even though the ability to absorb the sugar from the duodeno-jejunal area remains constant.

In view of these observations, serious doubt necessarily arises as to what, if any, value the glactose tolerance test has as a means of arriving at an index of intestinal absorption. Certainly, on the basis of these experiments, it seems valueless.

When glucose was given ½ hour prior to the administration of galactose, no matter whether the 2 sugars were administered orally or intra-duodenally, a considerable lowering of the concentration of the galactose in the blood occurred (Table V). This effect was not due to any decrease in the amount of galactose absorbed, thus indicating that the lowered blood concentration resulted from some other influence exerted by the glucose. These observations confirm those previously made, chiefly on experimental animals, which indicate that the metabolism of galactose depends in some way on the availability of glucose (20, 25).

TABLE V

The effects of the previous administration of glucose on the blood galactose concentration in normal subjects

Subject	Galactose administered	Method of administration	Galactose absorbed per sq. meter of body surface area per ½ hour	Blood galactose concentration: ½ hour	1 hour	2 hours
	grams		*grams*	*mgm. per cent*	*mgm. per cent*	*mgm. per cent*
G.C.	40	Oral		38	16	10
	30	Tube	12.1	88	69	
	30*	Tube	12.0		12	
M.B.	40	Oral		62	45	24
	30	Tube	15.5	58	22	
	30*	Tube	14.2		17	
C.B.	40	Oral		77	110	84
	30*	Oral		2	17	13
	30	Tube	13.2	42	29	
	30*	Tube	12.2		16	

* In this instance 30 grams of glucose were administered ½ hour before the galactose and by the same route.

The values obtained by us for the concentration of galactose in the blood of normal subjects were higher than those reported by Althausen (5), but they were of the same order of magnitude as have been reported by other observers (28, 29a, 30).

CONCLUSIONS

1. Employing the technique of Nicholson and Chornock in a study of the absorption of a 10 per cent solution of galactose from the upper human intestine, administered at a rate of 10 ml. per minute, the rate was found to range from 8.8 to 15.7 grams per square meter of body surface area per ½ hour, with an average of 11.2 grams.

2. The thyrotoxic patient, under identical conditions, does not absorb galactose any faster than the healthy individual.

3. The degree of galactemia bears no constant relation to the amount of galactose absorbed from the intestine in either the normal subject or the thyrotoxic patient.

4. Galactemia may be depressed by the previous administration of glucose without any decrease in the absorption of the galactose. This tends to provide further evidence to Folin's, Berglund's (20) and Bodansky's (25) statements that the retention and utilization of galactose by the body depend to a large extent on the availability of glucose and are not due to any decrease in absorption of the galactose as was thought to be the explanation in animal experiments (11, 12).

THE NUTRITIONAL REQUIREMENTS FOR NITROGEN BALANCE IN SURGICAL PATIENTS DURING THE EARLY POSTOPERATIVE PERIOD[1]

By CECILIA RIEGEL, C. EVERETT KOOP, JOHN DREW, L. W. STEVENS, AND J. E. RHOADS

WITH THE TECHNICAL ASSISTANCE OF LOUISA BULLITT, DOROTHY BARRUS, ROZANNE P. GRIGGER, MARIE BARNES, ANNE BARNHART, JANET BOGER, FRANCES BOWEN, EINA GOULDING, AND ELEANOR MCGINLEY

(From the Harrison Department of Surgical Research, Schools of Medicine, University of Pennsylvania and the Surgical Clinic of the Hospital of the University of Pennsylvania, Philadelphia

(Received for publication February 25, 1946)

The role of protein nutrition in the convalescence of surgical patients has been emphasized by many authors during the past 15 years, and much of this work has recently been ably reviewed by Lund (1). The observations of Cuthbertson (2), confirmed by Howard and his co-workers (3), that fractures of long bones resulted in a marked negative nitrogen balance which could not be overcome by substantial increases in the protein intake, raised certain questions regarding the possible effects on nitrogen requirements and nitrogen balance of extensive surgical operations. It seemed important to know how soon after operation a positive nitrogen balance could be re-established, and what levels of nitrogen and caloric intake would be required to accomplish this.

Many of the previous concepts of the protein nutrition of surgical patients have been based on changes which were found in the serum protein concentration at different periods. It is generally acknowledged that the use of such data may lead to erroneous conclusions, but they have continued to be used by many investigators chiefly because of the difficulties in carrying out the more informing balance studies. In this project, additional technical aid made it possible for us to carry out both types of study. Our results indicate that the serum protein concentration may, at times, increase in spite of a negative nitrogen balance during the period of study.

It has also been possible to compare the effectiveness of whole protein with various preparations of hydrolyzed protein in the maintenance of the patient's nutrition after an operation on the gastro-intestinal tract.

PROCEDURE

In selecting patients, we gave preference to young adult males, but we did not limit the study to this group. The patients selected had usually undergone an extensive surgical operation, and usually one which interfered, at least to some extent, with the ability to eat. Thus, preference was given to patients who had had a gastric resection, and to neurosurgical patients who had had a craniotomy or craniectomy. The latter group will be considered in more detail in a separate paper, but the entire series is presented in Table I.

In the gastric cases, Abbott-Rawson tubes were frequently placed at operation either according to the oro-jejunal method of Stengel and Ravdin (4) or according to the gastro-jejunal method of Bisgard (5). In the craniotomy cases, Levine tubes were often passed into the stomach. Some patients in both groups were fed by mouth.

The various types of feeding used may be listed as follows:

1. Food from a metabolic kitchen, either in the form of a liquid, soft or full hospital diet.
2. Amigen (enzymatic digest of casein and pancreas).[2]
3. Amigen and hospital diet.
4. Lactalbumin hydrolysate.[3]
5. Gastrostomy mixture prepared in the following proportions:

Skim milk	500 ml.
Skim milk powder	50 grams
Cottage cheese	50 grams
Soybean flour	50 grams
Egg	1

Preparation of feedings.

The desired amount of Amigen was dissolved in water and either glucose, starch or Dextrimaltose added to make

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research between the Office of Scientific Research and Development and the University of Pennsylvania.

[2] Amigen powder (Mead Johnson & Co.).

[3] Wyeth and Co.

up the predetermined number of calories. In some patients the Amigen was given in water, and additional calories were furnished by a glucose solution given intravenously. The volume of solution given by mouth or tube was approximately 200 ml. at a single feeding, and the frequency of feeding was varied so as to provide the total amount of nitrogen and the calories desired in any 24-hour period. Usually 200 ml. were given every 2 to 3 hours. Lactalbumin hydrolysate was administered in the same manner as Amigen. The gastrostomy mixture was prepared in the laboratory, and carbohydrate was added to provide the desired number of calories.

In the early part of the work the patients were studied for 10 days postoperatively. It became apparent that the usual negative nitrogen balance found following operation became a positive balance as the patients began to eat larger quantities of food. In the latter part of our work, therefore, we limited our nitrogen balance studies to the first 5 days of the postoperative period.

Methods of administration.

When food was given by mouth, it was offered at regular hours, and records were kept of the food actually ingested. When the patient was on a constant intake, the portions not eaten at the regular meal hour, or equivalent substitutes, were offered between meals.

When the patient was fed by tube, the feeding was administered by the drip method. Small portions (usually 200 ml.) were given at intervals of 2 to 3 hours throughout the day. When the gastrostomy mixture was too thick to run by gravity through small tubes, the feedings were injected slowly into the tube by syringe.

Collection of specimens.

All urine was collected under toluene for 24-hour periods throughout the period of study, and sent to the laboratory where volume measurements were made.

Feces were collected in many, but not in all cases; but when they were, the patient was given carmine by mouth at the beginning of the study and at the end of 5 days. Feces were collected as 24-hour specimens from the day of appearance of the first carmine up to and including the day of appearance of the second carmine.

Vomitus was collected and analyzed for total nitrogen. Material obtained by suction drainage was carefully collected and analyzed.

Methods of analysis.

All total nitrogen determinations were done by a semimicro Kjeldahl method (6a and b) and nonprotein nitrogen by a colorimetric method using Nessler's reagent (7).

Samples of Amigen, of lactalbumin hydrolysate, and of the gastrostomy mixture were analyzed for nitrogen. Food furnished as "Hospital Diet" was not analyzed in the laboratory, but values as given in standard diet tables were used (8a and b). Urine was usually diluted 1:50 or 1:100, plasma 1:10, and appropriate samples taken for analysis. Feces were thoroughly mixed by mechanical stirring in acidified water, and an appropriate sample taken for analysis.

Hematocrit readings were determined in Sanford-Magath tubes, using heparin as the anticoagulant.

RESULTS

Nitrogen balance.

Table I shows the results of studies on 55 patients fed by mouth or tube. The results are arranged in order of an increasing nitrogen intake. It is evident that:

1. Thirty-seven (67 per cent) of the 55 patients were in negative nitrogen balance for the first 5 postoperative days; 5 were in equilibrium,[4] and 13 were in positive nitrogen balance.

2. Of 18 in equilibrium or in positive nitrogen balance, 12 fell in the group receiving 0.3 gram of nitrogen per kgm., and 30 calories per kgm. or more daily.

3. Of 18 getting 0.3 gram of nitrogen or over, 12 were in positive nitrogen balance; 6 were in negative nitrogen balance. Of these 6, 3 were on low caloric intakes.

Type of operation.

Most of the patients studied fell into two groups, (*1*) gastric and (*2*) cranial operation. Dividing the patients into these 2 groups failed to show any gross difference in the results of feeding on nitrogen balance; *i.e.*, in both groups, most of the patients who were in balance received 0.3 gram of nitrogen and 30 calories per kgm. daily, or over.

Age and sex.

No correlation was found between age or sex of patients and their ability to attain nitrogen equilibrium with comparable nitrogen and caloric intake.

Nitrogen losses in feces.

There was considerable variation between patients in the amount of nitrogen excreted in the feces. Table II gives figures for the range of excretion and average of a number of patients grouped according to the method of feeding. Those patients who were fed by tube into the jejunum showed the greatest average loss of ni-

[4] If the patient had a daily average nitrogen balance of −1.0 to 0.0, he was considered to be in nitrogen equilibrium.

§ Jejunal feeding.

TABLE II

Fecal nitrogen

Type of feeding	No. of patients	Daily nitrogen output		
		Maximum	Minimum	Mean
		grams	*grams*	*grams*
By mouth— Hospital diet	18	1.5	0.1	1.0
By tube into stomach— Hydrolyzed protein or hydrolyzed protein plus hospital diet	12	25.0	0.1	1.4
By tube into jejunum— Hydrolyzed protein or whole protein as liquid feeding	13	25.0	6.2	3.3

trogen in the feces, and likewise the greatest variation in fecal nitrogen excretion was found in those fed by tube, into either the stomach or jejunum. The mean figures given in Table II were used in calculating balances in the cases where fecal nitrogen was not actually determined. The mean values for excretion of fecal nitrogen when food is given by mouth or by tube into the stomach agree with those given by Reifenstein, Albright and Wells (9).

Plasma proteins.

Because of the close relationship between hypoproteinemia and certain postoperative surgical complications (10 to 12), we were interested in studying the plasma protein concentration of surgical patients on various dietary regimes, but found that there was no significant correlation between the food intake and changes in plasma protein concentration, nor between nitrogen balance and changes in plasma protein concentration in this series of patients.

DISCUSSION

From the results obtained, it is apparent that surgical patients after operation require a larger intake of nitrogen to maintain positive nitrogen balance than has been recommended for normal individuals. Sherman (13) gives figures of 0.1 gram of nitrogen per kgm., and approximately 35 calories per kgm. for 1 normal individual. Rose and MacLeod (14) in a study of 4 normal active women found that 0.5 gram of protein (0.08 gram of nitrogen), and approximately 40 calories per kgm. daily, were sufficient. Mueller, Fickas and Cox (15), using an Amigen supplement to a basal diet, were able to produce considerable diminution in the amount of negative nitrogen balance in 4 normal men, and even to get positive balance in 2, giving 0.1 gram of nitrogen per kgm., and 26 to 28 calories per kgm. daily. The only nitrogen figures for normal individuals which approach the level found necessary by us for the immediate postoperative period are the amounts recommended by Howe (16) or the United States Army (men on moderate activity), 107.0 grams of protein and approximately 3,500 calories (for a 65 kgm. person this is 0.26 gram of nitrogen per kgm., and 53 calories per kgm. daily).

The increased nitrogen loss following trauma has been extensively studied in fractures of long bones (2, 3) and in burns (17, 18). Similar data for patients undergoing other types of surgical treatment, such as gastric or cranial operations, are meager. Ariel and his associates (19) have reported hypoproteinemia following operation for cancer of the gastro-intestinal tract. Elman (20) has frequently written of the poor state of nutrition of surgical patients, and reported on the use of hydrolyzed casein intravenously in the correction of hypoproteinemia in patients undergoing surgical operation. Mulholland, Co Tui *et al* (21) described the results obtained in 4 carefully studied postoperative gastric cases who received hydrolyzed casein as the source of nitrogen, together with 4 controls. Co Tui, Wright, Mulholland *et al* (22) reported studies on 19 postgastrectomy cases, of whom 8 on a high nitrogen, high caloric intake were in positive nitrogen balance. Brunschwig (23), in a series of 41 patients undergoing various types of operation, found that negative nitrogen balances were present in the majority of them. The dietary regimen of Brunschwig's patients was similar to that of many of our patients (Table II) and is the common one of intravenous fluids (usually saline or glucose solutions) followed by liquids by mouth on the third or fourth postoperative day, and soft to regular ward diet thereafter.

From these previously reported studies, it is not possible to determine the minimum level of nitrogen intake required to maintain the patient in nitrogen equilibrium. In our series 0.30 gram of nitrogen and 30 calories per kgm. daily proved to

be a level at which we could expect to have most patients in positive nitrogen balance in the early postoperative period. The relation between nitrogen intake and total calories was, in part, arbitrary. We recognize that it may have been possible to decrease the nitrogen level with a concurrent increase in caloric intake and still keep the patient in nitrogen equilibrium. While nitrogen intake has probably been more neglected in the management of surgical patients than caloric intake, the latter must not be allowed to fall too low. This is borne out by the data in Table I from 2 patients who had high nitrogen but low caloric intakes. It is interesting to note that in the cases reported by other workers (21, 22), where calculations can be made, and where the period of study is the same in relation to day of operation as in our studies, the amounts of nitrogen and the total calories with which they achieved positive nitrogen balance were well above the minimum effective level found in our studies.

It is clear from Table I that there are marked individual differences in the nitrogen excretion of patients on about the same nitrogen and caloric intake. Undoubtedly this is affected by anesthesia, the extent of operation, the degree of trauma, the previous nutritional history of the patient, the degree of postoperative pyrexia and many other factors. It, however, seemed useful to determine approximately the amount of food required to keep the majority of patients in balance after gastric and intracranial operations.

A criterion frequently used as a measure of the effectiveness of procedures intended to correct protein deficiencies in surgical patients is the concentration of plasma or serum protein. Our results indicate that plasma protein concentration may be misleading as an index of whether or not the patient is overcoming excessive nitrogen loss. In some instances, although the concentrations (corrected for change in hematocrit) were increased, the patients were in negative nitrogen balance.

In this study, hydrolyzed protein was found to be just as effective as whole protein in maintaining nitrogen balance.

A real difficulty in the forced feeding of patients in the early postoperative period is the frequency with which vomiting, diarrhea or distention follows such a program. Usually it was possible to overcome these obstacles by symptomatic treatment, but occasionally it was necessary to abandon the intended regimen. It is quite possible that intravenous feeding, rather than mouth feeding, may have a place of special importance in maintaining the nutrition of the patient in the first 48 to 72 hours after operation.

It should be emphasized that this study is concerned mainly with types of patients which are apt to present nutritional problems before and after operation. It is recognized that such patients represent a small minority of all general surgical patients, and it is not the intention of the authors to suggest that the forced feeding methods described are indicated for the majority of surgical patients.

CONCLUSIONS

1. Surgical patients after gastric or cranial operations were usually in negative nitrogen balance for the first 5 postoperative days on the dietary regimen customarily followed in this clinic.
2. Surgical patients undergoing gastric or cranial operations require a greater intake of dietary nitrogen and of total calories than do normal individuals to keep them in nitrogen equilibrium for the first 5 postoperative days.
3. By increasing the nitrogen intake to 0.30 gram per kgm., and the caloric intake to 30 calories per kgm. daily, or over, patients fed by mouth or Abbott-Rawson tube were usually maintained in nitrogen equilibrium.
4. Hydrolyzed protein in the form of a casein hydrolysate, combined with carbohydrate, was equally as effective as whole protein when administered by the same routes.
5. The variations in fecal nitrogen were large, and they are an important part of the nitrogen balance study of patients in the early postoperative period, especially when tube feedings are used.
6. The plasma or serum protein concentrations were not an accurate index of the effect of a nutritional regimen on nitrogen equilibrium in postoperative patients.

THE METABOLIC EFFECTS OF STEROID HORMONES IN OSTEOPOROSIS

By EDWARD C. REIFENSTEIN, JR., AND FULLER ALBRIGHT [1, 2, 3]

(From the Medical Service of the Massachusetts General Hospital and the Department of Medicine of the Harvard Medical School, Boston)

(Received for publication May 7, 1946)

In a previous communication from this clinic (1), three metabolic studies on the effect of estradiol benzoate on the calcium and phosphorus metabolisms of patients with post-menopausal osteoporosis were published in abstract form. The first objective of the present paper is to report these studies in detail, supplemented by 2 additional studies: one in which testosterone propionate by itself, and in combination with estradiol benzoate, was used; and another in which diethylstilbestrol by itself, and in combination with progesterone, was employed. The subject of the last investigation had, in addition to post-menopausal osteoporosis, Paget's disease.

The second objective is to publish metabolic studies on the effect of testosterone propionate alone and in combination with estradiol benzoate in a male patient with senile osteoporosis.

The third objective is to present studies on 3 patients with the acute osteoporotic process which follows orthopedic operations, and the effect of estradiol benzoate on this process in 2 of these subjects.

In another previous communication from this clinic (2), metabolic studies of the effect of estradiol benzoate, testosterone propionate, and progesterone on 3 patients with Cushing's syndrome were reported. The fourth objective is to present these data more completely in graphic form, and especially to rectify an unwarranted conclusion as to the effect of estrogen on the calcium balance.

DEFINITION OF OSTEOPOROSIS

Osteoporosis is not synonymous with demineralization of bone; it is that category of too-little-bone where the primary disturbance is lack of bone matrix formation. It is not to be confused with osteomalacia, where the primary disturbance is failure of mineralization of bone, or with osteitis fibrosa generalisata, where the primary disturbance is increased bone destruction. For further discussion, see (1, 3, 4).

CONDITIONS ASSOCIATED WITH OSTEOPOROSIS

In clinical medicine one encounters the following conditions associated with osteoporosis: (*1*) disuse atrophy, where the normal stimulus to osteoblastic activity is absent (4, 5); (*2*) old age, where the bone tissue like other tissue (*cf.* hair, skin, muscles) atrophies; (*3*) malnutrition, where the protein requirements are not fulfilled, and the bone matrix, like other tissues, is depleted; (*4*)

[1] The expense of these studies was defrayed by grants from the Josiah Macy, Jr. Foundation, from the Rockefeller Foundation, and from the National Research Council (Committee for Research in the Problems of Sex). A bed supported by the Mallinckrodt Chemical Company on the Metabolic Ward was used for part of these studies.

[2] Presented in part at the twenty-sixth annual meeting of the Association for the Study of Internal Secretions, Atlantic City, New Jersey, June 8, 1942, in connection with a symposium on "Relation of Endocrines to Skeletal Development"; an outline of this presentation may be found in: Reifenstein, E. C., Jr.; Albright, F.; Parson, W.; and Bloomberg, E.: The effect of estradiol benzoate and of testosterone propionate and of combinations of both on post-menopausal osteoporosis and senile osteoporosis, Endocrinology, 30: S1024 (1942). Also presented in part at the first annual meeting of the American Federation for Clinical Research, Minneapolis, Minn., April 20, 1942. Preliminary reports of part of these data may be found in: Albright, F.; Reifenstein, E. C., Jr.; and Forbes, A. P.: Conferences on the Metabolic Aspects of Convalescence (Including Bone and Wound Healing), Transactions of the First Meeting, Sept. 11–12, 1942, pages 5–7, 37–38; Transactions of the Second Meeting, December 11–12, 1942, pages 69, 96–98; Transactions of the Third Meeting, March 12–13, 1943, pages 63–65; and Transactions of the Fourth Meeting, June 11–12, 1943, pages 77–85. Transactions distributed by the Josiah Macy, Jr. Foundation, New York, N. Y.

[3] The work described in this paper was done in part under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts General Hospital.

Dietary intake of periods 1 to 30 in amounts per 24 hours: protein (analyzed nitrogen × 6.25) = 48.1 grams, fat (estimated from tables) = 85.0 grams, carbohydrate (estimated from tables) = 212.8 grams, calories (calculated from the values 4 for 1 gram of protein, 9 for 1 gram of fat, and 4 for 1 gram of carbohydrate) = 1,809. In addition sugar was given *ad lib*, with an average intake of 30 grams (120 calories).

* Initial weight 51.14 kgm.

** Continued for 6 months.

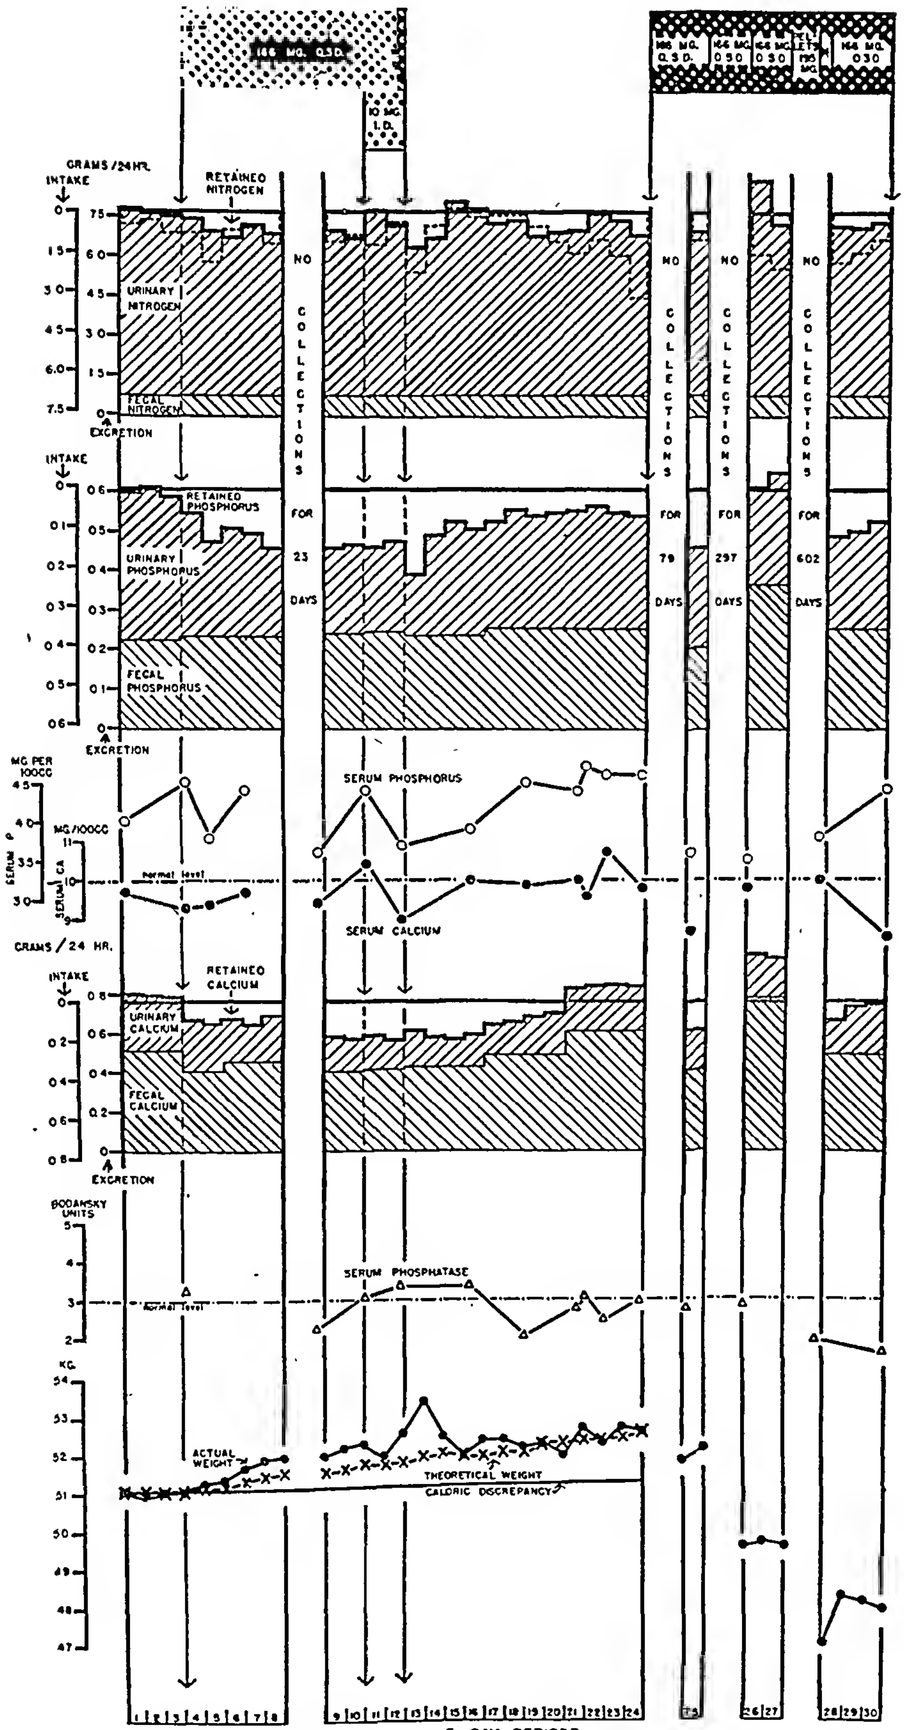

FIG. 1. CASE 1 (F. F., M.G.H. 156453): EFFECT OF ESTRADIOL BENZOATE ON NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES, ON SERUM

Cushing's syndrome where, we believe, an excess of the adrenal cortical "sugar" or "S" hormone inhibits anabolism of protoplasm including bone matrix (2, 6); (5) adaptation syndrome of Selye (7), where, we believe, the pathological physiology is the same as in Cushing's syndrome; (6) idiopathic osteoporosis, where the cause of the condition remains obscure; (7) acromegaly, where the cause may be the increase of pituitary hormone(s), or the secondary lack of gonadal hormones (8); and (8) the post-menopausal state, the commonest of all forms, where the difficulty is a deficiency in estrogen to stimulate the osteoblasts. Frequently 2 or more factors combine in one individual; thus, after an orthopedic operation (see Cases 7, 8, and 9, below) factors (*1*) and (*5*) probably both play a part.

METABOLIC STUDIES

For the methods employed in the accumulation, interpretation and presentation of these data, see (9). Case histories are abstracted in the appendix.

A. Post-menopausal osteoporosis

Case 1. Post-Menopausal Osteoporosis; Artificial Menopause; Estradiol Benzoate Therapy.

The metabolic data of Case 1 are shown in Figure 1 and Table I. The first part of the study, conducted in 5-day periods, consisted of: (*1*) three control periods; (*2*) five periods with estradiol benzoate 1.66 mgm. intramuscularly every 3 days; (*3*) twenty-three days with the same therapy at home; (*4*) two periods with the same therapy; (*5*) two periods with progesterone 10 mgm. intramuscularly daily in addition to the estradiol; and (*6*) twelve periods after the cessation of both medications. The patient was then discharged on estrogen therapy which was given continuously in varied dosage during the next 3 years; during this interval she was brought back to the metabolic ward for study (1 to 3 five-day periods) on 3 occasions.

The data (Figure 1) are self-explanatory. Attention should be called to: (*1*) nitrogen, phosphorus, and calcium equilibria during the control periods (1 to 3); (*2*) the high serum phosphorus level which tended to fall under estrogen therapy (less marked in this case than in the others [*vide infra*]); (*3*) the slight improvement in nitrogen balance under estrogen therapy; (*4*) the striking and growing decrease in calcium excretion, both fecal and urinary, with estrogen treatment and the gradual return (40 days) in calcium excretion to pre-treatment levels following cessation of estrogen therapy; (*5*) a decrease with estrogen treatment in the phosphorus excretion almost entirely confined to the urinary component, and reasonably proportional to the changes in the calcium and nitrogen metabolisms (see "Theoretical Nitrogen Balance"); (*6*) failure of the serum phosphatase level, the index of osteoblastic activity, to rise under estrogen therapy; (*7*) an increase in nitrogen, but not in calcium and phosphorus, excretions in periods 11 and 12 with progesterone therapy; and (*8*) the tendency to retain extracellular fluids with estradiol therapy, as suggested by the increase in the actual weight above the theoretical weight.

The apparent discrepancy in the effect of estrogen on the calcium and phosphorus balances during periods 26 and 27 is probably to be explained by erroneously high fecal excretions resulting from too short a period of observation (9).

Case 2. Post-Menopausal Osteoporosis; Physiological Menopause; Question of Superimposed Atrophy of Disuse; Estradiol Benzoate Therapy.

The metabolic data of Case 2 are shown in Figure 2 and Table II. The study, conducted in 5-day periods, consisted of: (*1*) five control periods; (*2*) thirteen periods during which the patient received estradiol benzoate 3.32 mgm. intramuscularly every other day. In addition, during the 3 periods 14, 15, and 16, testosterone propionate 25 mgm. were administered intramuscularly every other day.

The data in Case 2 confirm the main observations made on Case 1. The fall in the serum phosphorus level after estradiol medication was more pronounced than in Case 1, and in addition there was a fall in the serum calcium level. Again the serum phosphatase level failed to rise with the improvement in the calcium balance. The duration of the testosterone propionate therapy was too short to judge its effect on the calcium balance; it brought about the expected increase in the nitrogen retention and rise in the urinary 17-ketosteroid excretion. The theoretical nitrogen balance based on the phosphorus balance after it had been corrected for the calcium balance agrees quite well with the measured nitrogen balance.

CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE LEVELS, AND ON BODY WEIGHT IN A FEMALE PATIENT WITH POST-MENOPAUSAL OSTEOPOROSIS

For discussion, see text.

The dotted line in the nitrogen metabolism data represents the "theoretical nitrogen balance." The fecal nitrogen was estimated as 10 per cent of the intake. The fecal calcium and phosphorus values as charted are averages of 1, 2, 3, or 4 five-day periods as follows: 1 through 3, 4 through 5, 6 through 8, 9 through 10, 11 through 12, 13 through 16, 17 through 20, 21 through 24, 25, 26 through 27, 28 through 30; the individual values are given in Table I.

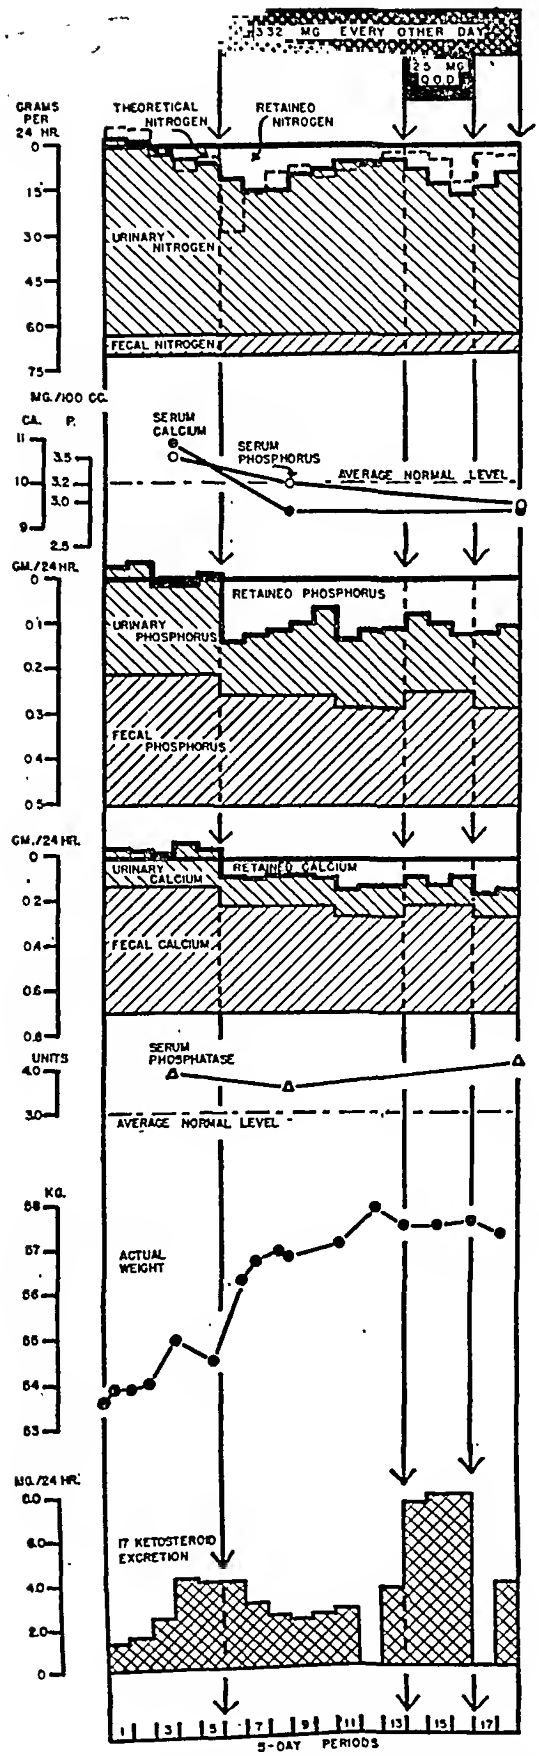

FIG. 2. CASE 2 (E. P., M.G.H. 203540): EFFECT OF ESTRADIOL BENZOATE AND TESTOSTERONE PROPIONATE ON

Case 3. Post-Menopausal Osteoporosis; Artificial Menopause; Estradiol Benzoate Therapy.

The metabolic data of Case 3 are shown in Figure 3 and Table III. The study, conducted in 5-day periods, consisted of: (*1*) four control periods; (*2*) nine periods in which 1.66 mgm. of estradiol benzoate were administered intramuscularly every 3 days; (*3*) ninety-three days at home on the same medication; (*4*) five periods on the same medication; (*5*) seven periods during which the estradiol dosage was doubled; and (*6*) five control periods of medication. During period 10 the patient was given in addition 10 mgm. of progesterone intramuscularly each day.

It will be noted in Figure 3 that the improvement in the calcium balance in this case following estradiol therapy was almost entirely due to the fall in the urinary calcium excretion. It is further suggested that the positive calcium balance tends to diminish with time (compare periods 14 to 18 with periods 11 to 13). Note, furthermore, that the calcium balance was not improved, and possibly reduced, when estradiol therapy was doubled in periods 19 through 25. The fall in the serum phosphorus level with medication was especially striking in this case. The actual weight was greater than the theoretical weight during the therapy, which suggests retention of extracellular fluids.

Case 4. Post-Menopausal Osteoporosis; Artificial Menopause; Methyl Testosterone, Estradiol Benzoate and Pregnenolone Therapy.

The metabolic data of Case 4 are given in Figure 4 and Table IV. The study, conducted in 6-day periods, consisted of: (*1*) four control periods; (*2*) four periods on methyl testosterone, 40 mgm. by mouth daily; (*3*) five periods in which 1.66 mgm. of estradiol benzoate daily by injection were added to the methyl testosterone therapy; (*4*) five periods back on the methyl testosterone therapy alone; (*5*) four more control periods off medication; (*6*) three periods on pregnenolone, 30 mgm. intramuscularly daily; (*7*) four more control periods off medication; (*8*) five periods back on methyl testosterone, 40 mgm. by mouth daily with a change in the nitrogen and phosphorus intakes during the last 3 of these; and (*9*) one final period where the methyl testosterone therapy was increased to 100 mgm. by mouth daily. The urinary determinations were made on 3-day periods throughout.

In Figure 4 it should be noted first that the theoretical nitrogen balance is consistently less than the actual

NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES, ON SERUM CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE LEVELS, ON BODY WEIGHT AND ON URINARY 17-KETOSTEROID EXCRETION

For discussion, see text.

The fecal nitrogen was estimated as 10 per cent of the intake. The fecal phosphorus and calcium values as charted are averages of 2, 3, 4, or 5 five-day periods as follows: 1 through 5, 6 through 9, 10 through 13, 14 through 16, 17 through 18; the individual values are given in Table II.

Dietary intake of periods 1 to 30 in amounts per 24 hours: protein (analyzed nitrogen × 6.25) = 53.5 grams, fat (estimated from tables) = 95.2 grams, carbohydrate (estimated from tables) = 241.6 grams, calories (calculated from the values 4 for 1 gram of protein, 9 for 1 gram of fat, and 4 for 1 gram of carbohydrate) = 2,037. In addition sugar was given *ad lib*, with an average intake of 30 grams (120 calories).

* Initial weight 74.65 kgm.

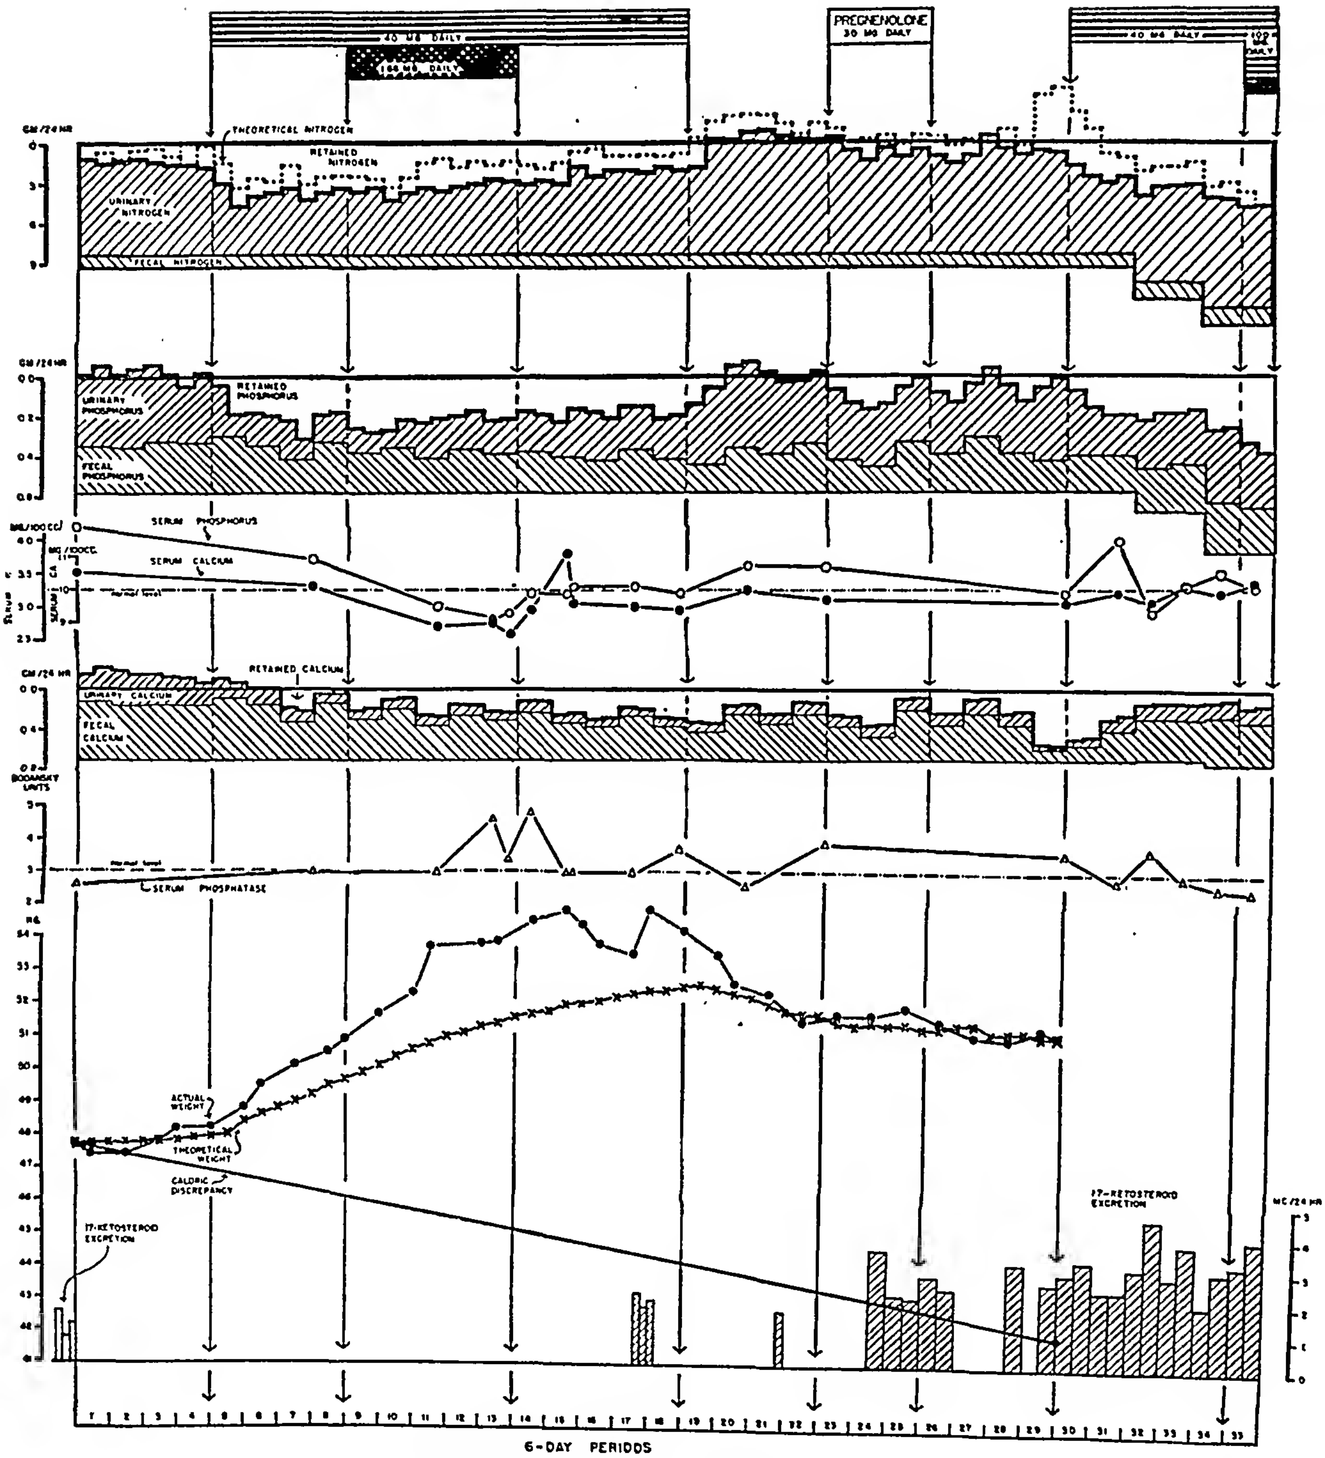

FIG. 4. CASE 4 (R. W., M.G.H. 319940): EFFECT OF METHYL TESTOSTERONE ALONE AND IN COMBINATION WITH ESTRADIOL BENZOATE, AND OF PREGNENOLONE ON NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES, ON SERUM CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE LEVELS, ON BODY WEIGHT, AND ON URINARY 17-KETOSTEROID EXCRETION IN A FEMALE PATIENT WITH POST-MENOPAUSAL OSTEOPOROSIS

For discussion, see text.

nitrogen balance, which indicates that there is some constant error throughout. Part of the error may be in the fecal nitrogen excretion which was not analyzed, but taken as 10 per cent of the nitrogen intake. In the absence of analyzed values, it would have been preferable, and the discrepancy would have been cut down, had we used the value of 1.283 grams per 24 hours, the average fecal nitrogen value for adults regardless of intake (9). The major part of the discrepancy is probably to be attributed to errors in the intakes. The daily diet was

Dietary intake of periods 1 to 31 in amounts per 24 hours: protein (analyzed nitrogen × 6.25) = 52.5 grams, fat (estimated from tables) = 63.5 grams, carbohydrate (estimated from tables) = 207.5 grams, calories (calculated from the values 4 for 1 gram of protein, 9 for 1 gram of fat, and 4 for 1 gram of carbohydrate) = 1,611; periods 32 to 33: protein = 63.7 grams, fat = 51.3 gram, carbohydrate = 197.9 gram, calories = 1,508; periods 34 to 35; protein 86.9 grams, fat = 61.1 grams, carbohydrate = 178.7 grams, calories = 1,612. In addition throughout sugar was given *ad lib*, with an average intake of 30 grams (120 calories).

analyzed twice with the following results: analysis October 1941: calcium 71 mgm., phosphorus 584 mgm., and nitrogen 9.31 grams; analysis February 2, 1944: calcium 64 mgm., phosphorus 611 mgm., and nitrogen 8.40 grams. Figure 4 was constructed from the analysis of 1941; had it been constructed from the analysis of 1944, the discrepancy would have been almost eliminated. Thus, if one recalculates on the basis of the 1944 analysis the theoretical nitrogen balance of period 4b, and in addition uses the value of 1.283 grams for the fecal nitrogen instead of 10 per cent of the intake, one obtains the values +0.65 and +0.45 grams for the theoretical and actual nitrogen balances, respectively, in contrast to the values of +0.18 and +1.71 grams. Since the above discrepancy is fairly constant, it does not affect the trends induced by treatment.

Figure 4 is self-explanatory. To be noted are: (*1*) the decrease in the nitrogen, phosphorus, and calcium excretions with methyl testosterone therapy, and the rebound of nitrogen and phosphorus excretions on cessation of therapy; (*2*) the fact that the fecal, as well as the urinary, excretions of both calcium and phosphorus were reduced under methyl testosterone therapy; (*3*) the fact that there was not an immediate rebound of the calcium excretion following cessation of methyl testosterone therapy; (*4*) the further improvement in the calcium balance, but not in the nitrogen balance, when estradiol benzoate therapy was added to the methyl testosterone therapy (periods 9 to 13); (*5*) the fall in serum phosphorus level with methyl testosterone and especially with estradiol benzoate therapy; (*6*) the definite tendency of the serum calcium level to parallel the serum phosphorus level (see also Figure 2); and (*7*) the failure of the serum phosphatase level to show a significant change. The effect of the pregnenolone therapy is inconclusive; it did not significantly affect the very low 17-ketosteroid excretion. No explanation is forthcoming in periods 29 and 30 for the low fecal calcium excretions not associated with low nitrogen and phosphorus excretions; as a result, the data during periods 30 through 36 are difficult to interpret. The actual and theoretical weight curves suggest that there was retention of extracellular fluid with methyl testosterone therapy which was augmented when estradiol benzoate therapy was added. Pregnenolone therapy had a minimal effect on extracellular fluid retention.

Case 5. Post-Menopausal Osteoporosis; Artificial Menopause; Paget's Disease; Diethylstilbestrol and Progesterone Therapy.

The metabolic data of Case 5 are given in Figure 5 and Table V. The study, conducted in 6-day periods, consisted of: (*1*) three control periods; (*2*) five periods on 1 mgm. of diethylstilbestrol by mouth daily; (*3*) seven periods on 15 mgm. of diethylstilbestrol by mouth daily, with an increase in the diet in the last 3 of these; (*4*) six periods with the same dosage of diethylstilbestrol in which progesterone by injection was given in addition (25 mgm. daily for the first 4 of these periods, and 100 mgm. daily for the last 2); and (*5*) three periods on 15 mgm. of diethylstilbestrol daily alone.

This patient was selected for the study not only because she had marked osteoporosis from an artificial menopause 30 years before, but because she had, in addition, Paget's disease. The primary pathologic process of the Paget's disease, bone destruction, was not being responded to with the usual amount of increased bone formation because of the menopause (4). Therefore, it was thought that any action of estrogen to stimulate bone formation would be magnified in this patient.

Figure 5 is self-explanatory. To be noted are: (*1*) the markedly negative calcium and phosphorus balances during the control periods; (*2*) the marked improvement of these balances with 1 mgm. of diethylstilbestrol daily; (*3*) the further improvement with 15 mgm. of diethylstilbestrol daily; (*4*) the lack of effect of progesterone on the calcium and phosphorus balances; (*5*) the high serum phosphorus before treatment; (*6*) the tendency of the serum phosphorus to fall during treatment; (*7*) the failure of the serum phosphatase to rise with improvement of the calcium balance; (*8*) the tendency of the 17-ketosteroid excretion to rise with progesterone; (*9*) the failure of the "11-oxysteroid" excretion[4] to fluctuate outside of the normal range with therapy; (*10*) the striking fall[5] in the urinary follicle-stimulating hormone (FSH) excretion with diethylstilbestrol therapy; and (*11*) the subsequent rise in the FSH excretion when progesterone therapy was superimposed on the diethylstilbestrol therapy. The increase in the positive nitrogen balance and the increase in weight during periods 22 to 24 may be indications that progesterone was acting unfavorably on the nitrogen balance (12). Not explained is the rise in FSH excretion in periods 23 and 24.

B. Senile osteoporosis

Case 6. Senile Osteoporosis in a Male of 72; Testosterone Propionate and Estradiol Benzoate Therapy.

The metabolic data of Case 6, which comprise studies done on 290 of 530 consecutive days, are shown in Figure 6 and Table VI. The study, conducted in 5-day periods, consisted of: (*1*) five control periods; (*2*) five periods on testosterone propionate, 25 mgm. by injection daily; (*3*) five periods in which estradiol benzoate 1.66 mgm. by injection on alternate days was added to the testosterone propionate therapy; (*4*) five periods back on testosterone propionate alone; (*5*) seven control periods off all medication; (*6*) five periods on estradiol benzoate 1.66 mgm. by injection twice daily; (*7*) ten days without collections on the same medication; (*8*) two more periods on the same medication; (*9*) ninety-three days at home on estradiol benzoate 3.32 mgm. by injection 3 times

---

[4] These observations were carried out by Dr. Nathan B. Talbot with his method (10). The normal range is 0.10 to 0.35 mgm. per 24 hours.

[5] The level fell from 200–300 units per day to less than 6 units per day. Normal range of FSH excretion is 6 to 50 mouse units per day (11).

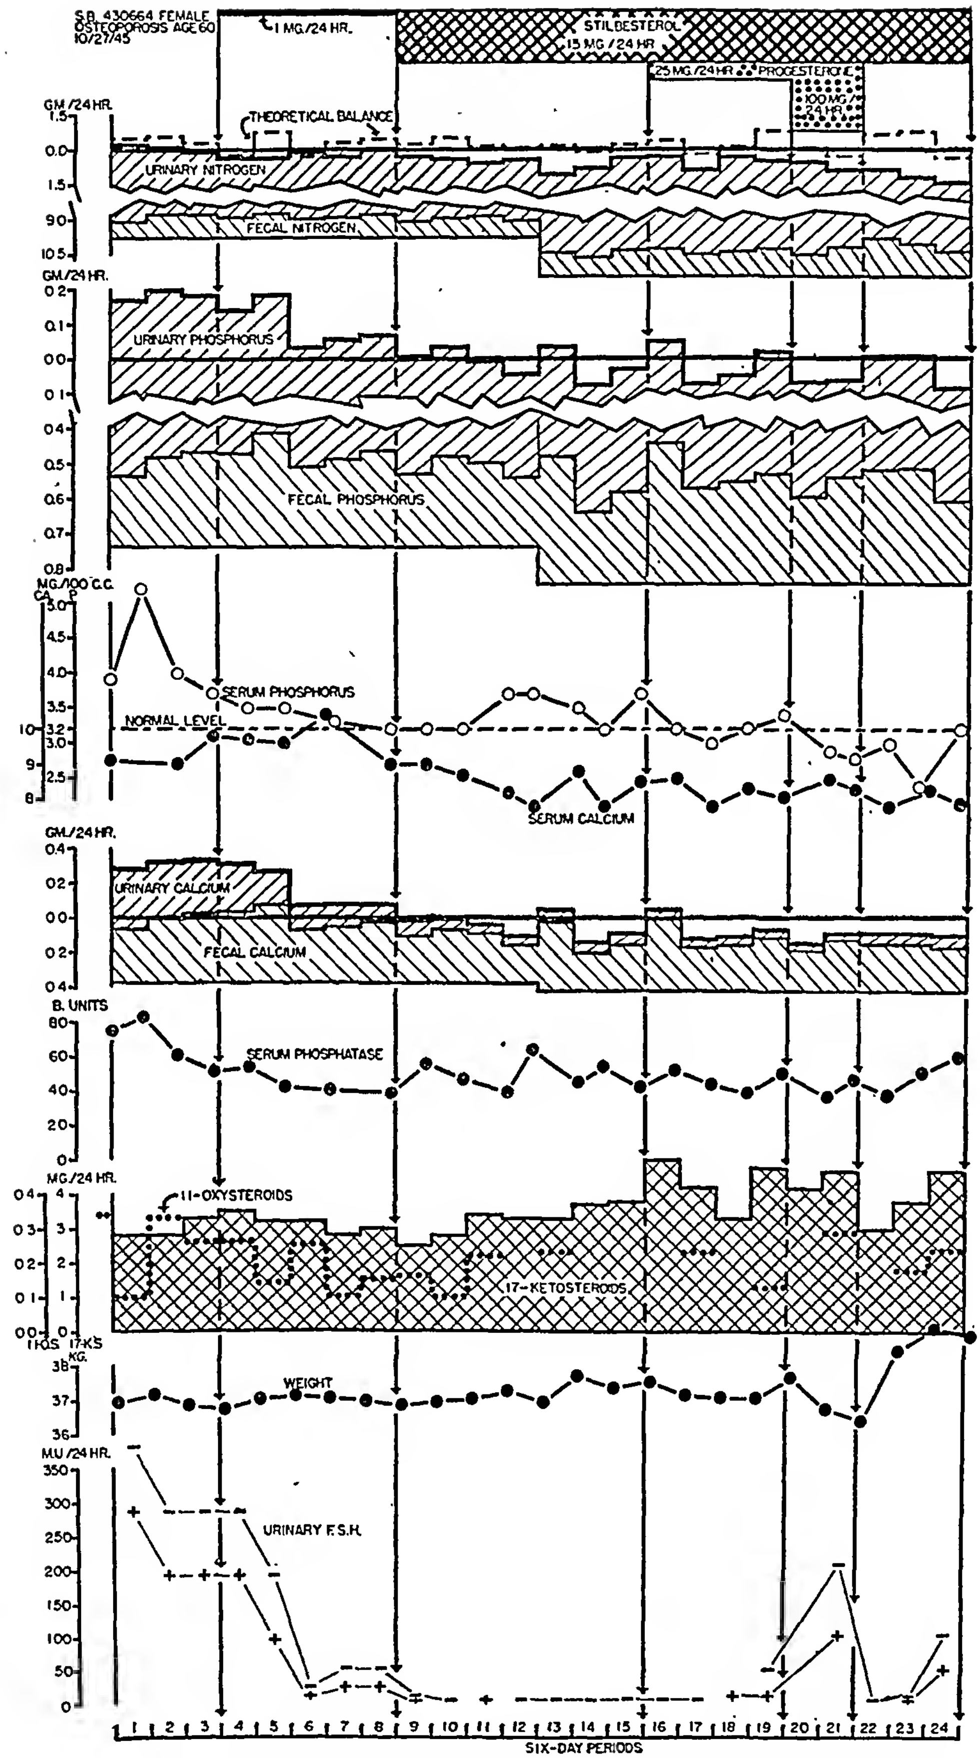

FIG. 5. CASE 5 (S. B., M.G.H. 430664): EFFECT OF DIETHYLSTILBESTROL ALONE AND IN COMBINATION WITH PROGESTERONE ON NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES, ON SERUM CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE LEVELS, ON BODY WEIGHT, AND ON URINARY 17-KETOSTEROID, "11-OXYSTEROID," AND FOLLICLE-STIMULATING HORMONE EXCRETION IN A FEMALE PATIENT WITH POST-MENOPAUSAL OSTEOPOROSIS AND PAGET'S DISEASE

For discussion, see text.

Dietary intake of periods 1 to 45 and 52 to 58 in amounts per 24 hours: protein (analyzed nitrogen × 6.25) = 52.5 grams, fat (estimated from tables) = 63.5 grams, carbohydrate (estimated from tables) = 207.5 grams, calories (calculated from the values 4 for 1 gram of protein, 9 for 1 gram of fat, and 4 for 1 gram of carbohydrate) = 1,611; periods 46 to 51: protein = 108.6 grams, fat = 73.8 grams, carbohydrate = 221.0 gm., calories = 1,983. In addition throughout sugar was given *ad lib*, with an average intake of 30 grams (120 calories).

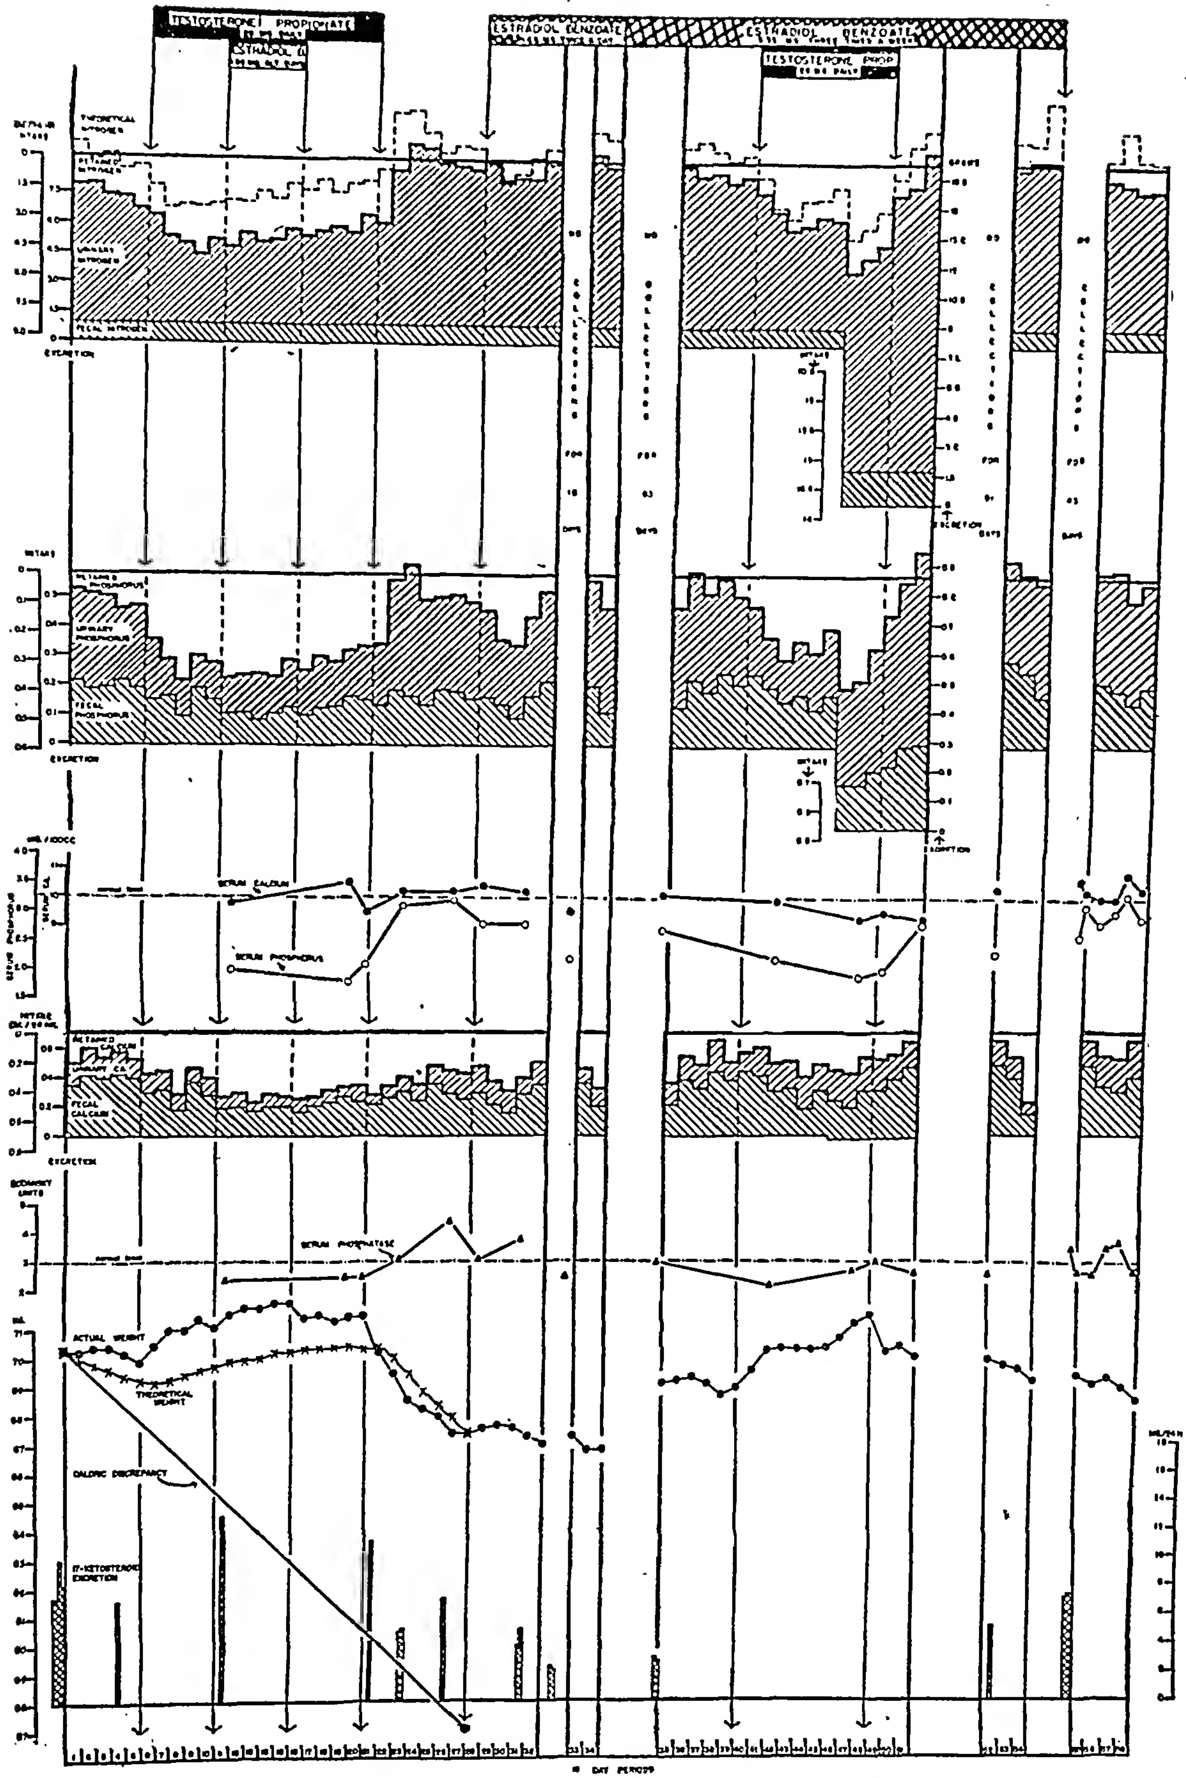

FIG. 6. CASE 6 (M. H., M.G.H. 278511): EFFECT OF TESTOSTERONE PROPIONATE ALONE AND IN COMBINATION WITH ESTRADIOL BENZOATE AND VICE VERSA ON NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES, ON SERUM CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE LEVELS, ON BODY WEIGHT, AND ON URINARY 17-KETOSTEROID EXCRETION IN A MALE PATIENT WITH SENILE OSTEOPOROSIS

For discussion, see text.

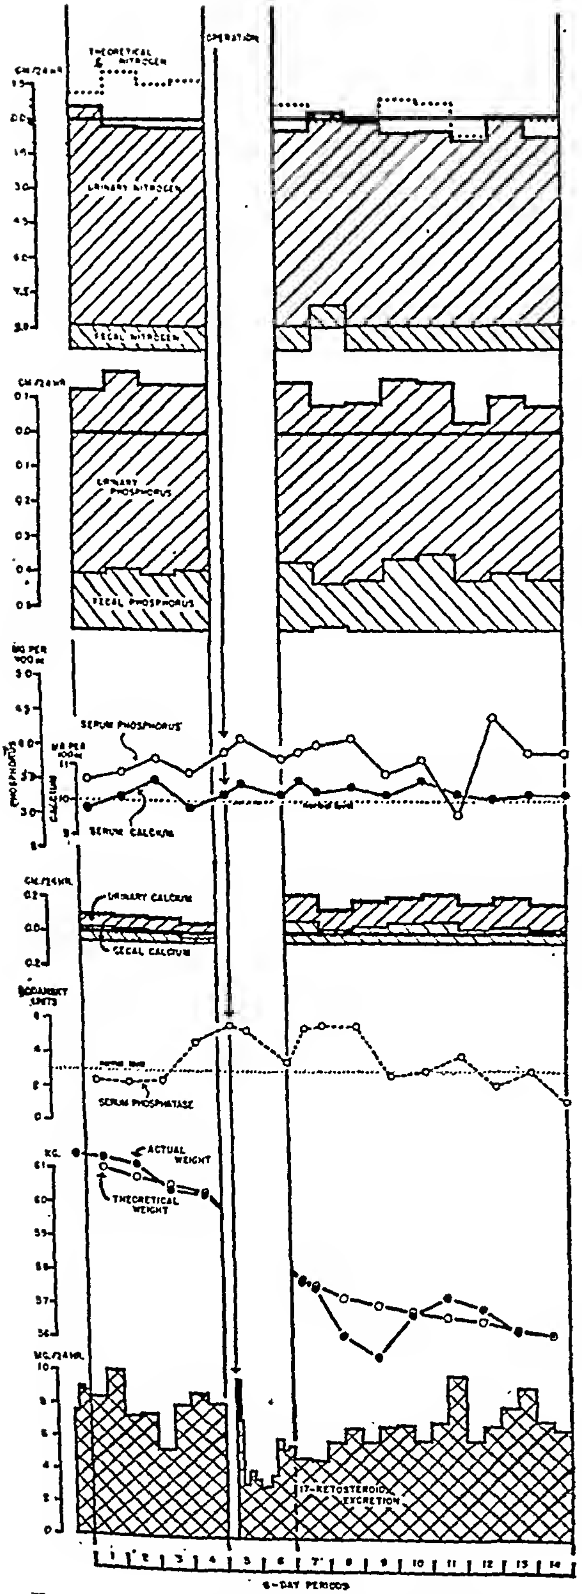

FIG. 7. CASE 7 (E. S., M.G.H. 360207): NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES; SERUM CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE LEVELS; WEIGHT; AND URINARY 17-KETOSTEROID EXCRETION IN A FEMALE PATIENT WITH OSTEOPOROTIC PROCESS INDUCED BY OPERATION AND IMMOBILIZATION

For discussion, see text.

a week; (*10*) five periods on the same therapy; (*11*) nine periods in which testosterone propionate 25 mgm. intramuscularly daily was added to the estradiol benzoate therapy, during the last 3 of which periods the intakes of nitrogen and phosphorus were markedly increased; (*12*) three periods on the same diet and the same estradiol benzoate therapy but off testosterone propionate therapy; (*13*) ninety-one days at home on the same estradiol benzoate therapy; (*14*) three periods on the original diet without change in the estradiol therapy; (*15*) forty-three days at home off all medication; and finally (*16*) four control periods on the original diet without medication.

Figure 6 is self-explanatory. The observations as a whole confirm those noted in Cases 1 to 4 with post-menopausal osteoporosis.

Again, as in Case 4, the theoretical nitrogen balance as charted is consistently less positive than the actual nitrogen balance which suggests some constant error. This discrepancy is probably to be attributed to errors in the intakes and to estimation of the fecal nitrogen as 10 per cent of the nitrogen intake (see discussion under Case 4). Case 6 received the same diet as Case 4; this diet was analyzed twice with the results given in the discussion under Case 4. Figure 6 was constructed from the analysis of 1941; had it been constructed from the analysis of 1944, as is Table V, the discrepancy would have been almost eliminated. Thus, if one recalculates on the basis of the 1944 analysis, the theoretical nitrogen balance of period 5, and in addition uses the value of 1.283 grams for the fecal nitrogen instead of 10 per cent of the intake, one obtains the values + 0.87 and + 1.30 grams for the theoretical and actual nitrogen balances, respectively, in contrast to the values of + 0.41 and + 2.21 grams. As was pointed out in connection with Case 4, since the above discrepancy is fairly constant, it does not affect the trends induced by treatment.

To be noted especially in Figure 6 are: (*1*) the marked reduction in nitrogen, phosphorus, and calcium excretions with testosterone therapy; (*2*) the lack of rebound in the calcium excretion as opposed to nitrogen and phosphorus following cessation of testosterone therapy; (*3*) the further reduction in the phosphorus and especially in the calcium excretion, but not in the nitrogen excretion, when estradiol benzoate therapy was added to testosterone propionate therapy (periods 16 to 20); (*4*) the improvement in all 3 balances when testosterone propionate was added to estradiol benzoate therapy (periods 40 to 45); (*5*) reduction in the fecal as well as the urinary calcium and phosphorus excretions by both testosterone propionate and estradiol benzoate therapy; (*6*) the effect of both testosterone propionate and estradiol benzoate therapy in lowering the serum phosphorus level; (*7*) the failure of marked increases in the nitrogen and phosphorus bal-

Dietary intake of periods 1 to 14 in amounts per 24 hours: protein (analyzed nitrogen × 6.25) = 61.9 grams, fat (estimated from tables) = 80.9 grams, carbo-hydrate (estimated from tables) = 179.4 grams, calories (calculated from the values 4 for

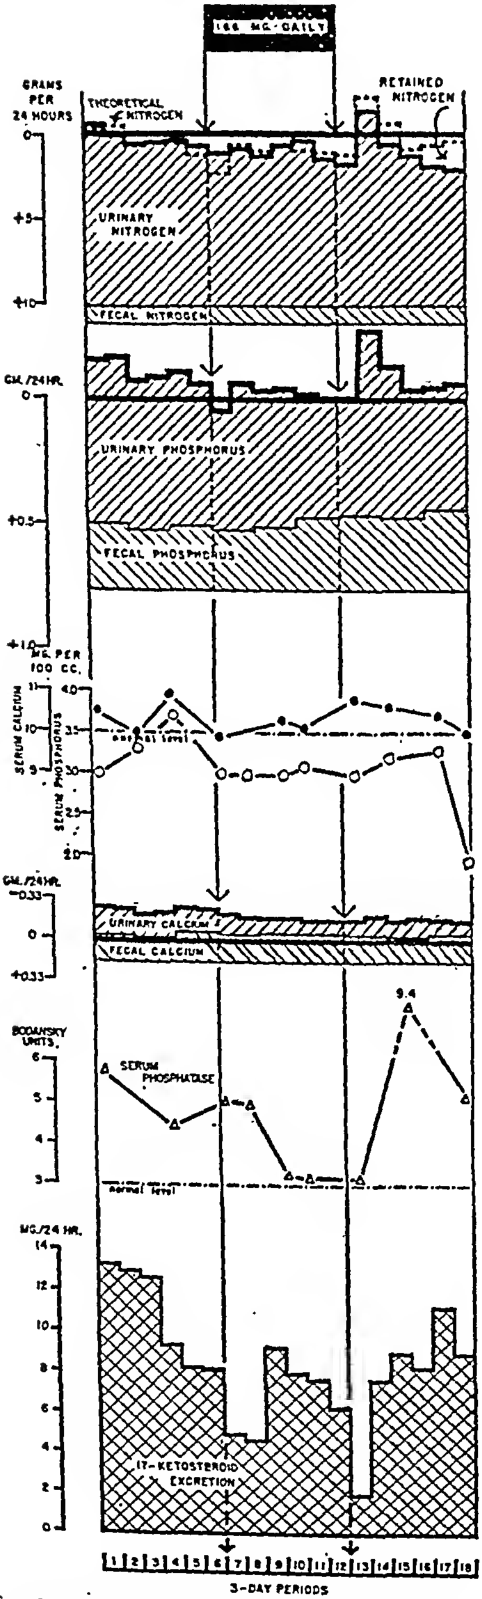

FIG. 8. CASE 8 (H. D., M.G.H. 382395): EFFECT OF ESTRADIOL BENZOATE ON NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES; ON SERUM CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE LEVELS; AND ON URINARY 17-KETOSTEROID EXCRETION IN A MALE PATIENT WITH OSTEOPOROTIC PROCESS INDUCED BY MULTIPLE FRACTURES, OPERATION, AND IMMOBILIZATION

For discussion, see text.

ances by increased diet to affect the calcium balance (periods 46, 47, 48); (*8*) the absence of any significant change in the serum phosphatase and calcium levels; (*9*) the fall in the urinary 17-ketosteroid level with estradiol benzoate therapy; and (*10*) the tendency to accumulate extracellular fluid during both testosterone propionate and estradiol benzoate therapy as suggested by the theoretical weight curves, with a prompt loss following the cessation of therapy.

C. *Osteoporosis resulting from disuse and/or adaptation syndrome*

Case 7. "Normal" Female; Effect of Orthopedic Operation; No Specific Therapy.

The metabolic data of Case 7 are shown in Figure 7 and Table VII. Throughout the entire experiment the patient was on a constant, neutral-ash, low calcium diet, except for the immediate post-operative period. She was up and active during the pre-operative period, and immobilized in a cast from the foot to the hip after operation. She underwent an arthrodesis of the right foot on the second day of period 5; there were no analyses for metabolic data during periods 5 and 6, but the 17-ketosteroid excretion was followed.

During the 4 control periods the patient was in negative calcium and phosphorus balance; the former was of the order of magnitude one would expect with patients on this diet (13). As expected, there was a marked increase in the calcium excretion after the operation, which persisted unabated to the end of the investigation (58 days after the operation) (14). The increase in calcium excretion was not entirely in the urine. The 17-ketosteroid excretion was normal pre-operatively, which confirms the contention that she was not debilitated; it rose immediately after operation, and then fell decidedly below the preoperative level for about 20 days. The pattern of response was thus similar to that encountered following any traumatizing event (15). The marked elevation in 17-ketosteroid excretion in period 11 coincided with the patient being allowed up in a wheel chair (16).

Periods 7 through 14 in this untreated case serve as a control for similar studies in Cases 8 and 9, who received estradiol therapy during the post-operative period (Figure 10).

Case 8. Multiple Traumatic Fractures with Operative Reduction of One in a Previously "Normal" Male; Effect of Estradiol Benzoate Therapy.

The metabolic data of Case 8 are shown in Figure 8 and Table VIII. The study, conducted in 3-day periods, consisted of; (*1*) six control periods; (*2*) six periods in which 1.66 mgm. of estradiol benzoate was given

Dietary intake of periods 1 to 18 in amounts per 24 hours: protein (analyzed nitrogen × 6.25) = 69.7 grams, fat (estimated from tables) = 50.1 grams, carbohydrate (estimated from tables) = 228.6 grams, calories (calculated from the values 4 for 1 gram of protein, 9 for 1 gram of fat ,and 4 for 1 gram of carbohydrate) = 1,644.

* Collections on 1/16/43 omitted.

** Initial weight 11/15/42 between 70 and 75 kgm.

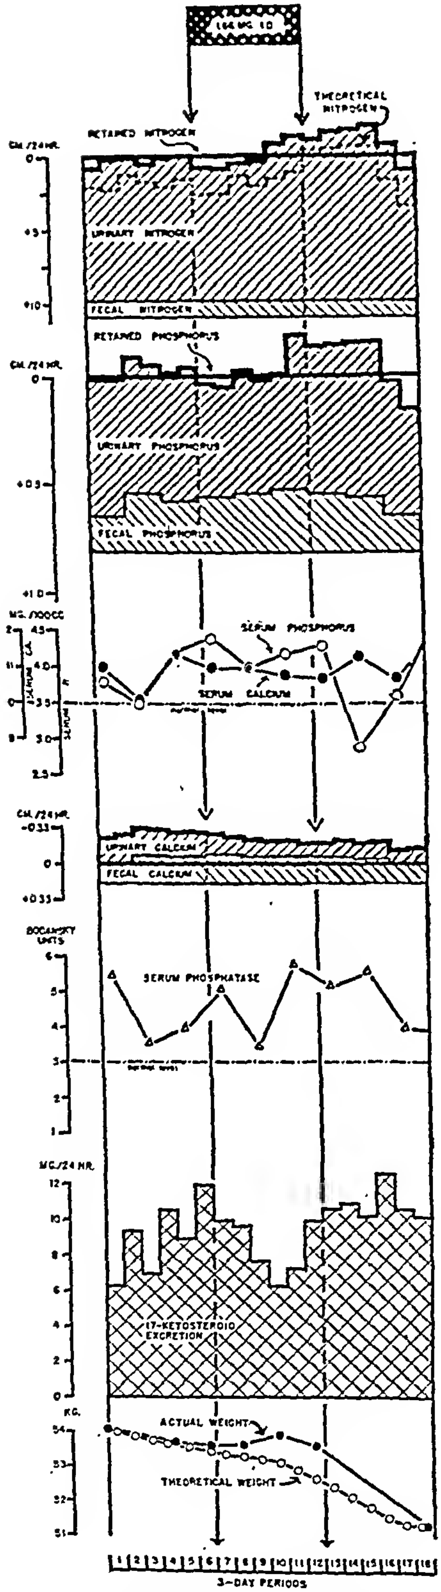

Fig. 9. Case 9 (C. M., M.G.H. 348774): Effect of Estradiol Benzoate on Nitrogen, Phosphorus, and Calcium Balances; on Serum Calcium, Phosphorus, and Alkaline Phosphatase Levels; on Urinary 17-Ketosteroid Excretion and on Weight in a Male Patient with Osteoporotic Process Induced by Operation and Immobilization

For discussion, see text.

daily by injection; and (*3*) six post-treatment control periods. The stool periods were analyzed 2 at a time.

Figure 8 is self-explanatory. The most important observations concern the calcium metabolism; these are better shown in Figure 10 and will be discussed below. Again, there was a fall in the serum phosphorus, and, if anything, a fall in the serum phosphatase. Of interest is the fall in 17-ketosteroids in period 13, followed by the rise in urinary nitrogen, phosphorus, and calcium in period 14; we believe these to be connected though unexplained phenomena.

Case 9. Bone Grafting Operation in an Ununited Femur of an Otherwise "Normal" Male; Effect of Estradiol Benzoate Therapy.

The metabolic data of Case 9 are shown in Figure 9 and Table IX. The study, conducted in 3-day periods, consisted of: (*1*) six control periods; (*2*) six periods in which 1.66 mgm. of estradiol benzoate was given daily by injection; and (*3*) six post-treatment control periods. The stool periods were analyzed 2 at a time.

Figure 9 is self-explanatory. The theoretical nitrogen balance shows a constant deviation from the measured nitrogen balance which suggests some constant error (*vide supra*). The calcium data, as in Case 8, are better shown in Figure 10, and will be discussed below. It should be noted that the serum phosphorus in this case, as opposed to all of the other cases, did not fall during estradiol therapy. The 17-ketosteroid excretion showed a tendency to fall during the estradiol benzoate therapy, which is also somewhat suggested in Figure 7.

Further analysis of calcium data of Cases 7, 8, and 9

In Figure 10 the calcium data of Cases 8 and 9 with estradiol benzoate therapy are compared with those of Case 7 without such therapy. It is quite clear that estradiol benzoate therapy resulted in a decrease in the urinary calcium excretion, but had little effect on the fecal calcium excretion during the 18 days of administration. However, the tendency for the fecal calcium to decrease in Case 9 after the therapy was stopped may well have been a delayed response to the therapy. The urinary citric acid values carried out and interpreted by Dr. Ephraim Shorr confirm his finding (17) of a rise during estrogen therapy.

D. Osteoporosis of Cushing's syndrome

Case 10. Cushing's Syndrome; Nephrolithiasis; Estradiol Benzoate and Testosterone Propionate Therapy.

The metabolic data of Case 10 are shown in graphic form in Figure 11. For data in tabular form for periods

Dietary intake of periods 1 to 18 in amounts per 24 hours: protein (analyzed nitrogen × 6.25) = 67.9 grams, fat (estimated from tables) = 57.2 grams, carbohydrate (estimated from tables) = 210.1 grams, calories (calculated from the values 4 for 1 gram of protein, 9 for 1 gram of fat, and 4 for 1 gram of carbohydrate) = 1,627.

* Initial weight 54.06 kgm.

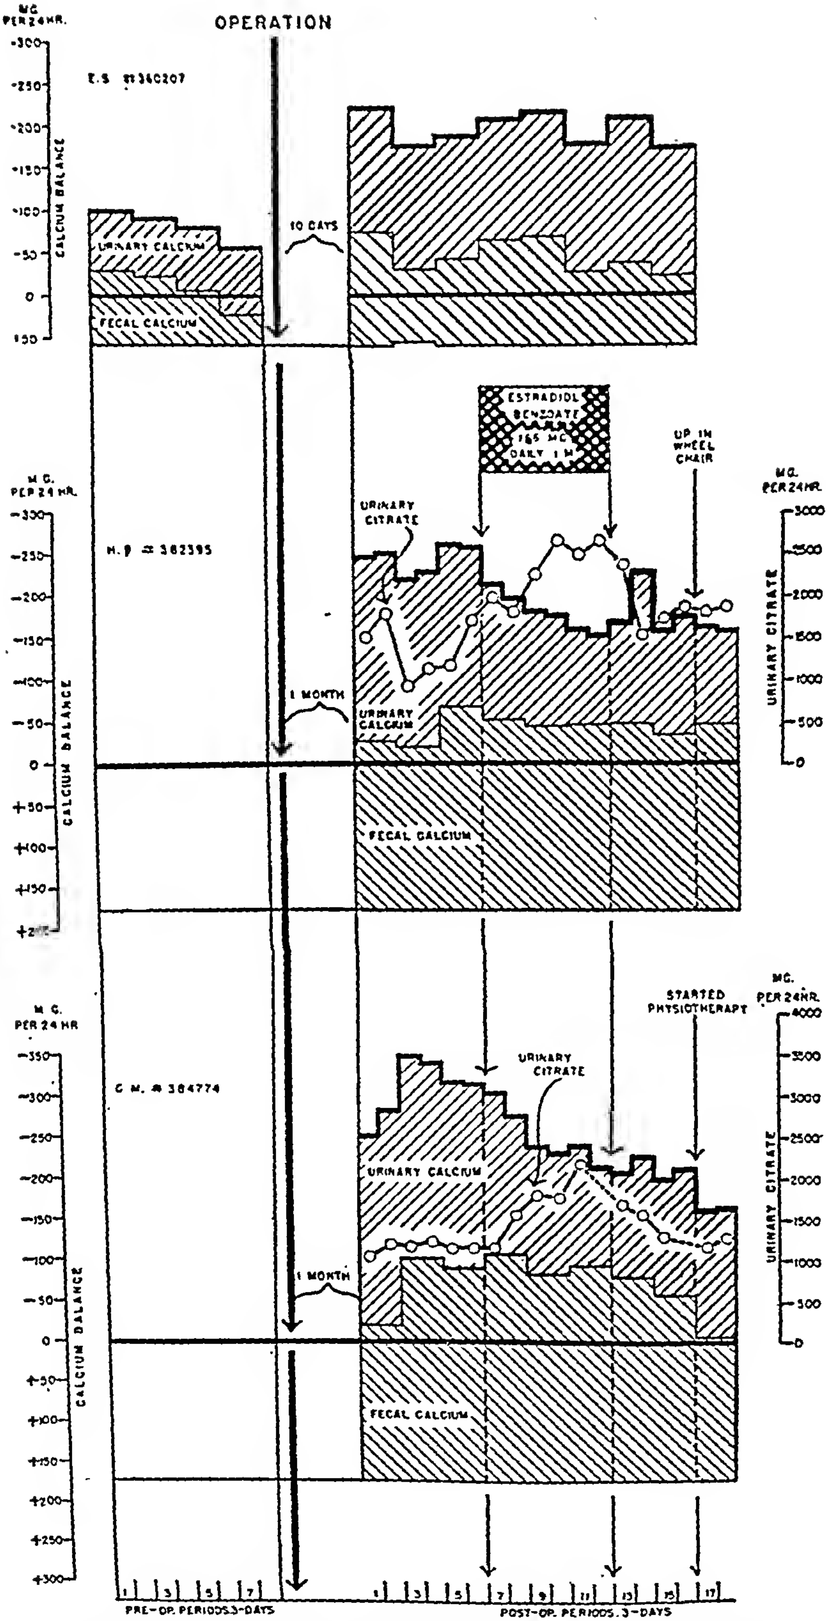

Fig. 10. Metabolic Data for Calcium of Cases 7, 8, and 9. Effect of Estradiol Benzoate as Compared with No Therapy on the Calcium Balances in Patients with Osteoporotic Process due to Operation and Immobilization

For discussion, see text.

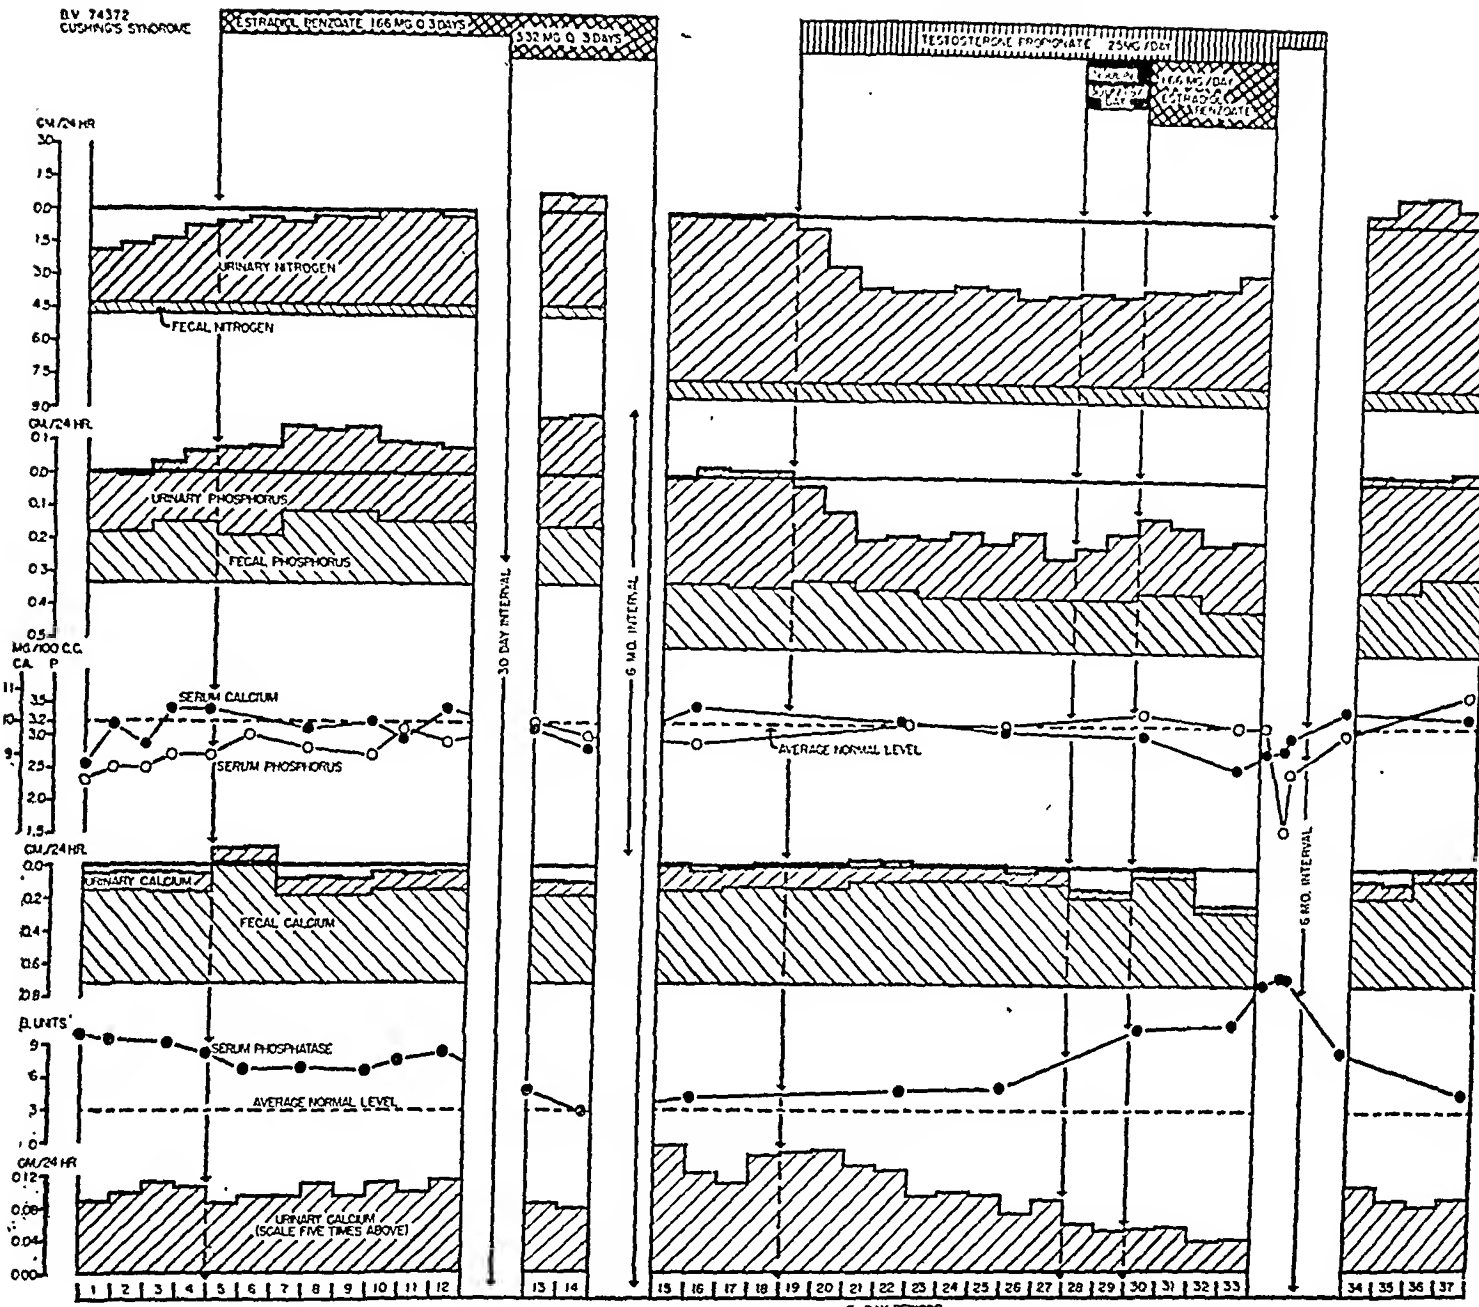

Fig. 11. Case 10 (B. V., M.G.H. 74372): Effect of Estradiol Benzoate and Testosterone Propionate on Nitrogen, Phosphorus, and Calcium Balances, and on Serum Calcium, Phosphorus and Alkaline Phosphatase in a Female Patient with Osteoporosis due to Cushing's Syndrome

For discussion, see text.

At the bottom of the chart, the urinary calcium is shown separately on an enlarged scale.

1 through 33, see (2). The study covers 37 five-day periods obtained on 4 hospital admissions. Two diets were used: one for periods 1 through 14, and a second for periods 15 through 37. The nitrogen intake shown in Figure 11 for periods 17 through 33 is an analyzed value, and differs from that previously published which was taken from a table. The data in Figure 11 are self-explanatory. It should first be noted that the phosphorus balance corresponds reasonably well with the sum of the nitrogen and calcium balances during the last 23 periods, but not the first 14. This suggests some constant error in the first 14 periods, probably the value for the nitrogen intake. A more detailed analysis to emphasize the close agreement between the nitrogen, potassium, phosphorus, and sulphur balances of periods 15 through 33 has already been published (9). Although Albright *et al* (2) concluded from these studies that estrogen was without beneficial effect, this was true with respect to the nitrogen balance but not altogether true with respect to the calcium balance. Thus, with the larger dose of estradiol benzoate in periods 13 to 14 there is an increase, probably significant, in the calcium balance. Further-

more, when estradiol benzoate was added to testosterone propionate therapy in periods 30 through 33, there was a further fall in the urinary calcium excretion and an increase in the positive calcium balance. Other observations to be underlined in Figure 11 are: (*1*) the marked decrease in the urinary nitrogen, phosphorus, and calcium excretions with testosterone propionate therapy; (*2*) the marked rise in the serum phosphatase level when the increase in calcium balance became appreciable (see periods 30 through 33). Whereas Figure 11 suggested that insulin had a marked effect on calcium balance (see periods 28 and 29) the authors are inclined to discount this because of the essentially negative result in a second patient with Cushing's syndrome so treated (18).

Case 11. Cushing's Syndrome with Osteoporosis; Estradiol Benzoate, Testosterone Propionate, and Methyl Testosterone Therapy.

The metabolic data on Case 11 are shown in graphic form in Figure 12. For data in tabular form for periods 1 through 36, see (2). The study covers 55 five-day periods obtained on 6 hospital admissions. The data in Figure 12 are self-explanatory. It should first be noted that the phosphorus balance corresponds reasonably well with the sum of the nitrogen and calcium balances throughout. As in Case 10, one cannot conclude, as did Albright, *et al* (2), that estrogen therapy is without beneficial effect. It was started before the metabolic study was initiated; so its initial effect is hard to evaluate (see periods 1 through 7); however, further studies undertaken 35 days after omitting estrogen show that the calcium balance has changed from positive to negative (compare periods 8 and 9 with 6). Other points to be noted in Figure 12 are: (*1*) the lowering of the urinary nitrogen, phosphorus, and calcium excretions with testosterone propionate therapy (periods 10 through 18, and 23 through 36) and with methyl testosterone therapy (periods 50 through 55); (*2*) the fact that the fecal phosphorus and calcium excretions were also lowered with these 2 testosterone compounds; (*3*) the quick rebound in the nitrogen and phosphorus and not the calcium metabolisms on cessation of testosterone propionate therapy (see periods 19 through 22); (*4*) the steady improvement in calcium metabolism with continued administration of testosterone propionate therapy; (*5*) the elevation of the serum phosphatase with improvement in the calcium balance; and (*6*) the rise in the serum phosphorus level following omission of estradiol benzoate therapy in period 6. The marked improvement in calcium balance in periods 29 through 36 is probably to be attributed to continued testosterone propionate therapy, but the initiation of vitamin D therapy in period 29 makes the exact interpretation difficult. Dehydroisoandrosterone acetate in periods 42 to 46 did not prevent the rebound in nitrogen and phosphorus metabolisms from omission of testosterone propionate therapy.

Case 12. Cushing's Syndrome with Osteoporosis; Progesterone and Testosterone Propionate Therapy.

The metabolic data of Case 12 are shown in graphic form in Figure 13. For data in tabular form, see (2). The study, conducted in 5-day periods, consisted of: (*1*) five control periods; (*2*) seven periods on progesterone therapy, 25 mgm. per day; and (*3*) four periods on testosterone propionate therapy, 25 mgm. intramuscularly per day.

The data in Figure 13 are self-explanatory. As pointed out by Albright, *et al* (2), the progesterone therapy, if anything, had a slightly beneficial effect on nitrogen, phosphorus, and calcium. The effect was not nearly so marked as that obtained in periods 13 to 16 with testosterone propionate therapy. Of interest is the rise in the alkaline phosphatase level in period 16, when the calcium balance became appreciable. It should be noted that the 17-ketosteroid excretion was not lowered by progesterone or elevated by testosterone propionate; the latter finding is surprising, and not in agreement with other studies.

CERTAIN THERAPEUTIC ASPECTS CONCERNING POST-MENOPAUSAL OSTEOPOROSIS

A large number of cases, many complicated by fractures, have been treated with estrogens alone and in combination with testosterone compounds during the past 5 years. As a group, these patients have responded very satisfactorily. Within weeks to months, the pain in the spine and other bones usually has been considerably or completely eliminated. There has frequently been an increase in weight, apparently an increase in the thickness of the skin and an improvement in the general well-being Whereas the study is impossible to control, we have the impression that fractures, especially of the hip, in old ladies have responded better than they would have otherwise. However, in spite of these favorable clinical manifestations, it has been difficult to produce undisputed evidence that the bones (excluding fracture-sites) as visualized by x-ray have become more calcified than before the therapy was instituted. Nevertheless, the recent films of several of the longest-treated cases are fairly convincing.

Dosages have ranged as follows: diethylstilbestrol 0.5 to 1 mgm. daily p.o., estrone sulfate [6] 2.50 to 3.75 mgm. daily p.o., estradiol benzoate 1.66 to 3.32 mgm. 3 times a week i.m., and estradiol dipropionate 5 mgm. weekly i.m. A few patients have been treated by implantation of pellets. Excessive estrogenic effect on the endometrium has been controlled whenever a responsive uterus was present, by interrupting the estrogenic therapy periodically (every 4 to 6 weeks

[6] Conjugated equine estrogens (Premarin [Ayerst, McKenna and Harrison]).

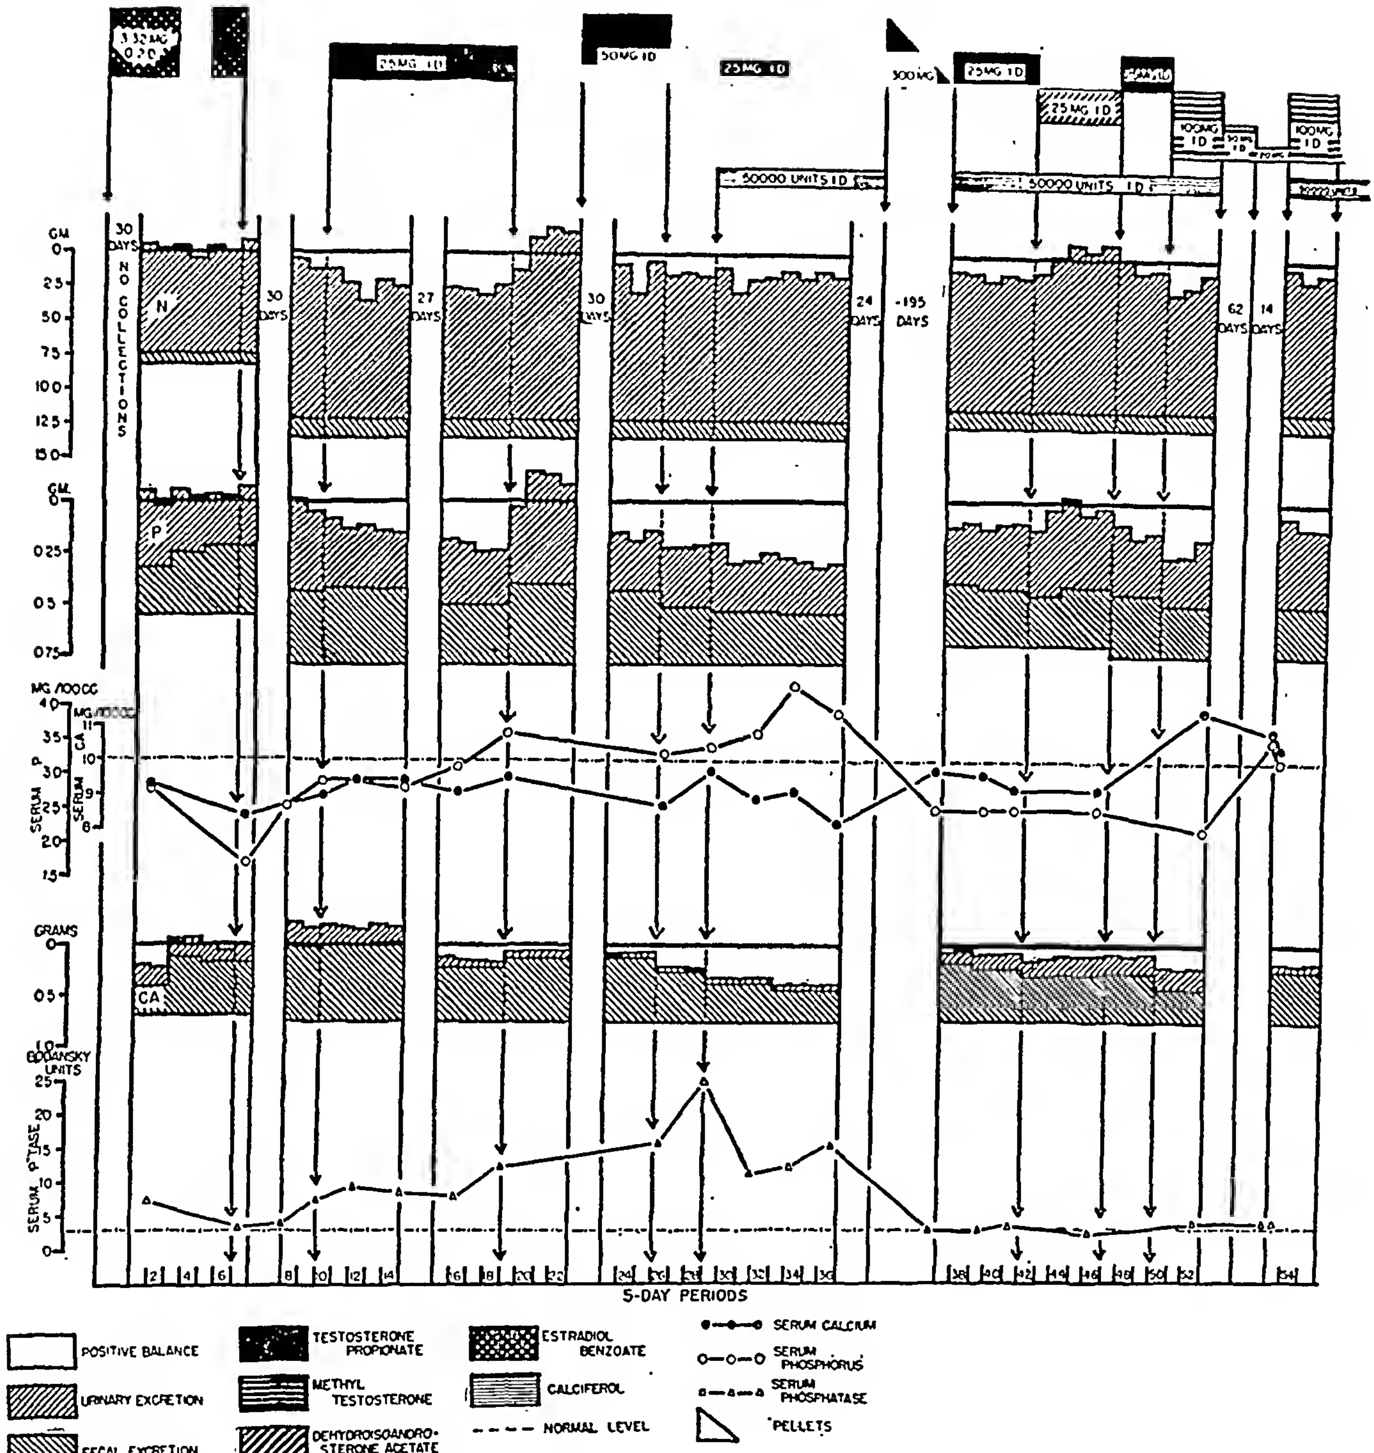

FIG. 12. CASE 11 (R. B., M.G.H. 3397): EFFECT OF ESTRADIOL BENZOATE, TESTOSTERONE PROPIONATE AND METHYL TESTOSTERONE ON NITROGEN, PHOSPHORUS, AND CALCIUM BALANCES; AND ON SERUM CALCIUM, PHOSPHORUS, AND ALKALINE PHOSPHATASE IN A FEMALE PATIENT WITH OSTEOPOROSIS DUE TO CUSHING'S SYNDROME

For discussion, see text.

for 1 to 2 weeks), or by administering at regular intervals (every 4 to 6 weeks) a course of progesterone (5 mgm. daily i.m. for 5 days) or of anhydro-hydroxyprogesterone (40 to 60 mgm. daily p.o. for 5 days). Testosterone compounds cannot be given in most patients with the impunity suggested from Case 4; she was remarkably free from the masculinizing effect of such medication. Most women will not tolerate more than 300 mgm. per month of androgen. We have given methyl

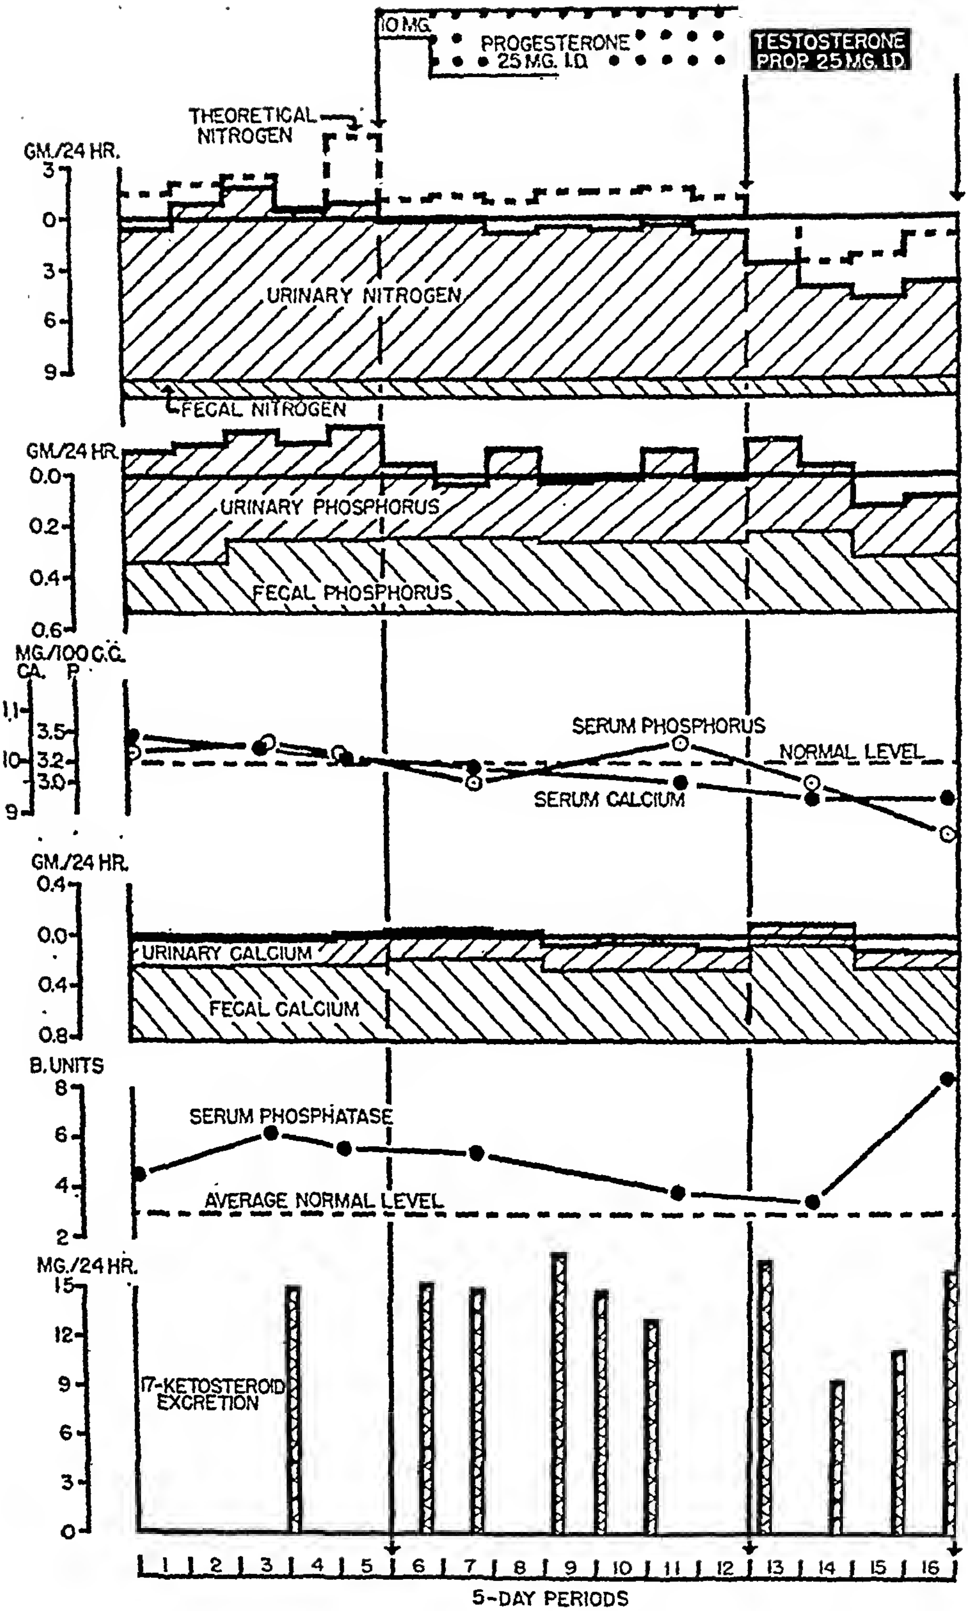

Fig. 13. Case 12 (B. A., M.G.H. 234190): Effect of Progesterone and Testosterone Propionate on Nitrogen, Phosphorus, and Calcium Balances; on Serum Calcium, Phosphorus, and Alkaline Phosphatase; and on Urinary 17-Ketosteroid Excretion in a Female Patient with Osteoporosis due to Cushing's Syndrome

For discussion, see text.

testosterone 10 to 20 mgm. daily p.o., and testosterone propionate 10 to 20 or 25 mgm. a week i.m. One of the most successful methods of administering testosterone compounds to these patients is to implant one or two pellets of testosterone (75 mgm. each [Schering]) every 3 to 4 months. We usually give some form of testosterone at least for the first 6 to 12 weeks.

Since many of the steroids cause sodium retention, the above endocrine therapy may cause edema in certain elderly patients, especially if they have low serum protein levels. If this is not controlled by a low sodium chloride diet, and/or ammonium chloride, the steroid therapy may have to be modified.

Because of the possible danger that continued estrogenic medication may lead to cancer, it has been our practice to interrupt the medication for 7 to 14 days every 4 to 6 weeks, even though the uterus is out. An examination of the vaginal smear every 6 months provides a further safeguard (19). If the uterus is in, a record should be kept of the vaginal bleeding; any bleeding not according to plan (that is, not following estrogen or progesterone withdrawal) should promptly be investigated further.

Since osteoporosis is a deficiency in bone matrix protoplasm, a high protein diet is probably indicated; since it is not a disease of calcium and phosphorus metabolism, excessively high intakes of these minerals and of vitamin D are probably not indicated. Prolonged immobilization should, of course, be avoided if possible, because of the danger of superimposed atrophy of disuse.

SUMMARY

1. Osteoporosis is defined as that form of undermineralization of bone in which the primary defect is a hypofunction of the osteoblasts in laying down bone matrix; eight etiological subgroups are listed.

2. The effect of certain steroid hormones (notably estrogens, androgens, and progesterone) has been studied in 11 cases of osteoporosis: 5 cases of the post-menopausal type, 1 case of the senile type, 2 cases of the type seen following orthopedic operations (atrophy of disuse), and 3 cases of the Cushing's syndrome type.

3. Estrogens in the 2 forms used (estradiol benzoate and diethylstilbestrol) decreased the calcium and phosphorus excretions in the 4 types of osteoporosis studied. Additional observations on estrogen therapy follow.

a. The fecal as well as the urinary calcium and phosphorus excretions were decreased in most instances.
b. The effects were usually manifested within 6 days; did not reach a maximum until after 30 days; and persisted for 30 to 50 days after cessation of therapy.
c. The synthetic estrogen, diethylstilbestrol, appeared to be as effective as the naturally-occurring estrogen, estradiol.
d. The ranges of dosages employed were for estradiol benzoate 3.32 mgm. daily to 1.66 mgm. every 3 days intramuscularly, and for diethylstilbestrol 1 to 15 mgm. daily by mouth. There was no convincing evidence that the larger doses of estradiol benzoate were more effective than the smaller; in one instance (Figure 3) 3.32 mgm. seemed less effective than 1.66 mgm. every third day. In the one case studied, 15 mgm. of diethylstilbestrol daily was probably more effective than 1 mgm. daily.
e. The serum phosphorus levels, which tend to be high in the post-menopausal group, fell in almost all instances.
f. The serum alkaline phosphatase levels, contrary to expectations, did not rise.
g. The urinary nitrogen excretion showed a poorly-sustained decrease.
h. The urinary 17-ketosteroid excretion showed a moderate decrease with estradiol.

4. Androgens in the 2 forms used (testosterone propionate and methyl testosterone) likewise decreased the calcium and phosphorus excretions in the 3 types of osteoporosis (post-menopausal, senile, and Cushing's syndrome) studied. Additional observations on androgen therapy follow.

a. As in the case of estrogens, the fecal as well as the urinary calcium and phosphorus excretions were decreased; the effect of the therapy on the calcium metabolism was slow in reaching its maximum, and persisted for a long time after cessation of therapy; the serum phosphorus levels tended to fall; the

serum alkaline phosphatase levels failed to rise except in the three cases of Cushing's syndrome.

b. In contrast to estrogens, the decrease in the urinary nitrogen excretion was marked and prolonged.

c. The ranges of dosages employed were for testosterone propionate 25 to 50 mgm. daily intramuscularly, and for methyl testosterone 40 to 100 mgm. daily by mouth.

d. Methyl testosterone appeared to be as effective as testosterone propionate.

5. Progesterone, in the dosages of 10, 25, and 100 mgm. daily, had no definite effect whether given alone or in combination with estrogen.

6. The effect on the calcum metabolism of estrogen and androgen in combination was greater than that of either alone in the post-menopausal and senile groups.

7. In Cushing's syndrome estrogen probably does have a beneficial effect on the calcium balance, previous statements to the contrary from this clinic notwithstanding! However, testosterone compounds have a much more striking effect in this condition, as opposed to other types of osteoporosis.

8. The data contain observations on the effect of pregnenolone and dehydroisoandrosterone acetate.

9. A short discussion of certain therapeutic aspects of post-menopausal osteoporosis is included.

The authors are grateful to Drs. Max Gilbert and Erwin Schwenk of the Schering Corporation, Bloomfield, New Jersey, for generous supplies of estradiol benzoate (Progynon-B), estradiol dipropionate (Progynon-DP), testosterone propionate (Oreton), methyl testosterone (Oreton-M), progesterone (Proluton), anhydro-hydroxyprogesterone (Pranone), dehydroisoandrosterone acetate, pregnenolone, and other steroids.

The authors are indebted to Drs. Charles H. Burnett, Russell W. Fraser, Anne Pappinheimer Forbes, Laurence W. Kinsell, Harry F. Klinefelter, Jr., William Parson, Patricia H. Smith, and Hirsh W. Sulkowitch for professional assistance; and to Esther Bloomberg, Dorothy F. Bryant, Evelyn Caroll, Lowell D. Cox, Eleanor F. Dempsey, Elizabeth C. Donaldson, Grace C. Griswold, Marion MacAulay, Robin M. Suby, Shirley L. Wells, and Priscilla White for technical assistance.

APPENDIX

Case histories

Case 1. F. F. (M.G.H. 156453), a 42-year-old woman, had a bilateral oophorectomy at the age of 41 for endometriosis; following the operation she had "nocturnal seizures," the exact nature of which was not determined. During the following year there was a gradual onset of back pain with increasing dorsal kyphosis and a loss of energy. On admission one year after operation, the patient was in good physical condition except for the deformities of her spine; her blood pressure was 130/80. X-rays revealed typical codfish deformity of many of the dorsal and lumbar vertebrae, a collapse of some vertebrae, and anterior wedging of others. Laboratory studies: serum calcium 10.5 mgm. per cent, serum phosphorus 4.2 mgm. per cent, serum alkaline phosphatase 3.6 Bodansky units, serum total protein 7.3 grams per cent, normal glucose tolerance test, some hypoglycemia unresponsiveness in an insulin tolerance test, basal metabolic rate of minus 6, follicle-stimulating hormone test positive for 25 mouse units per 100 ml., and 17-ketosteroid excretion of 4.3 mgm. per 24 hours. This case was mentioned in previous communications (1 [Case 1], 3 [Case 37], 20 [Case 82], 21).

Case 2. E. P. (M.G.H. 203540), a 60-year-old patient, had a physiological menopause at 53. Thirteen months before admission she fell down 6 steps and fractured her first lumbar vertebra; she was kept in bed 5 months for this injury, and then allowed up with a brace. Eight months before admission the 9th dorsal vertebra collapsed. Except for back and chest pain, the patient had no complaints, and was in good general health upon admission. Her blood pressure was 120/90. X-ray examination revealed the fractures of the first lumbar and the 9th dorsal vertebrae, marked osteoporosis of the spine and pelvis, but not of the skull, and gall stones. Laboratory studies: serum calcium 10.1 mgm. per cent; serum phosphorus 3.5 mgm. per cent; serum alkaline phosphatase 3.7 Bodansky units; serum total protein 7.6 grams per cent; no Bence-Jones protein in the urine. This case was mentioned in previous communications (1 [Case 2], 3 [Case 13], 20 [Case 85], 21).

Case 3. A. M. R. (M.G.H. 29358), a 60-year-old physician, developed menopause at 45 following radium treatment of submucous fibroids. Four years before admission she experienced pain in the back while trying to raise a window, and in the ensuing 4 years developed several fractures of vertebrae and progressive deformity of the spine. Physical examination on admission revealed the deformity of the spine and otherwise no abnormalities. Her blood pressure was 148/90. X-ray examination showed deformities of several thoracic and the first lumbar vertebrae, and osteoporosis of the bones of the spine and pelvis but not of the skull. Laboratory studies: serum calcium 10.1 mgm. per cent; serum phosphorus 3.0 mgm. per cent; serum phosphatase 3.7 Bodansky units; serum total protein 6.3 grams per cent. This case has been mentioned in previous communications (1 [Case 3], 3 [Case 32], 20 [Case 84], 21).

Case 4. R. W. (M.G.H. 319940), a 56-year-old woman, had a cholecystectomy at 26, and thyroidectomy for thyrotoxicosis at 46. At 48, an artificial menopause was induced with radium for metropathia hemorrhagica. Three years before admission the patient strained her back opening a heavy window, and thereafter had several episodes of sharp pain in the back when lifting. Physical examination showed a nervous woman with a tremor of her head, and considerable deformity of her back. Her blood pressure was 115/75. X-ray examination revealed extensive osteoporosis with multiple fractured vertebrae; bones of skull were approximately normal in density. Laboratory studies: no abnormalities of the urine, stools, or blood cells; urine calcium 2 to 4 plus by the Sulkowitch test; serum calcium 10.6 mgm. per cent; serum phosphorus 3.1 mgm. per cent; serum alkaline phosphatase 3.7 Bodansky units; serum chloride 93.2 m.eq. per l.; serum carbon dioxide combining power 28.1 m.eq. per l.; non-protein nitrogen level 26 mgm. per cent; and total protein 7.8 grams per cent with an albumin/globulin ratio of 1.7. Electrocardiographic tracing was normal; follicle-stimulating hormone excretion in the urine was high (consistent with the menopause). This case has been mentioned in a previous communication (21).

Case 5. S. B. (M.G.H. 430664), a 58-year-old woman, had at the age of 28 a bilateral oophorectomy with a hysterectomy for pelvic lacerations following childbirth. For some years she had occasional hot flashes and attacks of palpitation and nervousness. At the age of 50 she began to notice weakness and the gradual onset of skeletal deformities involving the skull, shoulder girdle, lower ribs, pelvis, and bones of the legs. At 54 she had acute tonsillitis, and then a tonsillectomy. At 57 she had pneumonia, and after 3 weeks in bed, increased weakness and pain in her tibiae. About this time she used braces on her legs because of difficulty in walking. Shortly afterward she developed low-back pain on weight-bearing.

On admission, the patient was undernourished and deformed with atrophic skin and muscles, dorsal kyphosis and right cervical-dorsal scoliosis, enlarged parietal bosses, bowing of the femora and tibiae, and collapse of the lumbar spine so that the ribs touched the wings of the iliae. The chest was distorted; veins of the neck were distended; cor pulmonale was present; blood pressure was 156/80.

X-rays of the skull, shoulder girdle, lower ribs, pelvis, femora, tibiae, and entire thoracic and lumbar spine except for the upper three dorsal vertebrae showed Paget's disease; in addition there were marked generalized decreased density of bones and typical codfish deformity of many vertebrae. There were pulmonary fibrosis, cardiac enlargement and displacement, and tortuosity of the aorta. Laboratory studies: serum calcium 10.5 mgm. per cent, serum phosphorus 4.2 mgm. per cent, serum alkaline phosphatase 34.3 Bodansky units, serum total protein 7.3 grams per cent, serum non-protein nitrogen 31 mgm. per cent, serum sodium 140.0 m.eq. per l., serum potassium 4.7 m.eq. per l., serum chloride 101 m.eq. per l., serum carbon dioxide content 34.2 m.eq. per l., follicle-stimulating hormone test positive for 192 mouse units per 24 hours, and 17-ketosteroid excretion of 2.6 mgm. per 24 hours. The venous pressure was 65 mm. of water; the vital capacity was 1,200 ml.

Case 6. M. H. (M.G.H. 278511), a male of 72 years, developed pain in the back after a minor injury 1 year before admission (1–1–41). The symptoms persisted in spite of local therapy, and he was referred to the hospital. The only abnormal findings on physical examination were a thin skin and deformities of the spine; his blood pressure was 140/80. X-ray examination of the spine showed marked decrease in density of the vertebrae with a codfish deformity of some, and wedging or collapse of others. Laboratory studies: serum calcium 10.0 mgm. per cent; serum phosphorus 3.1 mgm. per cent; serum alkaline phosphatase 4.2 Bodansky units; serum total protein 7.0 grams per cent; non-protein nitrogen 18 mgm. per cent; urinary 17-ketosteroid excretion 7.2 and 6.9 mgm. per 24 hours; follicle-stimulating hormone excretion in the urine normal; gastric acidity normal. The normal level of the follicle-stimulating hormone excretion is evidence against the idea of the osteoporosis having been due to the "male menopause." This case has been mentioned in previous communications (6, 9, 21).

Case 7. E. S. (M.G.H. 360207), a female of 35 years, had poliomyelitis at the age of 9 involving the left leg alone, and since the age of 14 had worn a 6-pound brace on the left leg. She had always been very active. For the 10 years prior to study she had had metatarsal pain in the right foot, and for 3 years had turned her right ankle frequently. She was admitted for a triple arthrodesis and muscle transplant to strengthen the right ankle. The menstrual history was normal. From the point of view of the experiment the patient can be considered a normal adult female in every respect, except for the residuals of the poliomyelitis of the left leg; her blood pressure was 120/80. Laboratory studies: serum calcium 9.8 mgm. per cent; serum phosphorus 3.5 mgm. per cent; serum alkaline phosphatase 2.4 Bodansky units; and serum total protein 4.7 grams per cent; urinary 17-ketosteroid excretion 7.6 mgm. per 24 hours. This case has been mentioned briefly elsewhere (22).

Case 8. H. D. (M.G.H. 382395), a male fireman of 50 years, fell 3 stories and suffered fractures of ribs, pelvis, right tibia and right fibula, and multiple contusions and abrasions. The patient was in shock on admission, but responded promptly to a blood transfusion. On physical examination he was found to be a well-preserved man without organic disease; blood pressure was 110/60. A Kirschner wire was inserted through the os calcis and a Zimmer bow applied. During the next 2 weeks the fractures were reduced by traction and by several manipulations under anesthesia. The patient was transferred to the metabolic ward where studies were begun 44 days after the accident. Laboratory studies: serum calcium 10.7 mgm. per cent; serum phosphorus 3.3 mgm. per cent; serum alkaline phosphatase 2.7 Bodansky units; serum total protein 6.7 grams per cent. This case has been mentioned briefly elsewhere (23).

Case 9. C. M. (M.G.H. 348774), a male of 24 years, sustained a fracture of the pelvis and of the right femur in an automobile accident 9 months before study. The fe-

mur failed to unite properly and, although the patient was active and able to walk about with a cane, he had unusual motion and instability in his right femur because of the poor union. He was readmitted for bone grafting. Physical examination revealed a young adult male who was normal in all respects except for the incomplete union of his right femur; his blood pressure was 105/60. Laboratory studies: serum calcium 10.3 mgm. per cent; serum phosphorus 4.5 mgm. per cent; serum alkaline phosphatase 2.9 Bodansky units, and serum total protein 6.0 grams per cent. This case has been mentioned briefly elsewhere (24).

Case 10. B. V. (M.G.H. 74372), a female of 25 years, with Cushing's syndrome of 5 years duration. The case history of this patient has been published elsewhere (2 [Case 1]). This case has been mentioned also in other previous communications (6, 9, 20 [Case 37]).

Case 11. R. B. (M.G.H. 3397), a female of 50 years, with Cushing's syndrome of 5 years duration. The case history of this patient has been published elsewhere (2 [Case 2]). This case has been mentioned also in other previous communications (6, 9, 20 [Case 36], 25 [Case 2]).

Case 12. B .A. (M.G.H. 234190), a female of 43 years, with Cushing's syndrome of 6 years duration. A complete case history with autopsy findings is reported elsewhere (26). This case has also been mentioned in previous communications (2 [Case 3], 20 [Case 38]).

IMMUNOLOGIC STUDIES IN INSULIN RESISTANCE. III. MEASUREMENT OF AN INSULIN ANTAGONIST IN THE SERUM OF AN INSULIN-RESISTANT PATIENT BY THE BLOOD SUGAR CURVE METHOD IN MICE

By FRANCIS C. LOWELL

(From the Robert Dawson Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston)

(Received for publication July 19, 1946)

The detection of an insulin antagonist in the serum of insulin resistant subjects has been attempted on a number of occasions. In certain instances, the excessive quantities of insulin used in the neutralization experiments in animals may explain the failure to obtain evidence of an insulin antagonist. In the few successful experiments which have been done, little information of a quantitative nature has been obtained. Glen and Eaton (1) and Marble, Fernald and Smith (2) were able to demonstrate decreased responsiveness to insulin in rabbits injected with serum from insulin resistant patients. This change in the experimental animal was still demonstrable a week after injection of the serum. In the same year, Banting *et al.* (3) described experiments in which the incidence of hypoglycemic convulsions was reduced in mice injected with mixtures of serum and varying amounts of insulin. The serum was obtained from a patient with schizophrenia who developed insulin resistance during insulin shock therapy. This case is especially interesting because *diabetes was not present,* suggesting that the resistance was directed against prepared insulin only. When the same serum was retested a week later in mice maintained on a high carbohydrate diet, practically no insulin neutralization could be demonstrated. Lerman (4), in studying serum of 5 patients with insulin resistance, obtained evidence for the presence of an insulin antagonist in 2. One of these serums was provided by the writer, and was obtained from a diabetic patient, A. M., the subject of this and previous reports (5, 6). A high degree of allergy to insulin, coupled with marked insulin resistance, combined to make the giving of insulin to this patient both disagreeable and ineffective. A further important feature was the presence of a relatively mild degree of diabetes, making possible prolonged periods during which insulin therapy could be omitted without immediate danger to the patient's life. A number of hospital admissions provided opportunity to show that:

a. At the end of a period of 5 months or more without insulin therapy, small doses of insulin would give rise to urticaria, constriction in the chest, and, on one occasion, collapse.

b. After desensitization with graded doses of insulin, a period of 3 to 5 days followed during which the injection of relatively small doses of insulin would be followed by a fall in blood sugar.

c. Within about 11 to 15 days of starting desensitization and treatment with insulin, a solid resistance to insulin developed.

These changes were correlated with the absence, and then the appearance, of insulin-neutralizing activity in the patient's serum. The allergic reactions appeared to be mediated by a mechanism quite independent of that giving rise to resistance (5).

The method previously used for the demonstration of insulin-neutralizing activity of the patient's serum (6) consisted in observing the incidence of hypoglycemic symptoms in mice injected with a mixture of serum and insulin. This method had a number of disadvantages which outweighed its simplicity. A relatively large dose of insulin was required in order to produce symptoms of hypoglycemia with some regularity when normal serum was used, and because of this the chance of detecting small amounts of neutralizing activity in the serums to be tested was decreased. This, in turn, led to the use of a large amount of serum

in each animal, a circumstance which in itself introduced non-specific blood-sugar raising effects (see below). These effects had to be distinguished from specific insulin neutralization, and tended to decrease the regularity of symptoms in control tests. Furthermore, the recognition of truly hypoglycemic symptoms was not always easy. Finally, reliance on the incidence of hypoglycemic symptoms as an indication of insulin effect provided no direct measure of the effect of the injected mixture on the blood sugar itself. With the present method, some of these difficulties are avoided, and the small amounts of serum required made possible a more detailed study of the behavior of the serums tested. One serum, obtained from A. M. before insulin therapy was started in the patient's final and hitherto unreported hospital admission, will be referred to below as "before" serum, and a second specimen, obtained 25 days after insulin treatment had been started, at a time when resistance had been reestablished, will be referred to as "after" serum.

CASE REPORT

(*Final hospital admission* [1])

After discharge from the Evans Memorial Hospital on 11/15/42, the patient, a 45-year-old, white female, was seen at infrequent intervals. In the fall of 1943, a diagnosis of pulmonary tuberculosis was made, and she spent several months in a sanatorium for tuberculosis. She refused to stay, however, and received no further hospital care until April, 1944, when she was readmitted to the Evans Memorial Hospital with advanced pulmonary tuberculosis. With the exception of this, examination revealed findings similar to previous admissions. No insulin had been given since November, 1942, and it was thought advisable to try insulin therapy again. The patient was intolerant of many procedures, and no attempt was made to restudy the effect of insulin therapy in detail. As shown in Table I, the administration of insulin in daily doses of between 40 and 102 units brought about a marked reduction in the 24-hour output of glucose for a period of 6 days. This was first apparent on the third day of insulin treatment, at which time the blood sugar fell from an average of 300 to 154 mgm. per 100 ml. Some degree of insulin effect was apparent up to the ninth day of therapy. Thereafter no response to insulin occurred with daily doses of 120 to 280 units. All insulin therapy was stopped on 5/20/44 after a total of 3,969 units had been given in a period of 33 days. During the treatment with insulin, the patient complained of itching and soreness at the site of the injections, and, in addition,

[1] Previous hospital admissions have been reported (5).

had several attacks of urticaria while desensitization was in progress. The sequence of events following attempted therapy with insulin was similar to that following earlier attempts (5), and the presence of active tuberculosis appeared to have no influence on the patient's resistance.

The patient refused sanatorium care, and finally left the hospital against advice. It was learned later that she died at home in the fall of 1944, and that no autopsy was done. The discharge diagnoses were: Diabetes mellitus with diabetic retinitis and peripheral neuritis; insulin allergy and resistance; chronic pyelonephritis; pulmonary tuberculosis.

MATERIALS AND METHODS

Each of 6 large white mice, starved for 18 hours, was injected intra-abdominally with 0.2 ml. of a mixture of serum, diluted or undiluted, and a dilution of insulin, after a fasting blood specimen had first been obtained. Subsequent blood samples were taken 30 minutes and 60 minutes after the injection of the mixture to be tested. For each blood sugar determination, .1 ml. of blood was drawn from a clean cut across a tail vein into a .1 ml.

micro blood sugar pipette which had been rinsed with a heparin solution containing 20 mgm. in 1 ml. of distilled water and thoroughly dried. The presence of heparin reduced the incidence of clotting, and did not interfere with the blood sugar determinations. These were done according to the technic of Folin, and the color readings were made in an Evelyn colorimeter. No animal was used more than once. The flow of blood was found to be freer when the animals were kept warm during the test. This was done with an ordinary desk lamp held at such a distance from the animals that a temperature of 27° C. to 30° C. was maintained. The performance of the test was facilitated by first drawing up a schedule in which the times at which blood samples were to be obtained and injections given were noted. A period of 5 minutes was allowed for each procedure.

Serum for testing was obtained from clotted blood, drawn with sterile precautions, and was stored in the frozen state at −10° C. The "before" and "after" serums from A. M., and serum from a case of uncomplicated diabetes, all of which contained high concentrations of glucose, were dialyzed in 10 ml. amounts in cellophane bags against 40 ml. of buffered salt solution at pH 7.4 for 18 hours at 4° C. No significant change in volume occurred.

* Average based on 4 animals.

** Average based on 5 animals.

Glucose determinations were made on the dialyzed serums, as well as other serums which were not dialyzed, and all serums tested contained between 40 and 55 mgm. glucose per 100 ml. Dialysis produced no observable change in the behavior of serums in mice, other than that attributable to the reduction in the glucose content.

RESULTS

Six tests in which mice were injected with mixtures of a serum and saline with no added insulin are shown in Table II (tests 1 to 6). Of the 35 mice tested, all but 1 showed a rise in blood sugar following injection. The rise was greatest in the first 30-minute period. Wide variations occurred in the responses of individual mice and, with the small number of animals used, the difference in the degree of the rise from test to test is hardly susceptible of interpretation. These results stand in sharp contrast to those obtained when insulin was injected with normal serum, serum from an uncomplicated case of diabetes mellitus, or "before" serum from A. M. A moderate but prompt fall in blood sugar followed the injection of .005 unit of insulin mixed with serum in 15 of 18 mice, and this fall was sustained or more marked at 60 minutes (Table II, tests 7 to 9). A greater fall occurred in mice receiving .01 unit (Table II, tests 10 and 11).

Tests with "after" serum from A. M., in which varying amounts of insulin were added to a constant volume of serum, are shown in Table III. In all tests with .06 unit or less, a rise in the average blood sugar occurred at the end of 30 minutes. Only in test 9 did a fall occur in the first 30 minutes, the amount of insulin required to cause this, .075 unit, being 15 times greater than that required when a normal or "before" serum was used. A rise in blood sugar over the fasting level was also observed at the end of 60 minutes in 2 tests with .01 unit, 1 of 2 tests with .02 unit, and 2 tests with .03 unit. The fall in test number 3 is unexplained. With .05 and .06 units, a moderate fall was seen at 60 minutes. In the test with .075 unit, the fall in the blood sugar was of about the same degree as that seen with "before" and normal serums in combination with .005 unit of insulin.

Titration of the neutralizing activity of this serum was also attempted by mixing varying dilutions of serum with a small constant dose of insulin. The results are shown in Table IV. A rise

* Average based on 5 animals.

in the average blood sugar occurred at the end of 30 minutes in tests done with serum diluted 1:3, 1:6, 1:12 and 1:24. When diluted 1:48, a marked fall occurred in 30 minutes. At the end of 60 minutes the results in this group of tests were less regular. A rise occurred in 3 tests (Table IV, tests 1, 3 and 4) with serum diluted 1:3, 1:6, and 1:12, but a fall occurred in 1 test done with 1:6, and 1 done with 1:24. When compared with the results obtained with undiluted normal serum (Table II, tests 6 to 9), these 2 tests suggest that some neutralization of insulin took place. Marked variation in the behavior of individual mice is evident in all but the first and the last.

The effect of injecting .1 ml. of "after" serum 18 hours before the injection of insulin was also tried. The amounts of serum and insulin were such as to make the tests comparable to those done with mixtures of insulin and serum. With a dose of .005 unit per mouse there was a rise in blood

sugar in 5 of 6 mice in 30 minutes, and in 4 of 6 mice at 60 minutes with an average rise of 11 mgm. per 100 ml. in 30, and of 9 mgm. per 100 ml. in 60 minutes. With .01 unit per mouse there was a rise in all 6 mice at 30 and 60 minutes. However, with .03 unit per mouse, the average change was downward at 30 and 60 minutes. Thus, as would be expected, the anti-insulin effect of the serum was diminished when a period of time was allowed to elapse between the injection of the serum and the administration of insulin. It appears, therefore, that the insulin antagonist in the "after" serum of A. M. is most active when it is injected simultaneously with insulin. This suggests that this antagonist is not the glycotropic factor of the pituitary. This hormone, when injected, produces no immediate effect on the susceptibility of the animal to insulin, but on the contrary, a period of several hours is required before interference with the action of insulin becomes demonstrable (7).

No decrease in the insulin-neutralizing effect of the serum could be demonstrated when insulin was added to the serum in 3 to 6 divided doses at 5-minute intervals in amounts totaling .03 unit per mouse and .06 unit per mouse. This was done in an unsuccessful attempt to demonstrate a Danysz phenomenon.

DISCUSSION

The performance of the test, irrespective of the injection of insulin, may be assumed to have effects on the experimental animal which, in themselves, may cause elevation or depression of the blood sugar. Unexplained falls in blood sugar of individual mice receiving serum or saline without insulin were occasionally seen in some earlier unreported experiments, but were not observed in later experiments. The marked tendency for the blood sugar to rise when serum alone was injected (Table II) may probably be explained as being due to the animal's fright and anger at being held, bled, and injected, and to the non-specific effect of injecting foreign material. The regular rise in the blood sugar of mice following the injection of serum without any added insulin casts some doubt on the significance of experiments which have been carried out in the past, allegedly demonstrating a specific blood-sugar raising effect of serum from an insulin-resistant subject (8).

The results of this study support, in a roughly quantitative manner, the conclusions reached in the earlier qualitative tests (6). An estimation of the insulin inactivating capacity of the patient's plasma volume at the time the "after" serum was drawn readily explains the resistance to insulin and, in addition, indicates that the doses given the patient during the final hospital admission were a fraction of what would have been required to induce a fall in blood sugar. The amount of insulin which, on the basis of the studies made, would be neutralized by the patient's entire plasma volume (2,500 ml.) can be estimated in a number of ways. One figure can be arrived at by using the largest dose of insulin per mouse with which neutralization of insulin was demonstrable, namely .06 unit per .1 ml. (Table III, test 8).

$$.06 \times 10 \times 2{,}500 = 1{,}500 \text{ units}$$

When calculated on the basis of tests in which dilutions of serum were made, the required dose for rapid insulin effect would be (Table IV, test 5)

$$.005 \times 24 = .12 \text{ u per .1 ml. serum}$$

and

$$.12 \times 10 \times 2{,}500 = 3{,}000 \text{ units}$$

In tests of this kind the agreement cannot be expected to be close, but the evidence clearly indicates that something well over 1,000 units would be required in order to bring about a rapid fall in blood sugar in the patient. This reasoning is based on the extremely doubtful assumption that the insulin-neutralizing factor was present in the circulating blood alone. If an antibody was actually involved, the tissues might also have played a large part in the inactivation of the administered insulin. Furthermore, the continuous production of the antibody would serve to augment the dose of insulin required to bring the diabetes under control if the doses were spread, as is usually the case, over a period of time. Thus, the reported instances of insulin-resistant individuals requiring 3,000 to 4,000 units of insulin daily can be explained on the very mechanism that accounted for insulin resistance in A. M.

Assuming the immunologic nature of insulin resistance in A. M., the fact that relatively little insulin could be tolerated because of the high degree of allergy provided a circumstance especially favorable for the demonstration of the insulin-neutralizing antibody. Administration of doses of insulin sufficiently large to have controlled the diabetes should at the same time have brought about a marked diminution in the antibody content of the circulating blood. This may in part explain the failure of many of the attempts in the past to demonstrate insulin-neutralizing activity in the serum of resistant subjects, who, after all, can be recognized clinically only by their failure to respond to any but very large doses of insulin. Inadequate treatment of the diabetes with insulin, or better still, no treatment at all for a brief period before obtaining serum, would probably facilitate the demonstration of insulin-neutralizing activity in the serum of resistant individuals.

The ready demonstration of insulin-neutralizing activity in the serum of resistant patients will probably depend on a high degree of resistance. Thus, patients who are resistant to insulin but who require only 300 to 500 units daily will, in all likelihood, have nothing in their serums that could be demonstrated by the technic described. Study of such patients with a view to determining the cause of the resistance will probably have to depend on different methods.

Failure of the usual *in vitro* immunologic tests for the demonstration of antibody in the serum of insulin-resistant subjects is, like the failure to demonstrate the Danysz effect in the serum of A. M., no argument against the immunologic nature of the resistance. Such methods depend for their success on suitable characteristics of both the antigen and the antibody, as well as adequate concentrations of the latter. The evidence to date (6) is against the view that the precipitins or complement fixing antibody occasionally encountered in the serum of patients receiving insulin (9), or animals injected with insulin in an attempt to induce allergy or antibody formation (10, 11), are actually concerned with insulin resistance.

SUMMARY AND CONCLUSIONS

1. A method is described which adequately demonstrates interference, by serum of an insulin-resistant patient, with the blood sugar lowering effect of insulin in mice, and which permits rough quantitation of this interference.

2. Estimation, on the basis of the results of this study, of the total insulin-neutralizing activity of the patient's blood volume, readily explained the patient's resistance.

3. The mechanism giving rise to insulin resistance in the patient studied, presumably immunologic in nature, can explain the extreme instances of insulin resistance which have been occasionally reported.

TRICHINELLA SKIN TESTS IN AN ORPHANAGE AND PRISON. COMPARISON WITH SEROLOGIC TESTS FOR TRICHINOSIS AND WITH THE TUBERCULIN REACTION [1]

By GEORGE T. HARRELL, S. F. HORNE, JERRY K. AIKAWA, AND NANCY J. HELSABECK

(From the Department of Medicine, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem)

(Received for publication August 5, 1946)

The possibility that an unrelated disease process may alter the reaction to the trichinella skin test was uncovered in the course of an investigation on the incidence of trichinosis. A higher percentage of positive skin reactions to trichinella antigen (18.3 per cent) was obtained in 674 patients with active tuberculosis confined in 3 sanatoria, than was found in 335 patients without tuberculosis (7.2 per cent) studied in 2 general hospitals for shorter periods of time (1). On the other hand, the incidence (18.4 per cent) in 825 patients without active tuberculosis confined in 3 hospitals for mental diseases was almost identical with that found in the sanatoria. This finding suggested that some factor connected with residence in an institution might account for the high incidence. An analysis of positive reactors according to the duration of stay in an institution revealed that the incidence of positive reactions reached a peak at 18 to 29 months; no history suggesting subclinical institutional epidemics was elicited (1).

Experiments were undertaken to determine whether positive trichinella skin tests could be produced in the absence of infection by the ingestion of killed trichinae, as in meat rendered non-infectious by cooking inadequate to denature the protein of the parasite. Sensitization was not induced in the animals used for these experiments (2). The possibility of a biologic cross reaction, detectable by skin test, between *Mycobacterium tuberculosis* and *Trichinella spiralis* was investigated in rabbits infected with trichinae and a bovine strain of tubercle bacilli simultaneously. No cross reaction was detected in these rabbits by skin tests (3).

The present experiments were undertaken to determine whether a biologic cross reaction detectable by skin test might be demonstrated in human beings. It was necessary to select subjects for testing who did not have active tuberculosis or acute psychiatric disturbances (1). In order to control adequately the factor of age in institutionalized individuals, it was desirable to choose one institution in which only children were in residence, and one institution where only adults were confined for comparable periods of stay. It had been found that the incidence of positive skin reactions decreases with advancing age, whereas the incidence of infection proved at autopsy increases with advancing age (1). An orphanage and a prison, both under close medical supervision, most nearly met the requirements.

MATERIAL

A total of 526 individuals were subjected to skin tests. Each person had been in residence in the institution for at least one year; the majority had been in residence for 2 to 15 years (Table III). In none was there a history of tuberculosis or of recognized mental disease. No patient was known to have had trichinosis, and there had been no epidemics in either institution which suggested trichinosis.

At the Methodist Children's Home, Winston-Salem, N. C., 285 children, varying in age from 6 to 19 years, were tested. The children are all white and are housed according to age in groups of 25 to 35 in 13 cottages; every 2 years they "graduate" from one cottage to another, so that the group is fairly homogeneous. Though there are kitchens in each cottage, only 3 are currently used to feed groups of boys included in this study. The remainder of the boys and all of the girls eat in a central dining room. Pork obtained from hogs raised on the orphanage farm is served twice weekly from November to February; the children eat little pork and prefer beef, which is also available. Routine chest x-rays are not made, but none of the children found to have a positive tuberculin skin test had clinical or roentgenologic evidence of tuberculosis when examined subsequently.

In the North Carolina Central Prison, Raleigh, N. C., a group of 241 prisoners, varying in age from 16 to 77 years, was studied. The 58 female prisoners are housed

[1] This study was aided by a grant from the John and Mary R. Markle Foundation.

in a separate building with a separate kitchen; hence, this group in effect represents 2 institutions. No prisoner had roentgenologic evidence of pulmonary tuberculosis when a photo-roentgen survey was made a few months prior to the initiation of this study. Pork raised on the prison farm is served once weekly. The quantity of pork eaten at the prison appears to have been slightly greater for the 2 years preceding the test than that eaten at the orphanage.

METHODS

In all instances, a 1:10,000 solution of trichinella extract (Lederle) and a phenolized phosphate buffer saline control solution were used.[2] A 1:1,000 dilution of tuberculin (Lilly) in distilled water and the tuberculin control solution were freshly prepared for use in each institution.

New syringes and needles were obtained for the skin tests, and were not used for any other purpose. One syringe and needle was always used for each test solution, and 2 others for the controls; the syringes and needles were never interchanged. After being used, they were washed with distilled water only, placed in marked tubes, and sterilized in an autoclave.

An area on the flexor surface of both forearms was cleaned with 70 per cent alcohol, and 4 workers simultaneously injected 0.02 ml. of the trichinella test and control solutions in the right arm, and 0.1 ml. of the tuberculin test and control solutions in the left arm. The test solution was always injected proximal to the control solution.

The reactions were read at 30 minutes and 24 hours after injection. The tuberculin reactions were graded by the usual scale from 1 to 4 plus. The trichinella reactions were also recorded on a scale of 1 to 4 plus, 1 plus denoting an immediate reaction which exceeded the diameter of the injected bleb by 5 mm. or more (1).

[2] The trichinella antigen and control solution used in this study were supplied by Lederle Laboratories, Pearl River, N. Y.

Ten weeks after the skin tests were performed, blood serum was drawn from the antecubital vein of the orphans for serologic testing. Serum was obtained from the prisoners 17 to 19 weeks after skin-testing.

Flocculation tests were performed according to the technique described by Suessenguth and Kline (4). The trichinae from which the antigen was prepared were recovered from rabbits fed 8 weeks previously on a rat infected with a strain of trichinella parasites obtained from the National Institute of Health (2). Precipitin reactions were done with a 1:200 dilution of antigen prepared from the same dried trichinae used for the flocculation test.

RESULTS

Skin tests

Orphanage. Fifty-seven children (20.0 per cent) gave positive trichinella skin tests; 51 were immediate reactions, and 9 were delayed reactions which appeared at 24 hours. Three tests were positive at both 30 minutes and 24 hours (Table I). Seven children reacted to both the test and control solution, and were calculated as negative in the statistical analysis. Forty children (14.0 per cent) gave positive tuberculin reactions at 24 hours. The immediate reactions to the tuberculin test and control solution were not thought to be significant. Six children reacted positively to both trichinella extract and tuberculin, and negatively to both controls. One hundred and ninety-five children gave negative reactions to all antigens at both times.

Prison. Sixty-five prisoners (27.8 per cent) gave positive reactions to trichinella antigen at some time (Table I). Fifty-two were immediate

* Three patients had positive reactions at both 30 min. and 24 hrs.

reactions, and 16 were delayed. Three were positive at both 30 minutes and 24 hours. Thirteen prisoners gave positive reactions to both the test and control solution at 30 minutes. Seventeen prisoners (7.1 per cent) had delayed reactions to tuberculin. Two prisoners reacted to both tuberculin and trichinella antigen, and did not react to the control solutions. One prisoner gave a positive reaction to both tuberculin and the tuberculin control solution at 24 hours. One hundred and sixty-three prisoners reacted negatively to all antigens at both times.

TABLE II

Comparison of tuberculin and trichinella skin tests

	3+	3	0	0	0	0
	4+	0	0	0	0	0

Since the interpretation of immediate and delayed reactions to trichinella antigen is still in doubt, positive reactions at either period were compared with late tuberculin reactions (Table II). No correlation between positive reactions to tuberculin and trichinella antigen was found.

The data were tabulated according to the extent of the trichinella reaction and the duration of stay in each institution (Table III). The duration of stay in an institution did not appear to affect the extent of the trichinella reaction. When the percentage of positive trichinella reactions was tabulated according to years of institutionalization, the incidence was found to be highest in the orphanage at the second and fifth years, with a secondary peak at the ninth year. In the prison, the peak incidence was reached at the sixth year.

* Sera with doubtful (±) flocculation gave negative precipitin test.
** Sera with 3+ flocculation gave negative precipitin test.

Serologic reactions

Orphanage. Flocculation tests for trichinosis were performed on serum from 38 children with positive trichinella skin tests, from 20 children with positive tuberculin and negative trichinella skin tests, and from 20 who reacted negatively to all antigens. All flocculation tests were negative (Table IV). No precipitin tests were done on the children.

Prison. Flocculation tests were performed on serum from 53 prisoners with positive reactions to trichinella antigen, from 5 with positive delayed tuberculin reactions, and from 51 who reacted negatively to all antigens (Table IV). Five sera from the group with positive trichinella skin tests, and 2 from the group negative to both antigens, gave doubtful flocculation reactions; 2 of the latter group gave strongly positive flocculation reactions. Precipitin tests were performed on serum from 20 prisoners with positive trichinella reactions, from 5 with positive tuberculin reactions, and from 18 who were negative to all antigens; none were positive. Serum had been collected from the other prisoners after a meal and was too cloudy for performance of accurate precipitin tests. Precipitin tests on serum from rabbits known to be infected with trichinae were strongly positive; these tests served as a control on the technique and the potency of the antigen.

DISCUSSION

No correlation has been found between the tuberculin and trichinella skin reactions; this clinical observation agrees with the results of experimental investigations in rabbits (3). No biologic cross reaction detectable by skin test appears to exist; the increased incidence of positive trichinella skin tests in tuberculous patients is still unexplained.

Whether the apparent increase in the incidence of positive trichinella skin tests among patients confined to any institution is connected with subclinical institutional epidemics, cannot be categorically stated. The fact that the flocculating antibodies and precipitins appear to bear no relation to positive skin reactions would argue against subclinical institutional epidemics. However, precipitins are known to persist for 2½ years after proven infection in human beings (5). The length of time for which flocculating antibodies persist in human beings is not known, but in swine the test remains positive for 10 months (4). It is possible that different antigens are involved in the production of the skin test and the serum reactions (6).

The increase in the incidence of positive skin reactions previously noted after 2 years' residence in an institution was confirmed at the orphanage; at the prison the peak was later, but in general the relation of positive skin tests to length of institutionalization followed the data previously reported (1). The explanation for this relationship is still obscure.

The wide variation in the incidence of positive reactions obtained in the 9 institutions which have now been studied cannot yet be explained.

While a positive tuberculin skin reaction does

not indicate the presence of active tuberculosis, it does indicate that the individual has been infected at some time and is allergic to some fraction of the organism. It would be reasonable to expect some degree of correlation between the skin reactions to tuberculin and trichinella antigen if one disease affects the severity of the other, as was suggested by the experiments in guinea pigs previously reported (7). Perhaps active tuberculosis is necessary for the infection with trichinae to be enhanced; the present study cannot answer this question.

That tuberculosis may affect the course of trichinosis was shown also by studies of the eosinophil response of guinea pigs (8). The injection of live virulent *M. tuberculosis* depressed the number of circulating eosinophils in trichinous animals. Since a rapid rise in eosinophils is the most frequent and easily detected early laboratory evidence of uncomplicated trichinosis, the absence of eosinophilia in a tuberculous patient with a positive trichinella skin test could cause confusion in diagnosis.

It is known that the electrical resistance of the skin of disturbed mental patients may vary markedly from that of the same patient after recovery (9). Previous studies with trichinella antigen in one mental hospital suggested that the reactivity to biologic products may be altered in the same way (1). Though none of the prisoners or orphans gave a history of active mental disease, it is true that all prisoners have committed an offense and may justly be suspected of having a psychiatric disturbance. Many orphans may likewise have some mild psychiatric manifestations. None of the individuals studied was acutely disturbed, however, and hence would not be expected to have an altered skin reaction.

SUMMARY

1. No correlation between the trichinella skin test and the tuberculin reaction was found in 526 individuals confined in an orphanage or a prison. The incidence of positive trichinella skin tests in 241 prisoners was 27.8 per cent; the incidence in 285 orphans was 20.0 per cent.

2. Positive serologic reactions to the flocculation or precipitin tests were not found in persons with positive trichinella skin reactions.

3. The duration of stay in an institution is apparently a factor in determining the incidence of positive trichinella skin tests. The explanation for this finding is obscure.

THE EFFECT ON THE TRICHINELLA SKIN TEST OF SIMULTANEOUS INFECTION WITH BOVINE TUBERCULOSIS IN TRICHINOUS RABBITS [1]

By GEORGE T. HARRELL AND NANCY J. HELSABECK

(From the Department of Medicine, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem)

(Received for publication August 5, 1946)

The possibility that infection with tuberculosis alters an individual's reactivity to trichinella antigen was suggested by the results of a survey on the incidence of trichinosis. It was noted that a higher percentage of positive reactions to trichinella antigen (18.3 per cent) was obtained in 674 patients with active tuberculosis in 3 sanatoria, than in 335 patients without tuberculosis (7.2 per cent) in 2 general hospitals (1). The explanation for this phenomenon has not been found by investigations on the possible effects of institutionalization and sensitization by the ingestion of nonviable trichinae (2, 3). The possibility of a biologic cross reaction, detectable by skin test, between *Mycobacterium tuberculosis* and *Trichinella spiralis* was investigated in guinea pigs infected simultaneously with tuberculosis and trichinosis (4). Because of the poor response of the guinea pig to trichinella skin test antigen, the possibility of such a cross reaction was neither confirmed nor denied, but it was found that guinea pigs infected simultaneously with both organisms showed heavier infections with *T. spiralis* than did similar animals suffering from trichinosis alone. The converse of this statement was not true, since the number of acid-fast organisms found on smears of the tuberculous lesions in trichinous guinea pigs was no greater than that observed in similar animals infected with *Mycobacterium tuberculosis* alone. It was postulated that an increased density of infection with trichinae in patients with active tuberculosis might explain the higher incidence of positive trichinella skin tests in such patients.

The present experiments were undertaken in an attempt to discover whether a true biologic cross reaction detectable by skin test exists between *Mycobacterium tuberculosis* and *Trichinella spiralis*. Since rabbits have been found to give better skin reactions to trichinella antigen than guinea pigs, this animal was selected for these experiments. This choice necessitated the use of a bovine strain of tubercle bacilli (2). Dogs have been found to give excellent skin reactions to trichinella antigen, but in preliminary experiments it was difficult to establish a uniform bovine tuberculous infection in them.

MATERIALS

Sixty rabbits of medium size were divided into 6 equal groups. The rabbits were between 4 and 9 weeks old, and weighed 2¼ to 7½ pounds. They were fed a stock diet (Kasco Complete Rabbit Ration, Kasco Food Co., Cincinnati, Ohio) supplemented with green vegetables 3 times weekly. Each animal was kept in a separate cage, and the groups infected with tubercle bacilli were kept in a separate room from those infected with trichinae alone.

The strain of *Trichinella spiralis* used was obtained from the National Institute of Health and was carried in albino rats. The culture of *Mycobacterium tuberculosis* (bovine, Ravenel strain) was obtained from Dr. Florence Seibert of the Henry Phipps Institute of the University of Pennsylvania, and was carried on plain glycerol bouillon agar medium titrated to pH 7.4. This highly virulent strain has been used by Opie and Freund (5). Intravenous injections of 0.5 ml. of a suspension of 1 loopful of culture in 5 ml. of saline solution resulted in death of a rabbit within 24 days.

Part of the dried trichinella larvae used was furnished by Parke, Davis and Co., Detroit, Michigan; the remainder was recovered from infected rabbits in our own laboratory. For skin testing, a 1:200 weight/volume emulsion in normal saline was made with dried powdered larvae, and was allowed to stand for 4 hours at room temperature, and overnight in the refrigerator at 12° C. The supernatant saline was then removed, placed in sterile rubber-stoppered vials, heated in a water bath at 60° C. for 1 hour daily on 3 successive days, and tested for sterility (2).

Tuberculin prepared from bovine strains of tubercle bacilli was furnished by Sharpe and Dohme, Glenolden, Pennsylvania. Purified protein derivative (PPD) of human strains of tubercle bacilli, furnished by Dr. Seibert, was also used; rabbits infected with bovine strains of tubercle bacilli react to this material (6).

[1] This study was aided by a grant from the John and Mary R. Markle Foundation.

METHODS

Experiment 1: Skin tests

Groups B and C were fed approximately 2 grams of meat which had been obtained from a rat heavily infected with trichinae 26 days previously. On the following day, groups A and C were injected in the groin with 0.1 ml. of a suspension of tubercle bacilli.[2] Thirty-nine days after the injections, the abdomen of the animals was clipped, and skin tests were done with 0.1 ml. of a 1:100 dilution of tuberculin in distilled water, with 0.1 ml. of physiological saline solution containing 0.005 mgm. PPD, with 0.02 ml. of 1:200 trichinella antigen, and with 0.1 ml. of saline solution as a control. The readings were made at 20 minutes, 24 hours, and 48 hours.

Experiment 2: Intensity of trichinella infection

Forty-five days after the injections, groups A and C were killed with a blow on the head; the rabbits in group B were killed 54 to 64 days after infection with trichinae. Three-tenths to 0.35 gram of muscle was removed from the right anterolateral aspect of the diaphragm, and from each of the right front and hind legs; 0.25 to 0.3 gram of intercostal muscle was removed. Because the degree of infection previously found in guinea pigs had varied so greatly between the group infected with both trichinosis and tuberculosis and the group infected with trichinosis alone, the samples were not accurately weighed, but were estimated (4). The tissues were examined in a muscle press using the 10 × low power objective and 10 × ocular lenses in the microscope. The absolute number of trichinae observed in each sample was recorded. Since the muscle press preparations on 2 animals (numbers 22 and 23 from group C) were negative, approximately 5 grams of muscle obtained from various sites in these animals was digested with 0.7 per cent pepsin and 1 per cent hydrochloric acid (7).

Groups E and F were fed 2 grams of trichinous rat meat, and the following day groups D and F were injected with 0.05 ml. of a 5 ml. suspension of tubercle bacilli prepared by the method described above. Two animals in group E (numbers 13 and 16) were fed 7 days later than the remainder of the group, and their meat was prepared from a different rat. The animals were killed 70 to 86 days after infection, and the muscles examined in the manner described. Smears were made from tuberculous lesions in the lung, the liver, the regional lymph nodes, and at the site of injection in the groin. Smears were stained by the Ziehl-Neelsen technique, and the data recorded by the Gaffky scale.

[2] The suspension was made from 1 medium-sized colony of a 6-weeks culture ground with 1 drop of sterile physiological saline in a small mortar. The suspension was subsequently diluted with saline to make the volume 10 ml. and the large clumps were centrifuged out; the supernatant fluid showed 10 to 20 organisms per field with an oil-immersion lens.

RESULTS

One animal in group C died before the skin tests were done, and 2 animals in group D died of intercurrent disease before the experiments were completed. None of these animals is included in the results.

In 2 animals in group C (numbers 22 and 23) no trichinae were found in any muscle press preparation, and digestion of muscle revealed no live trichinae. One animal from group B, 1 from group E, and 2 from group F had very light infections, 1 to 3 trichinae being seen in muscle from 1 site only.

Each animal in groups A, C, D, and F presented gross evidence of tuberculosis at autopsy. In 1 animal from group D, and 1 from group F, smears of tuberculous lesions were negative; in all others acid-fast bacilli were found.

Experiment 1: Skin tests

No essential difference in reaction to the 2 trichinella antigens was noted (Table I). Twelve

TABLE 1

Skin tests in trichinous and tuberculous rabbits

Group	Number animals	Tuberculin	Purified protein derivative	Trichinella antigen no. 1	Trichinella antigen no. 2	Saline control
A (tuberculosis)	10	3.2	3.5	0.1	0	0
B (trichinosis)	10	0	0.1	1.6	2.0	0
C (tuberculosis and trichinosis)	9	3.6	4.1	2.1	1.1	0

The data are the arithmetic means of the scores of skin tests on a scale of 0 to 4 plus; doubtful (±) reactions are calculated as negative (0).

Trichinella antigen no. 1 was prepared in our own laboratory; the larvae of antigen no. 2 were furnished by Parke, Davis and Co.

animals gave immediate positive skin reactions to trichinella antigen at 20 minutes; 11 animals gave 1 plus or greater reactions at 24 or 48 hours. Five animals, proved by muscle press preparations to be infected, gave negative skin reactions at all 3 periods to both antigens. One infected animal which failed to react at 20 minutes, gave a positive reaction at 24 hours, while 3 animals positive at 20 minutes failed to give reactions at 24 and 48 hours. One false positive reaction (1 plus) to a single trichinella antigen was encoun-

tered in a tuberculous animal which had not been fed trichinae.

No difference in reactions to bovine tuberculin and human PPD was noted in the infected animals. None of the tuberculous animals gave immediate reactions to either antigen, and only 1 animal gave a 1 plus reaction; all of the other animals gave 3 or 4 plus tests. No false positive reaction to tuberculin or PPD was encountered in non-tuberculous animals.

Experiment 2: Intensity of trichinella infection

No essential difference in intensity of trichinous infections was found between groups B and C, and between groups E and F (Table II). This

TABLE II

Density of trichinella infection of muscle

Group	Number animals	Diaphragm	Intercostal	Front leg	Hind leg	All sites
B (trichinosis)	10	65.3	14.2	28.5	17.6	31.4
C (trichinosis and tuberculosis)	9	42.9	4.2	12.1	5.9	16.3
E (trichinosis)	10	174.4	68.8	76.5	60.8	95.1
*	(8)	(125.0)	(60.1)	(45.2)	(24.6)	(63.7)
F (trichinosis and tuberculosis)	10	114.0	43.7	42.2	15.7	53.9

The data are the arithmetic means of the counts of larvae as seen in the muscle press. Groups B and C were fed on the same day, and groups E and F on another occasion.

* The data for group E have also been calculated omitting rabbits number 13 and 16 which were fed from a more heavily infected rat 7 days later than the remainder of the group. These data are recorded in parentheses for more accurate comparison with group F.

was true for the counts of trichinae in muscle from any single site, as well as for all sites calculated together.

No difference in intensity of tuberculous infection was noted between groups D and F either in the number and extent of gross lesions, or in the number of organisms seen on smears of the lesions.

DISCUSSION

No biologic cross reaction between *Mycobacterium tuberculosis* and *Trichinella spiralis* was detected by skin tests in rabbits. Judged by the extent of positive reactions to the concentrations of antigens used, tuberculin and PPD are more specific for tuberculosis than is trichinella antigen for trichinosis. The failure of 4 animals with proved trichinosis to react to trichinella skin tests could not be accounted for either by overwhelming or by very light infections. Only 1 of these animals had a very light infection; the other 3 had infections which were average in density. A single animal gave an immediate false positive skin reaction to one trichinella antigen, though no trichinae had been fed to it.

The differences in reaction to trichinella antigen at 20 minutes, 24 hours and 48 hours are of interest in the light of experiments recently performed on dogs, using trichinella antigen digested with pepsin or trypsin, and presumably containing no reaginic protein (8). It is impossible at this time to say whether the immediate reactions at 20 minutes in rabbits are due to carbohydrate and the late reactions at 24 and 48 hours to protein, as the experiments in dogs might suggest.

Further experiments have been carried out in orphanage and prison groups, in order to compare the tuberculin and trichinella skin reactions in non-tuberculous, non-psychiatric institutionalized persons. These clinical experiments, which are being reported separately (3), confirm the animal experiments reported here; no biologic cross reaction seems to exist between the 2 infectious agents.

The experiments in rabbits infected simultaneously with bovine *Mycobacterium tuberculosis* and *Trichinella spiralis* reported here do not confirm the previously reported experiment in guinea pigs infected simultaneously with human *Mycobacterium tuberculosis* and *Trichinella spiralis* (4). The density of trichinous infection in rabbits simultaneously infected with trichinosis and tuberculosis was not found to be greater than that in rabbits infected with trichinosis alone.

SUMMARY

1. No biologic cross reaction was detected by skin tests in rabbits infected simultaneously with bovine *Mycobacterium tuberculosis* and *Trichinella spiralis*.

2. Simultaneous infection with bovine tuberculosis did not increase the intensity of trichinous infections in rabbits.

THE EFFECT OF PEPTIC AND TRYPTIC DIGESTION ON THE ANTIGENICITY OF *TRICHINELLA SPIRALIS*[1]

By JERRY K. AIKAWA, GEORGE T. HARRELL, AND NANCY J. HELSABECK

(From the Department of Medicine, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem)

(Received for publication August 5, 1946)

In the course of a previous investigation, positive trichinella skin tests which could not be accounted for by a history of known infection were encountered (1). An attempt was made to explain these findings by inducing reactivity in non-infected animals through repeated feedings of antigen (2). Killed larvae of *Trichinella spiralis,* presumably containing denatured (cooked) or undenatured (frozen) antigen, were fed to guinea pigs and rabbits. Attempts to demonstrate reactivity in these animals by skin tests and flocculation tests on the blood serum were unsuccessful. Because some investigators have found that digestion may alter the reactivity of pollens, it was thought that the negative results might have been due to digestion of the trichinella antigen (3, 4). The present study was undertaken to determine whether or not peptic or tryptic digestion would deactivate the antigen of killed trichinae.

MATERIALS

Animals

Fifteen young dogs weighing 5 to 15 kgm. were de-wormed and divided into 3 groups of 5 each (groups A, B, and C). A fourth group of 15 dogs (group D) which had not been de-wormed was used as a control. All animals were fed a stock diet (Hunt Club Dog Food, Maritime Milling Co., Inc., Buffalo, N. Y.)

Trichinella larvae

The strain of *Trichinella spiralis* which we employed was obtained from the National Institute of Health and was carried in albino rats. Rabbits were given 1 feeding of trichinae-infected rat meat, and 8 weeks later were killed, skinned, and eviscerated. The muscle was removed, ground, and digested at 37° C. for 6 hours in a solution of 0.7 per cent pepsin and 1.0 per cent hydrochloric acid (5). The larvae were washed repeatedly in normal saline until the solution was biuret-negative, and were then frozen at −78° C. for 72 hours in carbon-dioxide ice, dried in a desiccator, and powdered.

METHODS

Preparation of the alkaline-trypsin digested antigen

Fifty mgm. of powdered trichinae were incubated for 48 hours with 5 ml. of 5 per cent trypsin (Armour and Co., Chicago, Ill.) in a 0.3 per cent sodium carbonate solution at 37° C. under anaerobic conditions. The anaerobic environment was chosen because Rockwell has suggested that oxidation may destroy antigenicity (6). As soon as the trichinae were added, a 22 × 200 mm. test tube was inverted over the 10 × 100 mm. unstoppered tube containing the digestion mixture, and a cotton plug was pushed into the larger tube to hold the smaller tube in place. The mouth of the larger tube was then placed in a beaker containing a mixture of pyrogallic acid powder and sodium hydroxide pellets. About 10 to 15 ml. of water were added to the reagents, and melted paraffin was poured on its surface. As the oxygen was utilized, the fluid column rose, effectively sealing the tube.

After digestion, the mixture was centrifuged for 30 minutes at approximately 3,000 RPM. The supernatant fluid was then removed with a pipet and neutralized to litmus with 5 per cent hydrochloric acid. Sufficient phenol was added as a preservative to make a final concentration of 0.04 per cent. A biuret test on the sediment was negative; the sediment was discarded.

A test for sterility on the solution of digested antigen revealed Gram-positive spore-bearing rods which were not further identified. Because of the contamination, the antigen was frozen for 48 hours in carbon-dioxide ice. A subsequent sterility test was negative. The Gram-positive bacilli were found to be a contaminant in the trypsin powder.

Preparation of the acid-pepsin digested antigen

Fifty mgm. of powdered trichinae were incubated for 48 hours with 5 ml. of 0.7 per cent pepsin (Merck, N.F. Granular) in 1 per cent hydrochloric acid at 37° C. under anaerobic conditions, by the method described above. The supernatant fluid, after centrifugation, was neutralized to litmus with 5 per cent sodium hydroxide. The sediment left after centrifugation was found to be very slightly biuret-positive; it was then discarded.

A sterility test on the digested antigen was negative, but in order to maintain conditions identical with the alkaline-trypsin digestion, the antigen was frozen for 48 hours in carbon-dioxide ice.

Preparation of the control antigen

Twenty-five mgm. of powdered trichinae were incubated anaerobically for 48 hours in 2.5 ml. of sterile 0.8

[1] This study was aided by a grant from the John and Mary R. Markle Foundation.

per cent sodium chloride solution. The mixture was then centrifuged and frozen exactly as in the preparation of the digested antigens. A biuret test on the sediment was strongly positive. A sterility test on the incubated antigen was negative.

Injections

Group A received the alkaline-trypsin digested antigen, group B the acid-pepsin digested antigen, and group C the undigested control antigen. Each animal was given an initial subcutaneous injection of 0.1 ml. of its respective antigen in the left pectoral region. One dog from each group (dogs 5, 10, and 14) was also given 0.1 ml. of its respective antigen intravenously on the same day, without reaction. Beginning 3 days later, all animals were given 3 successive daily intravenous injections of 0.1 ml. of their respective antigen, a total of 0.4 ml. of antigen to each dog, except dogs 5, 10, and 14, which received 0.5 ml.

Skin tests

In order to avoid the possibility of sensitization, no skin tests were performed before the injections were given. Nineteen days after the last intravenous injection, the abdomen of each animal in groups A, B, and C was clipped, and a skin test was done on each animal with a 1:100 dilution of antigen, prepared from desiccated and powdered trichinae recovered from the same rabbit that supplied the trichinae for the injected antigen. At the same time, each animal was given a skin test with a saline control. Subsequent skin tests with a 1:200 dilution of antigen from another rabbit were done at intervals of approximately 1 week through the sixth week after the last intravenous injection. All antigens used were found to give 4 plus reactions in a dog known to be infected with trichinae.

The reactions were read at 20 minutes. A 1 cm. wheal with surrounding erythema was considered to be a 1 plus reaction, if the skin test with a saline control produced a wheal less than 8 mm. in diameter. Reactions were graded progressively from 1 plus to 4 plus.

As a further control against non-specific or group skin reactions, 15 additional dogs (group D) which had not been de-wormed, or given any injections of antigen, were given skin tests with a 1:200 dilution of antigen.

Flocculation tests

Preliminary flocculation tests were done on the serum obtained from each dog in groups A, B, and C 9 days before the injections of antigen were begun. Eleven days after completion of the intravenous injections, 5 ml. of blood were obtained from the antecubital vein of each dog. The serum was separated and inactivated at 56° C. for 30 minutes. Tests were performed according to the technique of Suessenguth and Kline (7), except that the rotation was continued for at least 10 minutes. Judging by the negative control, this longer time interval did not give false positive results. Minimal but definite flocculation which could be seen only under the microscope was considered a doubtful reaction (±). Flocculation tests were repeated at intervals of approximately 1 week through the sixth week after the last intravenous injection.

RESULTS

Skin tests

In 13 of the 15 dogs in groups A, B, and C, skin tests were found to be positive on the nineteenth day after the initial injection, and continued to be positive for the duration of the experiment (Table I). One animal (dog 5) in group A (alkaline-trypsin digested antigen) failed to develop a definitely positive skin test during the 6-week period of observation. One animal (dog 9) in group B (acid-pepsin digested antigen) failed to react at 19 days, but subsequently developed a positive skin test. No difference in the extent of reactions was noted among the 3 test groups.

TABLE I

Skin tests

	Dog	Days following initial injection			
		19	24	30	41
Group A	1	++	+	+	++++
Alkaline-	2	+++	++++	++++	++
trypsin	3	+	++++	++++	++++
digested	4	++	++	+	++++
antigen	5	0	0	±	±

	14	0	0	++++	±	±
	15	0	0	+++	+	±

the 3 test groups. In general, the skin tests gave more strongly positive reactions than did the flocculation tests.

DISCUSSION

The effect of digestion on antigenicity

Acid-pepsin and alkaline-trypsin digestion of trichinella antigen did not destroy its reactivity for dogs, as measured by skin tests and flocculation tests on serum. Our results suggest that the antigenicity of trichinae does not reside solely in the protein fraction. Jadassohn found that peptic digestion of ascaris antigen did not alter its reactivity for skin tests (8). The results of our studies on another helminth parasite agree with his findings.

The reports in the literature concerning the effect of digestion on the antigenicity of grass pollens are conflicting. Coca and Grove were unable to find any diminution, as measured by skin tests, in the activity of ragweed and timothy pollen extracts after digestion with trypsin (10). Black obtained similar quantitative reactions with ragweed pollen extracts, as measured by endermic and intranasal tests, before and after tryptic digestion (11). He concluded that the substance responsible for pollen sensitization is not a protein, that it survives passage through the alimentary tract, and that it can be recovered from blood, urine, and feces (12). Thiberge, however, showed a reduction in the skin-test activity of ragweed pollen extracts after artificial digestion with pepsin and hydrochloric acid (3). Pancreatin digestion was said to intensify the reactivity of these extracts, but details of the technique used were not given (9). Harsh and Huber found that peptic or tryptic digestion of giant ragweed pollen caused a marked loss of activity of the antigen, as measured by scratch and intracutaneous tests (4). A small but constant amount of activity which was unaffected by proteolytic digestion remained.

Thiberge demonstrated by a passive transfer test (Prausnitz-Kustner phenomenon) that ragweed antigen was absorbed in an active form from the intestinal tract after being administered in enteric-coated pills. The preponderance of evidence indicates that the proteolytic enzymes of the gastro-intestinal tract destroy little of the active substance in pollen antigen. Little is known concerning the effect of carbohydrate-splitting enzymes on the antigen.

The experiments reported here do not explain, on the basis of digestion of antigen, the failure to induce reactivity to trichinella antigen in animals by repeated feeding of killed trichinae (2). The possibility that ingestion of killed trichinae by human beings may cause sensitization without actual infection still remains (1).

The antigenicity of trichinae fractions

Melcher, by chemical methods which did not employ enzymatic digestion, separated a polysaccharide and 2 protein fractions from trichinae (13). In infected rabbits, the protein fractions gave positive skin reactions at 24 hours, while the polysaccharide gave negative skin tests at 24 hours, but gave strongly positive precipitin reactions. The polysaccharide also induced precipitin formation when injected in non-infected animals, and the serologic studies suggested that the carbohydrate was associated with the acid-soluble protein fraction. Our experiments with dogs would suggest that the positive skin reactions at 20 minutes to antigen freed of protein by digestion might be due to a carbohydrate which need not be the same as that studied by Melcher. The experiments were done on a different species of animal, and the tests were read at a different time, but in human beings with pneumococcal infections the reaction in the skin to injected polysaccharide occurs at 20 minutes.

Bachman reported that the active antigenic fraction of trichinae is a glucoprotein, a substance chemically similar to mucin and containing carbohydrate in the molecule. He did not attempt to split the compound and study the protein and carbohydrate fractions separately (14). Cross-reactions between trichinae and other parasites, which occur at low dilutions of antigen (1:100), tend to disappear at high dilutions (1:10,000) (15). It is not known whether the cross-reactions are associated with a polysaccharide or with a protein fraction.

Proteolytic digestion of the trichinella antigen employed for skin tests may be found to reduce the incidence of non-specific false positive reactions commonly encountered with the protein-containing antigen now used.

The relative sensitivity of skin test and serologic methods

The fact that the skin tests gave more strongly positive reactions than the flocculation tests may indicate that the skin gives a greater quantitative response, and hence that the skin test is more sensitive. However, dogs known to be infected give 4 plus reactions to both skin and flocculation tests. The difference in intensity of reaction between the flocculation tests and the skin tests might be explained on the basis of 2 antigens, one elaborated continuously by the living larvae and resulting in flocculating antibodies; the other, an incomplete antigen incapable by itself of producing flocculating antibodies, and requiring the presence of another antigen not found in extracted whole killed trichinae, but present in living trichinae. Recent experiments by Roth suggest that precipitation of low titer immune serum around *living trichinae* is a more sensitive test than precipitation produced by antigen from dead parasites (16).

SUMMARY

1. Acid-pepsin and alkaline-trypsin digestion of *Trichinella spiralis* antigen did not destroy its antigenicity for dogs, as measured by skin tests and flocculation tests on serum.

2. The more marked reactivity of the skin test as compared with the flocculation test suggests that the same antigen may not be responsible for both reactions.

3. The failure of proteolytic digestion to destroy the antigens suggests that the antigenic fraction of *Trichinella spiralis* is not solely a protein.

PAMAQUINE NAPHTHOATE AS A PROPHYLACTIC FOR MALARIAL INFECTIONS [1]

By HARRY A. FELDMAN,[2] HENRY PACKER,[3] FRANKLIN D. MURPHY,[4] AND ROBERT B. WATSON [5]

(From the Department of Preventive Medicine, University of Tennessee College of Medicine, Memphis, and The Health and Safety Division of the Tennessee Valley Authority)

(Received for publication August 5, 1946)

Plasmoquine, 6-methoxy-8-(1-methyl-4-diethylamino)butyl-aminoquinoline, has been assigned the name "Pamaquine" by the United States Pharmacopea XII, and will be so referred to in this presentation. This anti-malarial has been so frequently discussed in the literature that a detailed review of its history will not be included here. Reference will be made only to those papers which bear directly upon the subject of this report.

In 1931, James *et al* (1, 2) conducted a series of experiments which showed that pamaquine in doses of 80 mgm. per day on a 1-1-6 regime (that is, administered on the day before, the day of, and for 6 days after inoculation with sporozoites) acted as a true causal prophylactic for both *vivax* and *falciparum* inoculations (Roumanian strain). This work is summarized in Table I. It will be noted that the number of subjects tested was small. In view of this fact, and because of the importance of the results obtained, it is surprising that despite the reputation for toxicity which the drug had acquired, it was not explored further until a decision was made by the Panel on Clinical Testing of Anti-malarials of the Committee on Medical Research to reevaluate this drug. This project was assigned the task of repeating and expanding the study of James during the summer of 1944. The information obtained to date forms the basis of this report.

MATERIALS AND METHODS

(*a*) *Drug.* Pamaquine naphthoate was the compound employed throughout this study. Approximately 45 per cent of this salt is considered to be active base. Consequently, dividing our doses by 2 yields a figure for comparison with doses generally referred to in the literature. The original lot of drug employed was supplied in the form of 20-mgm. tablets. A second lot came as powder, and was capsulated locally. Both drug lots had such similar assays that they may be considered identical.

(*b*) *Plasma concentrations.* The plasma concentration of pamaquine was usually determined daily by means of a macrocolorimetric method (3) devised by Brodie *et al.*[6]

(*c*) *Subjects.* Thirty-six white and colored males and females, who were relatively normal except for central nervous system syphilis, were employed in these experiments. Their ages ranged from 14 to 60 years. Each received complete physical, hematological, and blood chemistry examinations, urinalysis, x-rays of the chest, and electrocardiographic studies prior to the institution of treatment. Subsequently, these tests (except for the roentgenograms) were performed daily until experience indicated that with the exceptions of determinations of methemoglobin, plasma bilirubin, hematocrit indices, and leukocyte counts, such extensive tests were unnecessary, and they were discontinued as routine procedures.

(*d*) *Methemoglobin.* Methemoglobin formation is known to occur regularly during pamaquine administration. Since this may be a factor in the serious toxic reactions ascribed to the drug, it was considered necessary to determine its concentration daily. These determinations were performed by means of a simple procedure devised by Wendel (4). The test utilizes a photoelectric colorimeter, and requires only small amounts of blood.

(*e*) *Parasitological methods.* Inoculations were generally performed on the second day of treatment, although exceptions to this rule will be noted in the tabulated data. Laboratory-bred *Anopheles quadrimaculatus,* infected by feeding on patients with either *P. vivax* (McCoy) or *P. falciparum* (Costa) parasites, were allowed to inoculate by feeding. The mosquitoes were then killed, dissected, and the sporozoite content of their salivary glands estimated by a scale of pluses ranging from 1 (minimal) to 4 (maximal). Although in obvious excess, a goal of 16 pluses was sought for each infection. When necessary (and available) additional mosquitoes were fed on the same subject if the initial inoculum was less than 12 pluses. Ordinarily, *P. vivax* was reserved for whites and *P. falciparum* for negroes. However, it was sometimes necessary to use *P. falciparum* in whites, but no mishaps occurred.

* From a summary prepared by Dr. Thomas C. Butler for the Board for the Coordination of Malarial Studies.
** Presumed to be base, and thus equivalent to about 45 per cent of the naphthoate.

Each patient had a pretreatment negative thick film examination for malaria parasites. Similar smears were examined daily from the seventh postinoculation day until discharge from the hospital. All negatives were followed for at least 30 days in the hospital, and at intervals thereafter, depending upon the location of the individual's home or place of custodial hospitalization. Prior to the employment of penicillin for the treatment of the patients' neuro-syphilis, 3 subjects received trophozoite inoculations after 31 to 34 days of negative observation. The malarial course of each of these was perfectly normal.

Although it had been shown that penicillin had no effect upon malaria trophozoites (5, 6), no information was available concerning its action on sporozoite or "exoerythrocytic" forms. Consequently, 2 patients were given, in divided doses, 240,000 units of penicillin on each of 10 days. On the second day, one patient was inoculated by mosquitoes with sporozoites of *P. vivax* (McCoy), and the other with *P. falciparum* (Costa). Both developed malarial infections within normal prepatent periods, and so it was felt that the subsequent expression of infections in our experimental subjects was not influenced by intensive penicillin therapy received during the early prepatent phase.

RESULTS

The results of the experiments will be presented in relation to each of the parasite species employed, and in order of increasing drug dosage. This is not the chronological order of experimentation, but probably represents a more rational approach for the reader.

(*a*) *Experiments with* P. vivax (*McCoy*). The trials with *P. vivax* (McCoy) are summarized in Table II. Two patients who received 160 mgm. of pamaquine naphthoate a day for the second to sixth postinoculation days had prepatent periods of 15 and 19 days. Although slightly longer than usual, these periods are not significantly different from those normally encountered. This experiment was designed to test the thesis that pamaquine acted against other than sporozoite and trophozoite forms. The results in these 2 patients do not indicate that such, at least, is the sole case.

In order to determine whether the activity of pamaquine depended upon a slowly excreted degradation product, 180 mgm. were administered daily for 8 days to 1 patient. Inoculation was accomplished on the ninth day, and 12 days later he developed a demonstrable parasitemia. In this instance, at least, the hypothesis appears to have been unfounded.

Another patient, receiving 180 mgm. of pamaquine naphthoate a day, was inoculated on the second of the 2 days in which he received this dose. The appearance of an acute hemolytic anemia then necessitated drug withdrawal; parasitemia was evident on the eleventh postinoculation day.

One patient was given 160 mgm. of drug on the day before, the day of, and for 2 days following inoculation. The development of severe abdominal pain necessitated stoppage of the medication. He developed malaria on the eighteenth postinoculation day.

One patient was inoculated on the fourth of an 8-day course of 180 mgm. of pamaquine naphthoate daily. This was considered to represent a plasma mixture of "fresh" and "degraded" drug. Malaria was apparent on the twenty-third day, somewhat later than the normally expected date.

One subject received 80, and another 120 mgm. of pamaquine naphthoate daily on the day before, the day of, and for 5 days following inoculation. The former developed malaria on the fourteenth, and the latter on the sixteenth day. In view of other similar experiments (*vide infra*) these dosages appear to have been indaequate.

Another patient was given 160 mgm. of pamaquine naphthoate daily on the same schedule as the 2 patients just described. After 34 negative days he received an intravenous inoculation of *P. vivax* (McCoy) trophozoites, and a normal malarial course ensued. Two hundred and thirty days later he was admitted for a malarial attack. Since blood-induced infections do not ordinarily relapse, this probably represents a break-through of the original sporozoite inoculation, but the slight factor of uncertainty eliminates this patient from further consideration.

Five patients were administered 160 mgm. of pamaquine naphthoate for each of 3 days, and then 120 mgm. daily for 5 days. Inoculation was per-

* Where combinations of doses were employed, this figure was based upon the amount of drug administered during the first day.

** Sporozoite content of salivary glands of infecting mosquitoes estimated by scale of pluses ranging from one (minimal) to four (maximal). This column represents total for the individual patient.

*** The first number refers to the preinoculation period, the second, to the day of inoculation, and those that follow to the postinoculation period.

formed on the second day. None of this group suffered an immediate primary attack. One had a delayed primary episode at 194 days, another at 248 days, while the remaining 3 have now been followed for 413, 443, and 445 days respectively, without demonstrable evidence of malaria. Since no untreated patient on this service has ever failed to develop malaria within less than 20 days after mosquito inoculation, these results are of considerable significance.

Five patients received 180 mgm. of pamaquine naphthoate daily for 8 days with inoculation on the second day. One of these developed clinical malaria on the twenty-second day, another at 209 days, and the third at 262 days. The other 2 have not developed demonstrable infections during 121 and 187 observation days, respectively.

In view of the small numbers of subjects dealt with, no attempt will be made to explain the differences in the results obtained in the last 2 groups.

Four random-selected, untreated patients who received similar *P. vivax* (McCoy) inoculations at various times during this study had prepatent periods of 11 to 16 days.

(*b*) *Experiments with* P. falciparum (*Costa*). The experiments with this species are summarized in Table III.

One patient received 160 mgm. of pamaquine naphthoate on the day of inoculation only, and developed malaria 11 days later. The mosquitoes were fed midway during the drug course. In another instance, inoculation occurred after the administration of 157.5 mgm. of pamaquine naphthoate, when the drug had to be stopped because of what was interpreted as a severe lumbar puncture reaction. Malaria was evident 9 days later.

Of 2 patients who received 160 mgm. of drug a day for 3 days (inoculation on the second day), one had a prepatent period of 14 days, whereas the other has been negative for 489 days. The latter received the smallest sporozoite dose (8+) of any patient in our series, but such inocula ordinarily are sufficient to produce infection.

One subject, whose drug had to be withdrawn after 4 days on the 160 mgm. schedule because of an acute hemolytic anemia, developed malaria on the thirteenth day. Inoculation, as usual, was done on the second day.

* Identification corresponds to Tables II and III.
** The day drug administration was begun but prior to the first dose. — not done, 0 no drug detectable in plasma.
*** Drug stopped.
**** Determination of plasma concentration not done on 12th day and not detectable on 13th day.

In the next group, both patients received drug for 3 days following the day of inoculation, but whereas one had been treated for 3 days prior to that date, the other received the drug for only 1 day before inoculation. The dose was 180 mgm. a day. Neither has developed malaria during 254 and 184 days of observation.

Two others who received 180 mgm. of pamaquine naphthoate on the day before, the day of, and for 4 days following inoculation, have been free of disease for 158[7] and 189 days, respectively.

Of 3 patients who received 160 mgm. of drug for 7 days (inoculated on the second day), 2 were given trophozoites intravenously after 31 days of negative observation, and so have been dropped from the study, while the third has been free of malaria for 483 days.

Two subjects have had no demonstrable malaria for 349 and 455 days following a drug schedule of 160 mgm. a day for 3 days, followed by 120 mgm. for each of 5 days. Inoculation was accomplished on the second day.

Three patients who were on the 8-day, 180 mgm. daily schedule have not developed malaria during 245, 181 and 221 days, respectively.

A representative group of 6 untreated patients who received *P. falciparum* (Costa) sporozoites by the same inoculation method while these studies were in progress had prepatent periods of 8 to 12 days.

(*c*) *Plasma pamaquine levels.* The plasma concentrations of pamaquine determined in 28 patients are summarized in Table IV. These demonstrate quite clearly that measurable pamaquine is both rapidly absorbed into, and excreted from, the plasma. However, it is just as apparent that the plasma level attained (as measured by

[7] Died subsequently of non-malarial condition.

the method employed) bears little relationship to the mgm. per kgm. dose, the various toxic reactions produced, or to the degree of protection attained. In general, plasma concentrations were greater in those whose total drug intake was greater. This is illustrated by the averages for the dosage groups.

(*d*) *Toxic reactions.* Although methemoglobinemia was regularly encountered at all dosage levels (Table V), more tended to be formed as the pamaquine intake was increased. Such formation occurred quite soon after the initiation of therapy, and persisted for some days after the drug was withdrawn. No methylene blue could be employed for the treatment of this state because of its effect upon malarial parasites. Of itself, the methemoglobinemia did not appear to cause any difficulty, although high levels were attained in individuals who suffered other severe toxic reactions.

Two instances of acute hemolytic anemia were encountered. Both occurred in negro patients, and both had their onset soon after therapy was begun. In neither instance was there any history of preceding malaria or exposure to pamaquine. Prompt withdrawal of the drug and intensive erythrocyte transfusions produced complete recoveries. The data concerned with these 2 patients are summarized in Tables VI and VII. In addition, Table VII includes a summary of attempts to reproduce this hemolysis *in vitro*. All of the latter were failures.

An opportunity to restudy patient BRO presented itself some 3 months after the initial hemolytic episode. At this date he was fully recovered and normal in all respects. He was placed on a drug schedule which called for 160 mgm. of pamaquine naphthoate a day for 3 days, followed by 120 mgm. for each of 5 following days, but the drug had to be withdrawn on the fifth day because of another hemolytic reaction (Table VIII). This indicates that the susceptibility to acute he-

* Performed by Dr. Philip Levine, Ortho Research Foundation, Linden, New Jersey.

Abdominal pain occurred in 4 patients. One of these (STA) had such a severe episode that the drug had to be withdrawn (Table X). The pain was of a griping character, and was concentrated in the umbilical area. He also complained of moderate headache and nausea. The other 3 had short bouts of mild pain following some of the drug doses, but all were able to complete their schedules without mishap.

Of 26 patients (omitting the 2 hemolytic reactors), 11 had increases in serum bilirubin (7) of more than 0.5 mgm. per cent. These changes represent the differences between samples examined prior to, and at, the completion of treatment. Seven of these individuals were concentrated in the 11 patients who received 180 mgm. of pamaquine daily for 8 days.

Fourteen of 27 patients (omitting the 2 hemolytic reactors) had decreases in their hematocrit indices of the order of 3 or more. All 14 occurred among the 18 patients who received drug for 8 days.

The total leukocyte counts diminished by 1 thousand or more in 11 of 27 patients, remained unchanged in 9, and increased by 1 thousand or more in 7 others. Two of the 11 decreases finished with counts of 3 to 4 thousand per cubic millimeter.

Neither drug fever nor urinary abnormalities were encountered in any of the 36 patients.

COMMENTS

The data demonstrate quite clearly that when either 160 or 180 mgm. of pamaquine naphthoate are administered on the day before, the day of, and for 5 or 6 days (1-1-5 or 1-1-6) following sporozoite inoculation with *P. vivax* (McCoy), clinical expression of the disease may be delayed, or prevented, for months. Similar results may be anticipated with as few as 3 postinoculation days (1-1-3) treatment when *P. falciparum* (Costa) is the test parasite employed.

This is quite different from experiences with quinacrine (atabrine), for one achieves suppression (*P. vivax*) or suppression-until-cure (*P. falciparum*) with this compound only if its administration is continued through the period of the expected primary attack. A further indication of the differences between the mode of action of pamaquine and atabrine or quinine is demonstrated by the effect of combining pamaquine with 1 of the other 2 for the treatment of vivax relapses. Such combined therapy will usually prevent further relapses. Dixon's study (8), while not the first of its kind, illustrates this point quite clearly.

Our study also highlights again the fact that falciparum and vivax parasites differ considerably in their susceptibility to antimalarial drugs. Whether this means that the 2 have such different life cycles that a drug must have a particular form to affect adversely one species and not the other, is pure conjecture.

Although our experiments failed to demonstrate as complete protection as was achieved by James in his trials with the Roumanian strains, nor, on the other hand, were the attained results as poor as those reported by Alving *et al* (9) with the markedly relapsing Chesson strain of South Pacific vivax, they did accomplish their basic purpose, which was to determine whether James's results could be supported sufficiently to warrant an extensive chemical synthesis program to find other, less toxic, more active pamaquine analogs.

Alving *et al* employed doses of 90 mgm. of active pamaquine base per day on a 1-1-6 regime against the Chesson vivax strain in 5 subjects. Three of these patients developed malaria after 18, 19, and 106 days, whereas the remaining 2 have been observed for 402 negative days. These results, coupled with those of James and ourselves, illustrate again the danger of generalizing upon the subject of antimalarial therapy from experiences with a single strain of parasites.

SUMMARY AND CONCLUSIONS

1. Pamaquine naphthoate was administered to 36 paretics as a prophylactic against mosquito-induced infections with *P. vivax* (McCoy) and *P. falciparum* (Costa).

2. Daily doses of either 160 or 180 mgm. administered the day before, the day of, and for 5 or 6 days following the day of inoculation with *P. vivax* (McCoy) have prevented or postponed the primary attack for months.[8] In the case of *P. falciparum* (Costa) postinoculation treatment could be shortened to 3 days with similar results,

[8] *Addendum:* 15 January, 1947. The number of days of negative observation, through this date, for those patients still available for follow-up, were as follows:
P. vivax. POR, 690; LEW, 728; HAL, 648; BEA, 410.
P. falciparum. COO, 774; SMI, 340; BUT, 670; WEL, 465; RIN, 543; DAV, 345; PRO, 348; ScH, 474.

except that delayed primary attacks were not observed.

3. Two instances of acute hemolytic anemia were encountered among 11 negro patients. One of these was re-exposed to the drug, and promptly had another hemolytic episode. This type of reaction was not related to the recipient's blood group.

4. Methemoglobinemia was regularly encountered in all subjects.

5. Elevations of the serum bilirubin and moderate hematocrit decreases were commonly noted among those receiving the higher, more prolonged courses, regardless of race.

6. Pamaquine naphthoate is rapidly absorbed and excreted.

7. The mode of action of pamaquine as a malaria prophylactic or suppressive is not explained, although such activity appears to be a function of the parasite species (and strain) employed, the total amount of drug ingested, and the number of days the drug is administered in relation to the inoculation day.

The authors are indebted to Dr. William B. Wendel for his supervision of the chemical analyses, to Dr. Yan Tim Wong for clinical aid, and to Miss Anna MacNicholas for technical assistance.

ELECTROPHORETIC CHANGES IN THE SERUM OF A PATIENT WITH RHEUMATOID ARTHRITIS

By VINCENT P. DOLE, AND SIDNEY ROTHBARD, WITH THE TECHNICAL ASSISTANCE OF KENNETH WINFIELD

(From the Hospital of The Rockefeller Institute for Medical Research, New York)

(Received for publication August 8, 1946)

Various reports in recent years (1 to 5) have indicated that changes occur in the serum electrophoretic patterns of patients with rheumatoid arthritis. The present study is designed to supplement these generally isolated measurements with serial observations of the changing serum pattern through a cycle of the disease, correlated with immunological and clinical data. Of interest also is the comparison of data from this clinically typical case of rheumatoid arthritis with the data, previously reported (6), from patients with rheumatic fever of comparable severity and duration.

METHODS

All measurements, common to those of the earlier study (6), were made in the same way.

The antifibrinolysin antibody (AFL) was determined by the method of Tillett, Edwards and Garner (7), as modified by Boisvert (8).

The C-reactive protein was measured by a modification of the method of Tillett and Francis (9): 0.1 ml. of undiluted test serum was mixed with 0.1 ml. solutions of the pneumococcus C polysaccharide,[1] varying in concentration downward from 10^{-4}. After incubation at 37° C. for 2 hours, the tubes were left overnight at 4° C., then read for precipitation. A known strongly positive serum from a patient with acute rheumatic fever was included as a control.

SUBJECT OF THE STUDY

C. B. (No. 11, 113), a 28-year old machinist, was admitted to another hospital on the 8th day following the onset of polyarthritis. Prior to this, he had always enjoyed good health, and in particular had had no previous joint symptoms. The present attack was not preceded by any apparent respiratory infection. During a 2-month stay at that hospital, he had persistent painful swelling of an ankle, a knee and the small joints of the hands, not appreciably relieved by salicylates. An elbow had become involved shortly before admission.

When admited to the Rockefeller Hospital on the 64th day of illness he appeared chronicaly ill; his weight had fallen to 55 kgm. from a normal of about 72 kgm. Examination of the heart revealed no abnormalities either on admission or subsequently. There was definite atrophy of the muscles of the hands, both legs and one forearm. X-ray examination showed decalcification of the bones and periarticular swelling without narrowing of the joint spaces of the hands and knees. Cultures of nose and throat revealed no hemolytic streptococci, and the gonococcus complement fixation and Wassermann tests were both negative.

During 8 months of hospitalization he gradually improved under treatment with initial bed rest followed by slowly increased activity; hot packs to the affected joints with short periods of active exercise and plaster support as required were also employed. Aspiration of the right knee joint on the 248th day yielded 30 ml. of yellow, turbid and viscid fluid which contained 5,300 leuckocytes per c.m.m. (49 per cent polynuclear, 45 per cent lymphocyte, 6 per cent monocyte). The culture was negative.

At the time of discharge on the 332nd day, he was capable of doing light work; the only residual joint symptoms were slight swelling with limited flexion of one knee and weakness of one finger.

OBSERVATIONS AND DISCUSSION

The total protein concentration was not systematically affected. The relative proportion of albumin, and with it the A/G ratio, was considerably depressed in the earlier observations, but later returned toward normal. Both α globulins were markedly elevated (over twice their normal values) during the early stages, then fell to essentially normal proportions. β globulin was on the low side of normal throughout the study. γ globulin maintained a fairly constant level about 35 per cent over the normal value.

These changes generally conform to those described by other authors (1 to 5), who have reported increases in the α and γ globulins, independently or in combination, and decreases in albumin.

A slight elevation above normal limits was observed in the titer of antistreptolysin O. According to other workers (10) such increases may occur in rheumatoid arthritis, but are exceptional. More typical of the disease is the absence of an antifibrinolysin response (11 to 13).

The C-reactive protein is an interesting protein of unknown function that has been detected in the

serum during the early phases of diverse infectious diseases (14, 15, 9). It has not yet, however, been sufficiently studied to determine whether its appearance is confined to diseases of infectious etiology (16). The occurrence of this protein in association with increased α globulins accords with the findings of previous workers (17) that it is contained in the α_1 globulin fraction.

As might be expected, the serum protein pattern varied with change in the clinical status; it is possible that a sufficiently extensive study might reveal correlations of prognostic significance. It is clear, on the other hand, that electrophoretic measurement holds no diagnostic promise, since the present findings appear to be indistinguishable from those previously reported for rheumatic fever (6).

SUMMARY

1. Serial electrophoretic observations of the serum from a patient with rheumatoid arthritis showed a depressed proportion of albumin with increased relative amounts of α and γ globulins.

2. These abnormalities in serum protein pattern decreased with clinical improvement.

3. Antistreptolysin O antibody titer showed a low constant elevation. Antifibrinolysin activity was not detectable.

4. The C-reactive protein, which was present in high titer during the early acute phase of the disease, disappeared with clinical recovery.

VARIATION IN PROTEIN AND POLYSACCHARIDE CONTENT OF SERA IN THE CHRONIC DISEASES, TUBERCULOSIS, SARCOIDOSIS, AND CARCINOMA [1]

By FLORENCE B. SEIBERT, MABEL V. SEIBERT, A. JANE ATNO, AND HAROLD W. CAMPBELL

(From the Henry Phipps Institute, University of Pennsylvania, Philadelphia)

(Received for publication September 3, 1946)

It is well-known that marked changes may occur in the blood proteins in many diseases, and these changes have usually been expressed as variations in the albumin to globulin (A/G) ratio. In 1937, Tiselius (1) showed by means of the electrophoresis technic that at least 3 distinctly different globulins can be distinguished in serum, and later work (2) made it possible to measure them quantitatively from their electrophoretic diagrams. Furthermore, it has been shown that the relative amounts of these different protein components vary considerably in different diseases. For example, various pathological sera and plasmas were studied with this technic by Longsworth, Shedlovsky and MacInnes (3); pneumonia sera, by Blix (4); sarcoidosis, by Fisher and Davis (5), and also by Seibert and Nelson (6); disseminated lupus erythematosus, by Coburn and Moore (7); multiple myeloma, by Kekwick (8), and also Gutman *et al* (9); tuberculosis, by Seibert and Nelson (6); malaria, by Dole and Kendall (10); rheumatic fever, by Dole, Watson and Rothbard (11), and also by Rutstein, Clarke and Taran (12), and many other diseases.

In certain cases, extra specific serum components (2, 13) with mobilities different from those of the normal globulins appear. Such components have frequently been shown to be antibodies. In most cases, however, increases in the components with normal globulin mobilities occur, indicating an increase in the amount of the normal proteins or the presence of an additional substance such as another protein, lipoid (14), carbohydrate (15, 14), etc., having a similar mobility as, or attached to the normal protein. Thus, apparently similar changes, and therefore similar patterns, may be seen in different diseases, reflecting similar physiological disturbances; but they may also, on the other hand, be due to specific causes. However, if sufficient other supporting data are available, the electrophoretic patterns may become very useful in confirming a diagnosis, and certainly are valuable in prognosis. For example, the present study shows that there can, in most cases, be a helpful differentiation between sera in cases of pulmonary tuberculosis, sarcoidosis, and carcinoma.

A number of studies have shown that an abnormal increase in lipoid occurs in the sera in certain diseases (3, 14), and this increase is seen in the α and β globulin components, since the lipoid has been found usually to accompany these fractions. Less attention has been paid to another important colloidal constituent of the serum; namely, polysaccharide. While its concentration is very much less than that of the serum proteins, it is present in as high or higher concentration than glucose, and may increase as much as 100 per cent or more in some cases. Lustig and Langer (16) found increases in tuberculosis, carcinoma and pneumonia. Nilsson (15) and Blix, Tiselius and Svensson (14) also found an increase in cases of pneumonia. Friedmann and Sutliff (17) noted the presence of a substance in the serum in certain diseases, probably a polysaccharide, from which the pneumococcus is capable of forming large quantities of acid.

A preliminary report was published (18) showing that a progressive increase in serum polysaccharide parallels advance in the tuberculous process. It seemed of interest, therefore, to correlate this change with the changes observed by electrophoresis in the different protein components, and thus to determine whether the increase in polysaccharide could account for any of these changes.

In this study, therefore, cases of relatively uncomplicated tuberculosis were carefully selected from the Henry Phipps Institute Clinic by one of

[1] Aided by a grant from the Committee on Medical Research of the National Tuberculosis Association, and also by chemical assistance from the Tuberculosis Control Division of the United States Public Health Service.

us on the basis of the clinical findings, and classified as to the stage of tuberculosis. Cases of Boeck's sarcoid which were strongly suspected on the basis of the clinical examinations, or proved by biopsy, were studied. Sera from patients with carcinoma were obtained, and also 6 cases each of diabetes and of diabetes complicated with tuberculosis. Normal adult and also fetal sera were studied. All these sera were analyzed for total protein, albumin, α_1, α_2, β and γ globulins, glucose, polysaccharide, and also sedimentation rate (except the diabetics and carcinomas, which were not secured in our clinic).

METHODS

Clinical appraisal

The terms minimal, moderately advanced, and far advanced pulmonary tuberculosis are used at the Henry Phipps Institute in accordance with the definitions of the National Tuberculosis Association (19). In addition each of these classes is subdivided into 3 groups: (*1*) active lesions for which treatment is indicated, (*2*) lesions of questionable clinical significance, and (*3*) lesions which are apparently healed and presumably without present clinical significance.

The term "active lesions" is used in this study to indicate lesions which in x-ray *appearance* are soft and flocculent, or have shown recent fluctuation, and disease from which tubercle bacilli have been recently demonstrated in the sputum.

"Lesions of questionable clinical significance" include infiltrations that have an x-ray appearance suggesting chronicity or stability, as indicated by fibrosis and scarring in part or parts of the lesion, with softer or less well defined shadows elsewhere suggesting that the disease is in part unhealed.

"Lesions which are apparently healed and presumably without clinical significance" include disease that appears to be wholly fibrotic or fibrocalcific, and disease that shows no evidence of fluctuation on serial x-ray examinations.

For use in the punch card system, these lesions are given the following code numbers (which are used in the following tables).

81 active minimal pulmonary tuberculosis.
82 active moderately advanced pulmonary tuberculosis.
83 active far advanced pulmonary tuberculosis.
84 minimal pulmonary tuberculosis of questionable clinical significance.
85 moderately advanced pulmonary tuberculosis of questionable clinical significance.

In the sarcoidosis series, 4 of the cases have been verified by study of biopsy material. The diagnoses of the others were based upon the presence of extensive pulmonary fibrosis, usually with enlargement of the lymph nodes at the hilum or mediastinum, and upon the absence of significant symptoms or deterioration of health, particularly in relation to the extent and density of the pulmonary shadows roentgenologically. In these cases, repeated examinations of the sputum were negative for tubercle bacilli, and the reactions to standard doses of Purified Protein Derivative were generally slight or absent. In 6 cases there were skin lesions typical of sarcoid lesions. Three of these were confirmed by consultation elsewhere. X-ray examinations of the bones of the hands and feet were not routinely made.

The diagnoses on the cases of carcinoma and diabetes were confirmed in each case in the respective institutions from which they were received. The carcinoma cases included lesions of the lungs, colon, rectum, stomach, pancreas, liver, brain, temple, tongue, breast, uterus and cervix.

Diabetic cases were studied in order to determine whether a change in the polysaccharide content of serum may be associated with the disturbed carbohydrate metabolism of this disease.

No attempt was made to obtain fasting bloods, since it had previously (20) been shown that the polysaccharide content of the serum is almost independent of the state of metabolism. The bloods were taken, allowed to clot, and within several hours the sera were removed and placed in a freezing box which kept them just at the point of freezing until the analyses could be made. It was shown (20) that under these conditions no change occurs in the polysaccharide or glucose content of serum over long periods of time.

Sedimentation. A small sample of the blood, immediately after being drawn, was mixed with oxalate and used for the sedimentation test, according to the method of Cutler (21), in the routine clinical laboratory of our institute.

Polysaccharide was determined by the carbazole reaction according to the procedure outlined recently (20), using the glucose-galactose-mannose standard. In this study, the total polysaccharide of serum was determined, and from it the glucose concentration, determined by the Somogyi (22) method, was subtracted, giving the true polysaccharide concentration.

Total protein was determined by the Kingsley (23) biuret method, using the Klett colorimeter. The calibration curve was made against serum protein determined by means of the micro Kjeldahl method.

Protein patterns were made by means of the Tiselius electrophoresis technic (1). Earlier studies (24, 6) using phosphate buffer, pH 7.7 $\mu = 0.1$, showed that a progressive rise in γ globulin paralleled the development of tuberculosis. In addition to this change, abnormalities were noted in the form of the albumin curve, of such a nature that often there seemed to be present a component with a slightly greater mobility than the albumin. This abnormality in the albumin component does not occur if the electrophoresis is made in barbiturate buffer, but instead an extra α globulin appears, as first shown by Longsworth (25). It is possible, therefore, that the extra α globulin resolved in this latter buffer may represent the same component included in the albumin fraction in the phosphate buffer.

All the experiments in the present study were, therefore, carried out in barbiturate buffer (veronal) pH 8.5 to 8.6, $\mu = 0.1$, after the serum was dialyzed, for several days against this buffer at 1° C. and then filtered and diluted 1:2 with the same buffer.

In all determinations the same buffer concentration and pH and also the same protein concentration were used, since variation in these conditions leads to variation in the percentage of the different components (26, 27). In these experiments the crossed-slit arrangement of Svensson (28) was used. All electrophoreses were continued for exactly 2 hours at about 8.1 to 8.8 volts per cm., during which time the components spread throughout most of the long type cell.

Earlier reports favored using only the descending pattern for measurements, since fewer boundary errors occurred on this side, as evidenced by the smaller ϵ peak. The ϵ peak represents a gradient due to buffer electrolyte alone, whereas the δ boundary on the ascending side is due to concentration gradients of both buffer salts and proteins.

These boundary anomalies, the δ and ϵ effects, can be greatly reduced by reducing protein concentration and also by increasing the ionic strength of the buffer (29, 26, 27). In fact, they can be so much reduced, when a total ionic strength of 0.2 to 0.25 is used, that Svensson now recommends using the patterns on both sides, and taking an average of the results for the corresponding components on the 2 sides.

However, in the present study, since an ionic strength of 0.1 was used, calculations were made only from the descending patterns. Since relative rather than absolute values are desired, any error due to this method of calculation would have no significant bearing on the conclusions drawn. No difficulties were encountered with β anomalies so frequently reported by many workers.

Diagrams were enlarged 5 times, and the areas due to the different components were always resolved by the same individual into curves, as described by Pedersen (30), and measured with a planimeter. Since the components are not always definitely resolved into isolated peaks, a certain amount of personal error enters into these resolutions, and Table I will show the degree of error involved under the conditions described. In some cases, the same serum was examined on 2 successive days, and in others on widely different days, even as much as 3 months apart. Different exposures during the same experiment were also compared, using different angles on the diagonal slit, in order to obtain patterns of different sizes. No systematic error seemed to be caused by such variation, but nevertheless the same angle, 30°, was used in all experiments in the comparative series reported in this paper. In general, as much as 2 per cent error may be expected in the globulin components, and 3 per cent in the albumin, under these conditions.

Results are reported as percentage of the total gradient area (exclusive of the ϵ component), as the different components, albumin, α_1, α_2, β, and γ globulins. This method of calculation involves the least error, since no committal is made as to the composition of these components. It is known that a considerable percentage of some of these components is not protein. For example, it was emphasized earlier that considerable lipoid and carbohydrate accompany the α and β components. However, even these results do not give an entirely true picture for comparison, since the total protein and colloidal concentration of different sera vary. Therefore, in spite of the obvious errors involved, the method of calculating the actual grams per cent of each component from the total protein concentration, as used extensively by other workers (31, 32), is also used here, and the results are recorded as the second item under each component. While the actual content in grams of each component could also be calculated directly from the electrophoretic diagrams, no more accurate results would be obtained, since the refractive index increments of the various colloidal constituents necessary in the calculations are also not known.

In spite of the inherent errors indicated, the differences recorded for the different stages of disease and different diseases are so great that the conclusions drawn are, without doubt, valid.

TABLE I

Electrophoretic measurements of same serum at different times, and with different angles at same time in veronal buffer pH 8.5 to 8.7, $\mu = 0.1$

RESULTS

Since it is impossible to include the actual analyses of all cases, because of the large number, an attempt has been made to give summarizing tables which will contain data to show for each type of case the mean, the standard deviation, the probable error, the range, and also the significance of the deviations from the normal means.

The method of calculating this significance is as follows.

The standard deviation $(\sigma) = \sqrt{\frac{\Sigma d^2}{N}}$, where d = the difference from the mean, and N = the number of cases studied.

Probable error $(E) = 0.6745 \frac{\sigma}{\sqrt{N}}$.

$a_1 - a_2$ = the difference between the mean (a_1) of the normal group and that of the group under study (a_2).

Probable error of $(a_1 - a_2) = \sqrt{E_1^2 + E^2}$.

The significance of the differences from the normal mean is shown by the ratio

$$\frac{a_1 - a_2}{\sqrt{E_1^2 + E_2^2}}.$$

For example, if this ratio is 5, then, according to Gavett (33), the odds against getting a mean of a similar group which is outside of the probable error are about 1,300 to 1, and the difference is therefore highly significant. If the ratio is 3 the odds are only 22 to 1; if the ratio is 4 the odds are 142 to 1; if it is 6 the odds are 20,000 to 1; if it is 7 the odds are 445,000 to 1; etc.

Table II shows, in the top half, the number of cases studied and their means for the different analyses. The lower half gives the ratios, which show the significance of the deviations of these means from the normal. The electrophoretic data

were calculated both on the basis of percentage of the total, and also as the actual grams per cent, assuming that all of the components are protein, or that the error due to the presence of non-protein substances is negligible.

Table III contains the standard deviations and probable errors corresponding to the results in Table II. Table IV contains the data,

$$a_1 - a_2 \pm \sqrt{E_1^2 + E_2^2},$$

used for calculating the significance ratios, and also the ranges of the different analyses, for use in deciding what to expect from analyses on individual sera.

From these results it is readily seen that there is a significant increase in the mean total protein concentration in sarcoidosis, and a significant decrease in carcinoma, while in tuberculosis, regardless of the stage of the disease, neither an increase nor decrease is the rule.

Figure 1 shows typical electrophoretic diagrams of each type and stage of disease studied; the individual patterns were chosen because their analyses fitted most closely to the mean values for each particular type of case.

Figures 2, 3 and 4 show the individual polysaccharide concentrations plotted respectively against the α_2 globulin, γ globulin, and albumin, since it was in these components that there proved to be significant variations. In all cases the dots represent normal sera, the triangles minimal, the circles moderately advanced, the black squares far advanced tuberculosis, and the crosses carcinoma.

In minimal active tuberculosis (tuberculosis 81) a decrease in the mean A/G ratio is significant, and this is obviously due to the increase in the γ globulin, with a corresponding decrease in albumin. Therefore, the most significant change found in this early stage of the disease is the rise in the γ globulin. As the disease progresses to the mod-

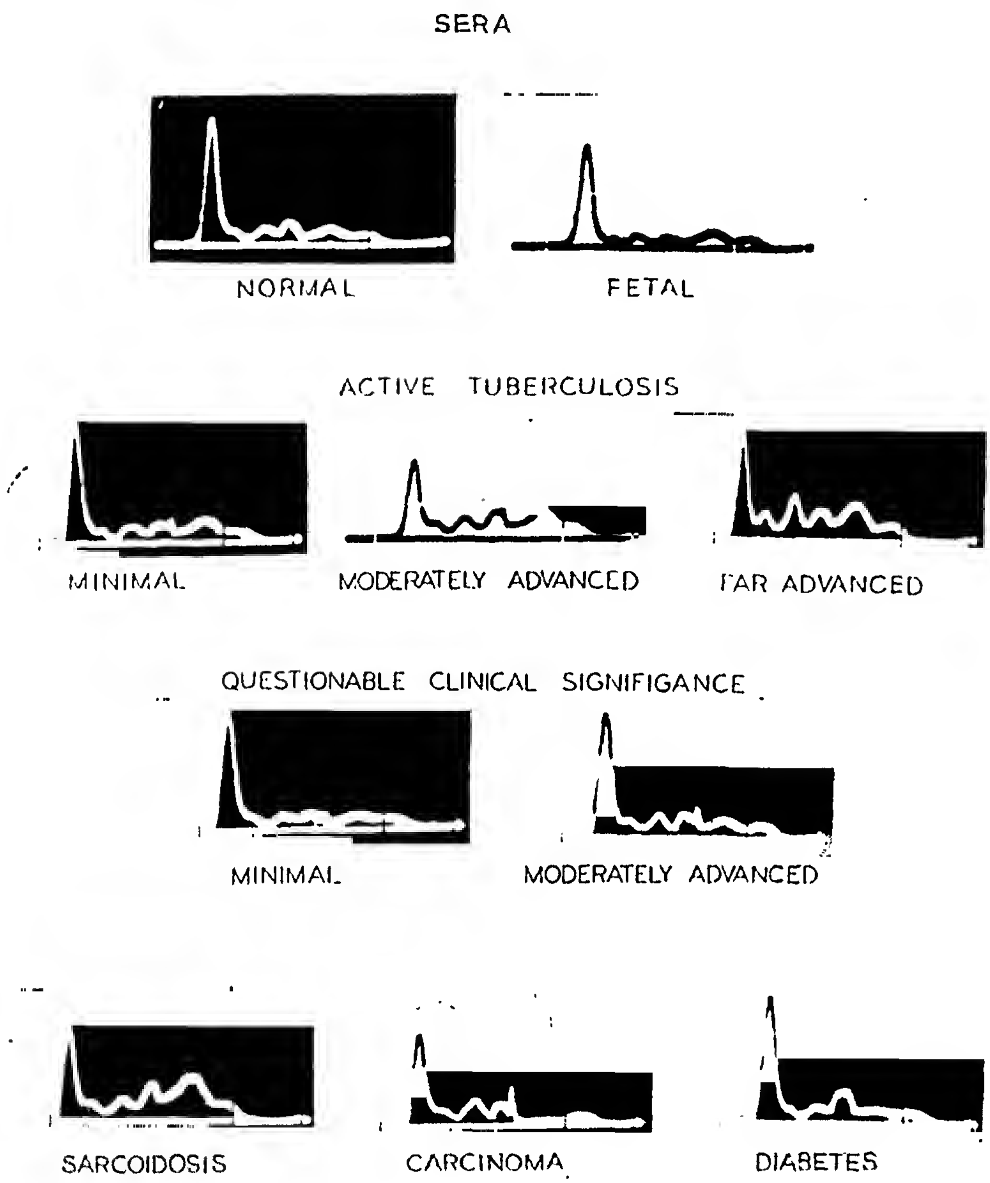

FIG. 1. ELECTROPHORETIC DIAGRAMS OF SERA EXAMINED IN VERONAL BUFFER pH 8.6, $\mu = 0.1$, AND AT A 30° ANGLE

Only descending patterns are shown. In all cases the albumin, α_1, α_2, β and γ globulin peaks and the ϵ boundary are evident.

erately advanced stage (tuberculosis 82), there appeared also a rise in the α_2 globulin and polysaccharide content. With far advanced disease (tuberculosis 83) all globulins, and especially α_2, as well as polysaccharide content, increased with a corresponding decrease in albumin, even though ıe total protein changed only slightly.

ı those cases of minimal tuberculosis classified as of questionable clinical significance (tuberculosis 84), no deviation from the normal was found.

In cases of moderately advanced tuberculosis of questionable clinical significance (tuberculosis 85), the only significant change is a decrease in the albumin and the corresponding lowered A/G ratio.

In sarcoidosis, a large increase occurred in the mean γ globulin, and also in the β globulin, a

simultaneous decrease in albumin and consequently in the A/G ratio. There was also some increase in polysaccharide but by no means as much as found in cases of far advanced tuberculosis, which showed similar increases in the γ globulin. The total protein also was always increased.

In only 4 of the 11 cases reported in this study was the diagnosis proved by biopsy. The others were strongly suspected to be sarcoidosis from the clinical data. While the number of cases is comparatively few, it is believed the conclusions are valid, since a previous group of sarcoid cases (6) yielded comparable results, and also Fisher and Davis (5) obtained similar results on a group of 12 cases of sarcoid, all of which were proved by biopsy.

Carcinoma sera showed, on the other hand, no increase in the mean γ globulin. In fact, in the majority of cases, a very much flattened γ peak (see Figure 1) occurred, which in further studies may be possibly resolved into a very small true γ globulin, and another small component with mobility between the γ and β globulins. Several sera, especially from those cases with metastases to the liver and a resulting jaundice, showed an abnormally high γ globulin, and these brought the average γ up to near the normal mean. The α_2 globulin, and also the polysaccharide content, in practically all cases were conspicuously increased and, of course, the albumin and A/G ratio were decreased. The total protein in most cases was reduced.

The series of diabetic cases is admittedly too small to permit reliable conclusions, but it is obvious that no great change occurred, except possibly in the β globulin. Since 5 out of the 6 cases showed a marked increase in this component, and since fat metabolism is known to be disturbed in diabetes, further study of this disease may yield helpful results.

The diabetics with advanced tuberculosis showed

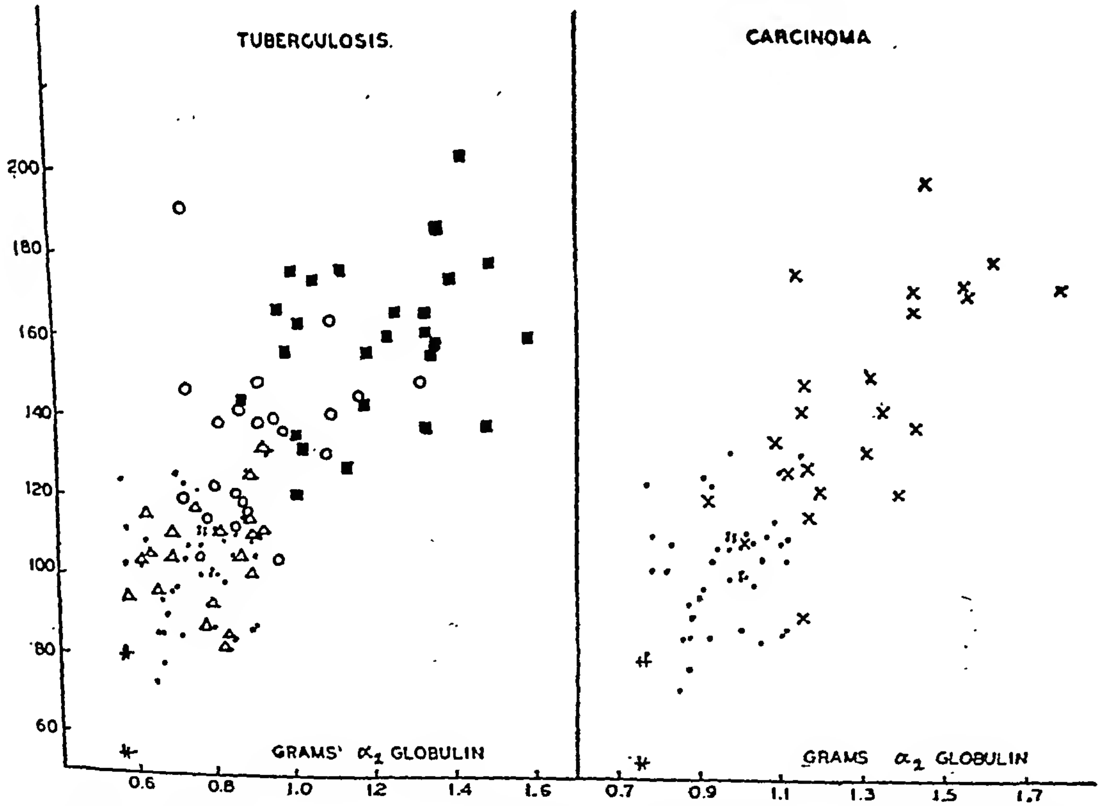

FIG. 2. GRAMS PER CENT α_2 GLOBULIN ARE PLOTTED AGAINST MGM. PER CENT POLYSACCHARIDE FOR NORMAL ADULT (•), FETAL (ɫɫ), MINIMAL (Δ), MODERATELY ADVANCED (O) AND FAR ADVANCED TUBERCULOSIS (■), AND CARCINOMA (X)

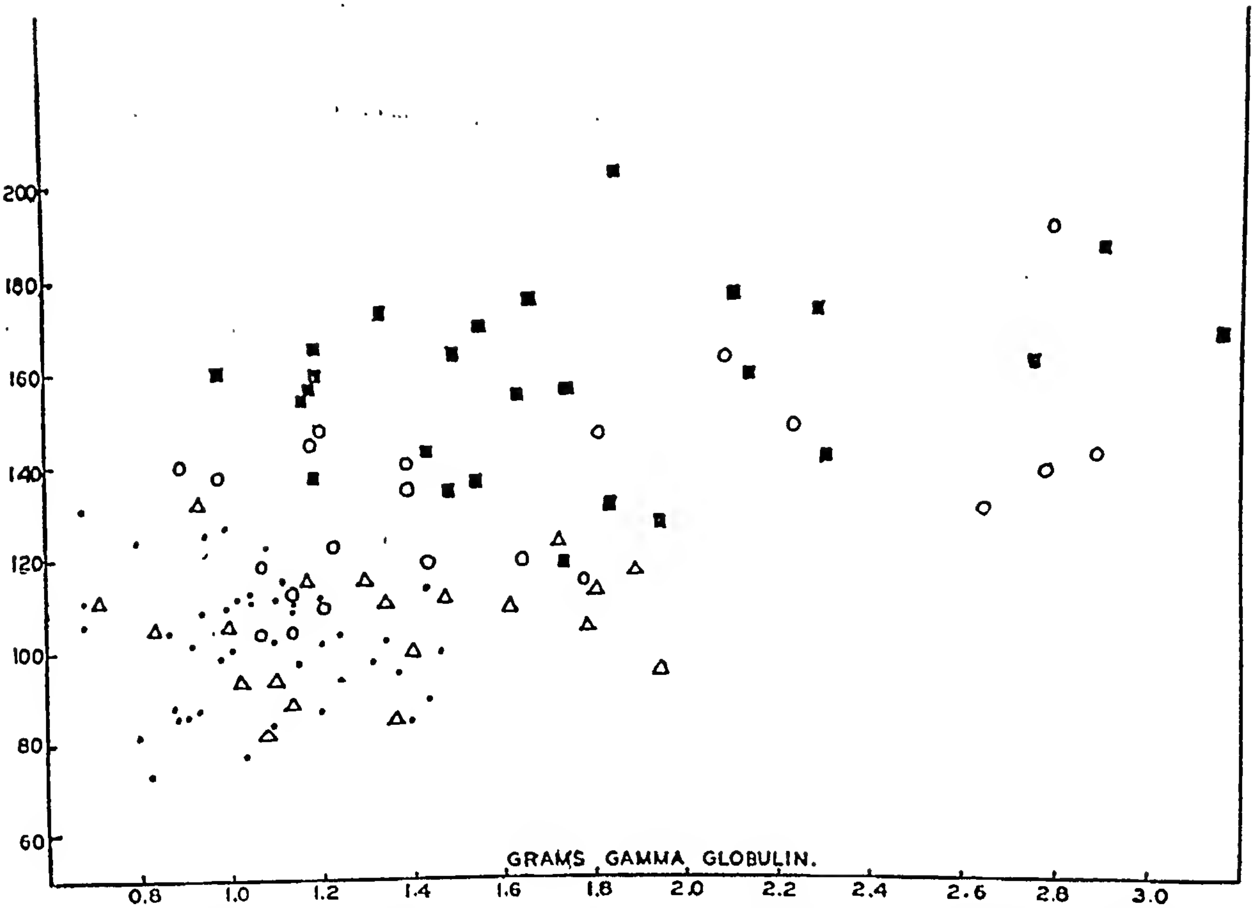

FIG. 3. GRAMS PER CENT γ GLOBULIN ARE PLOTTED AGAINST MGM. PER CENT POLYSACCHARIE FOR NORMAL ADULT (•), MINIMAL (△), MODERATELY ADVANCED (O) AND FAR ADVANCED TUBERCULOSIS (■)

changes similar to those found in the tuberculous patients, except possibly a still higher β globulin, thus adding significance to the increase in this component noted in the non-tuberculous diabetics.

Polysaccharide content of fetal serum.

Sera taken from the cord blood of 6 patients at parturition showed a very much lowered content of polysaccharide. Even if the lowered total protein content should be taken as an index of a dilution factor, still the corrected polysaccharide content would correspond only to the lowest figures obtained in a few adults in the normal group. There is an indication, therefore, that this constituent tends to increase with age.

Only 2 electrophorectic analyses were made of fetal sera, since the results obtained corresponded well with those already reported (32). The absolute and relative concentrations of γ globulin are higher than the adult values, and the other globulin concentrations are considerably lower, including especially the α_2 globulin.

Sedimentation test

In general, with far advanced tuberculosis, the sedimentation rate was abnormal and the serum constituents were also found to be abnormal; but with less advanced disease (tuberculosis 82), 6 cases out of 20 were found to have a normal sedimentation rate, while at the same time their sera showed a considerable increase over the mean of γ globulin and in some cases of polysaccharide. Among the group of 43 normal adults in whom no obvious clinical abnormality could be detected, 9 had sedimentation rates of 2 or more, and in all of these one of the globulins or polysaccharide, or both, was among the high range of normals. There were also 3 who had completely normal sedimentation rates, but had the highest values for polysaccharide (131, 124, 126 mgm. per cent) which were included among our normal group.

In view of the many factors which can influence the sedimentation rate, no definite correlations can be drawn on the basis of the present work.

They do not, however, conflict with the conclusion drawn by Shedlovsky (37) that there is a correlation between the increase in α globulin and increase in sedimentation rate, except in our group of sarcoids where 6 cases showed an increased sedimentation rate, but no increase in α globulin.

CONCLUSIONS AND DISCUSSION

The data show a slight but significant rise in the mean γ globulin component in early tuberculosis. Since antibodies for most diseases have been found in the γ globulin fraction (34), and, furthermore, since antibodies in tuberculosis have also been found in this fraction (35, 36), it is reasonable to suspect that the rise in this component in the early stage of the disease process may represent an antibody reaction to the organism. It will be of interest to determine whether the rise in this component has any prognostic value in differentiating potentially dangerous cases from the self-healing type. Such a study is in progress.

As the disease progresses, the next change to appear is an increase in the α_2 globulin and polysaccharide content of sera, and finally with far advanced disease, all of the globulins, and especially the α_2 globulin, increase, with a balancing decrease in the albumin, since the total protein content does not notably change. The polysaccharide also conspicuously increases. Therefore, with advance in the disease process, it appears that the accompanying tissue destruction may be reflected by this increase in the α_2 globulin and polysaccharide. It has been stated by Longsworth, Shedlovsky and MacInnes (3) that a rise in α globulin is found in febrile diseases. Shedlovsky and Scudder (37) concluded that a rise in α globulin indicated tissue destruction, and Perlmann, Glenn, and Kaufman (38) found an increase in the α globulin component of serum and of lymph in burns.

The argument that an increase in polysaccharide, as well as in α_2 globulin, indicates the presence of tissue destruction is supported by the

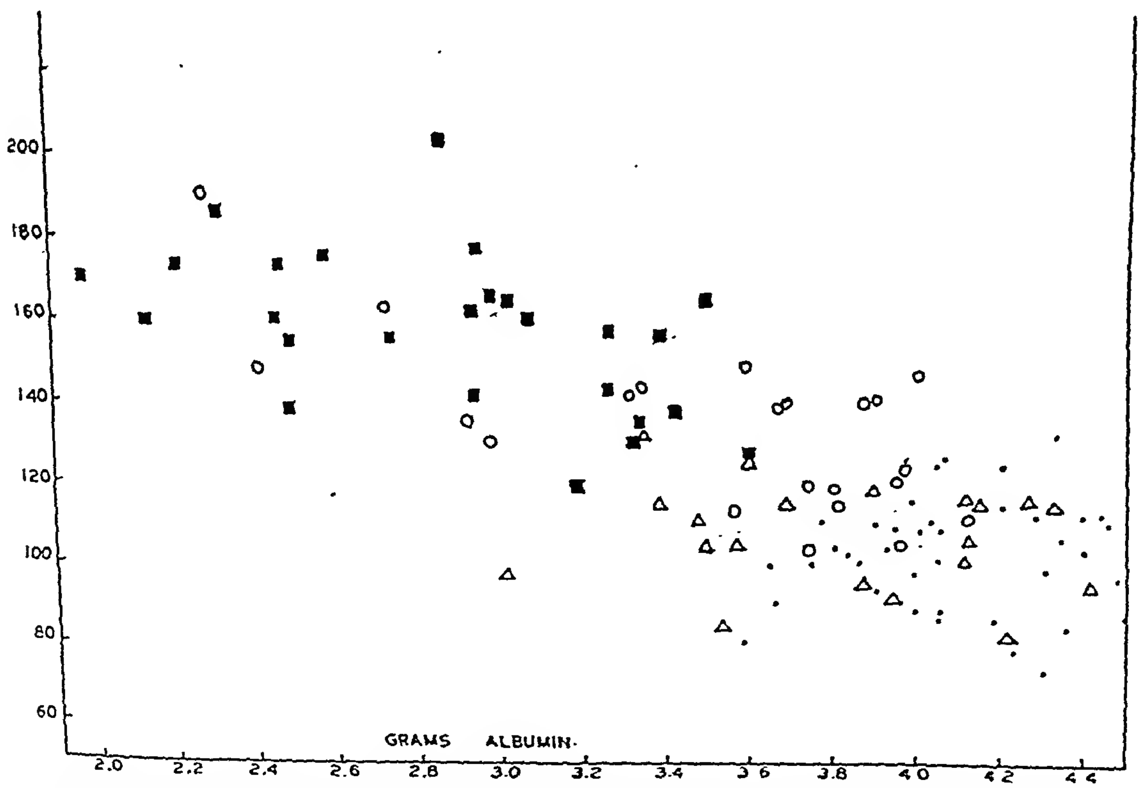

FIG. 4. GRAMS PER CENT ALBUMIN ARE PLOTTED AGAINST MGM. PER CENT POLYSACCHARIDE FOR NORMAL ADULT (•), MINIMAL (△), MODERATELY ADVANCED (O) AND FAR ADVANCED TUBERCULOSIS (■)

following facts. Isolated α_2 globulin contains a higher percentage of polysaccharide than do the other normal serum proteins (these results will be reported in a later communication), and these 2 constituents of serum always simultaneously increase. They are both low in fetal sera and, furthermore, increase in tuberculosis as well as in carcinoma, diseases where there is known to be tissue destruction, whereas in sarcoidosis, without tissue destruction, no comparable rise in α_2 globulin occurs, and, also, the rise in polysaccharide is much less. In this latter case the increase that is found in the polysaccharide is probably due to the rise in γ globulin which also does contain some polysaccharide, but possibly of a different nature.

As cases of tuberculosis tend to heal and are then viewed as of questionable clinical significance, there is a return to the normal serum picture. If the disease has been advanced, then a decrease in the albumin still persists. In other words, the albumin is the last component to return to normal, and this is especially significant in view of the fact that Zeldis and Alling (39) found the restoration of albumin to be slower than that of the other serum proteins following acute depletion by plasmapheresis.

It is of considerable importance that 3 diseases, which frequently are difficult to differentiate clinically or from the x-ray picture, namely, pulmonary tuberculosis, sarcoidosis, and carcinoma, present such different analytical pictures as here described. Such analyses could, therefore, be of considerable help in diagnosis.

SUMMARY

A statistically significant rise in the γ globulin occurs in the serum in minimal active tuberculosis, with a corresponding decrease in albumin. In moderately advanced disease, the α_2 globulin and polysaccharide content also increase. These changes are still further emphasized in far advanced tuberculosis, and all the globulins are also increased. The mean total protein, however, does not differ from the normal.

No deviation from the normal occurs in minimal tuberculosis of questionable clinical significance, except possibly in a slightly lowered A/G ratio. Moderately advanced tuberculosis of questionable clinical significance shows only a decrease in albumin, indicating that it is the last component to return to normal.

Sera from cases of sarcoidosis show an increase in total protein, a proportionately large increase in γ globulin, and only a moderate increase in polysaccharide content.

In carcinoma there is a decrease in total protein, a large increase in α_2 globulin and polysaccharide content.

Fetal sera show a low total protein and polysaccharide content and low globulins, except γ globulin, which is high.

It is suggested that the increase in γ globulin in minimal tuberculosis may indicate antibody formation, whereas the rise in α_2 globulin and simultaneous rise in polysaccharide in advanced tuberculosis and carcinoma may represent tissue destruction. Fetal sera as well as sera in sarcoidosis are characterized by high γ globulin.

Of protein fractions isolated from normal plasma, the α_2 globulin has the highest polysaccharide content. The increases in this component in the diseases studied apparently account for most of the increase in the polysaccharide of the sera. Some increase may be due also to the increase in γ globulin, as in sarcoidosis.

We express our appreciation to Dr. Katherine R. Boucot, of the Philadelphia Tuberculosis and Health Association, for referring a number of the tuberculous patients to us.

For some of the cases of suspected sarcoid as well as the cases of diabetes complicated with tuberculosis we are indebted to Dr. S. C. Stein of the Henry Phipps Institute.

We express our sincere thanks to Dr. T. Grier Miller, Dr. Ruth Breitwiesser, Dr. Jeannette McConnell, and Dr. Cecilia Riegel of the University of Pennsylvania Hospital, and to Dr. Catherine Macfarlane of Woman's Medical College, for securing the cases and diagnoses of carcinoma.

To Dr. Frieda Baumann of Woman's Medical College we express thanks for the cases of diabetes uncomplicated with tuberculosis.

Dr. Henry Lee of Children's and Lankenau Hospitals kindly supplied us with the fetal sera.

We express our thanks to Misses Mary Mullahay and Emma DuFour for taking the blood samples and making the sedimentation determinations.

THE ANEMIA OF INFECTION. III. THE UPTAKE OF RADIOACTIVE IRON IN IRON-DEFICIENT AND IN PYRIDOXINE-DEFICIENT PIGS BEFORE AND AFTER ACUTE INFLAMMATION [1]

By M. M. WINTROBE, G. R. GREENBERG, S. R. HUMPHREYS, HELEN ASHENBRUCKER, WANDA WORTH, AND RAE KRAMER

(From the Department of Medicine, University of Utah School of Medicine, Salt Lake City)

(Received for publication September 21, 1946)

In the first (1) of this series of studies on the pathogenesis of the anemia of infection, it was pointed out that there must be in association with infection a derangement in the intermediate metabolism of iron. This conclusion was based on the observation that in cases of infection associated with anemia, the plasma iron content is markedly lowered below the normal; this appears early, and is found even before anemia has developed. The injection of staphylococci or of turpentine in dogs was shown (2) to be associated with hypoferremia, and evidence was presented (1) which indicated that absorption of iron is probably adequate when infection is present, the hypoferremia being accompanied by a rapid removal of iron from the plasma. The present report, and those which follow, describe experiments which were designed to study the nature of the disturbance in the internal metabolism of iron.

When iron deficiency is present, anemia develops which is accompanied by marked hypoferremia. If iron is then given intravenously (3) it is taken up rapidly and quantitatively for erythropoiesis. The anemia associated with pyridoxine deficiency, on the other hand, is characterized by inability to use iron, with the result that it is deposited in the tissues and marked hyperferremia develops (4). Thus these conditions represent wide extremes in the ability to use iron for hemoglobin formation. It was thought that some insight might be gained as to the nature and severity of the alteration in iron metabolism associated with infection if hemoglobin synthesis and the uptake of radioactive iron by the red corpuscles were studied before and after acute inflammation was induced in these widely different types of anemia.

To measure the capacity to utilize iron for hemoglobin synthesis, 2 widely different quantities of radioactive iron (Fe^{59}) have been injected intravenously in the experimental animals. The smaller amount, 10 to 17 μg. per kgm. body weight, corresponds to the quantity which, in the normal human, may possibly be absorbed each day (5), namely 0.7 to 1.2 mgm. This is considerably lower than the amount of iron liberated from hemoglobin breakdown per day, which may amount to 25 mgm. The larger dose of Fe^{59} we have employed, 225 to 330 μg. per kgm. body weight, corresponds approximately to the amount derived each day from hemoglobin catabolism. Provided iron metabolism in the pig is similar to that in man, the smaller injection of Fe^{59} may therefore be regarded as much below the amount which the hemopoietic system can use, while the larger amount slightly taxes the metabolic system, since it presumably doubles, approximately, the quantity of iron which is available for the formation of hemoglobin.

In order to make certain that the radioactive iron appearing in the blood was present in hemoglobin, in a number of instances hemin was crystallized from the blood of animals which had received Fe^{59}. The radioactivity of the crystalline material was then compared with the activity in the whole blood per mgm. of iron.

METHODS

The experimental animals were growing pigs, similar to those used in studies already reported from this laboratory (6).

Inflammation or infection was produced in the following manner. Sterile abscesses were produced by intramuscular or subcutaneous injections of 4 ml. of turpen-

[1] The work described in this paper was commenced under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Utah. The expenses of this investigation were also defrayed in part by grants from the United States Public Health Service, Parke, Davis and Company and the Upjohn Company.

tine. Bacterial infection was induced by the daily intramuscular injection of 5 ml. of a mixed culture of *S. aureus* and *E. coli*. To produce burns, the bottom of a 125 ml. Erlenmeyer flask containing boiling water was placed on the flank of the animal for 20 seconds.

For intravenous injection the radioactive iron was prepared in the following manner. An aliquot of the Fe^{59}, obtained as $FeCl_3$ in hydrochloric acid, was reduced with ascorbic acid. To this 2 N sodium hydroxide was added drop by drop, until the solution just became violet brown. The solution was then diluted to volume with water. If a greater quantity of iron per unit volume was desired, non-radioactive $FeCl_3$ was added before reduction with ascorbic acid. The purity of the radioactive iron employed was ascertained by the rate of decay.

Hemin was isolated from blood samples by the method of Schalfejeff (8) as follows. A sample of blood cells was allowed to drip for a period of 15 minutes from a small separatory funnel into a 50 ml. centrifuge tube containing 3 volumes of glacial acetic acid saturated with sodium chloride. The tube was kept at 90 to 95° C. by using a hot plate, and the solution was agitated constantly with an electric stirrer. After it had cooled to room temperature, the material was allowed to stand over night in the refrigerator. The hemin was centrifuged down and, in sequence, it was washed with 50 per cent acetic acid, distilled water, 95 per cent ethyl alcohol (twice) and ether (twice). The yield of crystalline hemin was 50 to 70 per cent. In order to determine the quantity of hemin, the dry material was dissolved in a known volume of 0.1 NaOH, and a dilution of this solution was read in the photoelectric colorimeter at 520 mμ using a standard curve constructed with hemin of known purity as determined by iron measurement and spectrophotometric analysis. The hemin solutions were then digested and prepared for counting just as in the case of blood. Along with the hemin isolation and analysis, Fe^{59} analyses were made of the same original blood, the plasma being removed prior to preparation.

Hemoglobin determinations were carried out on the samples taken for Fe^{59} estimation. The volume of blood used was noted in order to calculate the number of grams of hemoglobin analyzed. The photoelectric oxyhemoglobin method of Bell, Chambers and Waddell (9) was employed, the instrument having been standardized by several procedures, including the oxygen capacity method (10) and the hemin method (11).

Calculation of Fe^{59} uptake. In studies with human subjects the uptake of Fe^{59} is usually calculated as follows (12):

$$\text{Total circulating hb.} = \frac{\text{blood volume}}{100} \times \text{grams hb. per 100 ml. blood;}$$

$$\text{Circulating counts} = \text{total circulating hb} \times \text{counts per gram hb.}$$

Many workers have assumed that the total blood volume is 80 ml. per kgm. body weight, believing that this assumption is at least as accurate as most total blood volume estimations made by calculation from the measured plasma volume and volume of packed cells (12).

In the case of growing pigs we have encountered considerable difficulty because of obvious shifts in plasma volume. In such pigs, especially in anemic animals, the hemoglobin per 100 ml. of blood shows wide and rapid variations. As a result, with sharp changes of hemoglobin one may get such impossible values as negative uptakes well beyond the range of error. In order to overcome this difficulty, we have devised a method of calculation which is based on the following assumptions.

(*1*) The total circulating hemoglobin is relatively constant, or increases or decreases consistently, and under our experimental conditions does not vary as much as is indicated by the changes in hemoglobin per 100 ml. of blood.

(*2*) The variations of the total circulating hemoglobin as obtained by the formula,

$$\frac{\text{weight of animal (kgm.)} \times 80}{100} \times \text{hb. per 100 ml.,}$$

range about the true value in a homeostatic manner. Accordingly, in these studies the body weight and the hemoglobin, in grams per 100 ml. of blood, have been plotted for each pig against time. From these values the total circulating hemoglobin has been calculated, and this also has been plotted on the graph. A line has then been drawn through the estimated average of the plotted values for the total circulating hemoglobin. It is assumed that this line presents a picture of the true alterations in total circulating hemoglobin. When for the calculation of Fe^{59} uptake it has been necessary to know the total circulating hemoglobin, the value has been taken from the appropriate point on this mean curve.

In the case of iron-deficient pigs, the actual mass of circulating hemoglobin was also determined by assuming that in such animals Fe^{59} is completely used for hemoglobin formation in 7 to 14 days or less. The following formula may be applied when Fe^{59} utilization is complete:

$$\frac{\text{Total counts injected intravenously}}{\text{counts per gram hemoglobin}} = \text{total circulating hb.}$$

The correlation of the estimated values for total circulating hemoglobin with those obtained by the radioactive method is shown in Figure 1. Since both methods entail sources of error the degree of correlation found is of interest.

RESULTS

Figure 2 illustrates the type of uptake curves obtained in different pigs. The complete data are recorded in Tables I to IV.

It will be observed that the iron-deficient animals usually showed rapid uptake, with little difference in the degree of uptake of the small and large doses of iron. This was to have been expected, since it is well known that such animals

can utilize iron very rapidly, even when it is given in large quantities. On the other hand the pyridoxine-deficient pigs were able to use a good percentage of the small dose only, a negligible percentage of the larger dose being used. In terms of absolute quantities of iron, the uptake was of the same order of magnitude when the large or the small dose was given. In the pyridoxine-deficient pig, hemoglobin formation is limited because of deficiency of this vitamin (4). That the iron not used in hemoglobin formation is stored, is indicated by the observations illustrated in Figure 3,

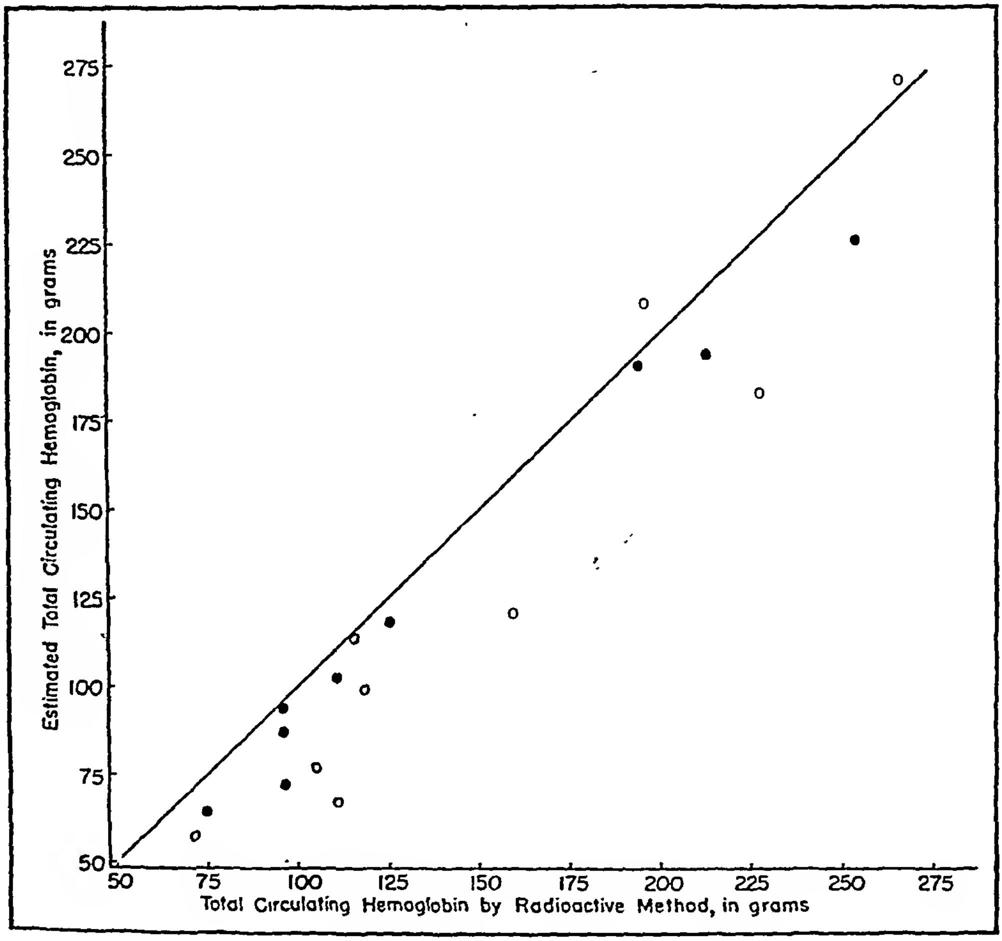

Fig. 1. The Correlation of Total Circulating Hemoglobin as Estimated from a Line Best Fitting the Plotted Values for Total Circulating Hemoglobin (see text) ("Estimated Total Circulating Hemoglobin") with the Total Circulating Hemoglobin as Determined From the Dilution of Radioactive Iron Injected Intravenously in Iron-Deficient Pigs

The closed circles represent the correlation with the values based on the first injection of radioactive iron, and the open circles refer to values after a second injection. In these calculations the total amount of radioactive iron injected in the animal has been divided by the number of counts per gram. The necessity for assuming that all of the injected Fe^{59} has been incorporated in the hemoglobin, even when more than one injection has been made, limits the accuracy of this method. The trend for higher values for total circulating hemoglobin, as measured by the radioactive method as compared with those based on the estimated values, can be explained, at least in part, by failure to use Fe^{59} completely for hemoglobin formation. Consistent with this view is the fact that the best correlation was found with the values obtained after the first injection of radioactive iron, when the likelihood of complete utilization of iron for hemoglobin formation was greater.

in which Fe^{59} uptake by the red cells is seen to increase sharply when pyridoxine is supplied.

The uptake of iron by the red cells of the normal animals was intermediate between that observed in the pyridoxine-deficient and the iron-deficient pigs. In the normal mature pig the small dose was used more rapidly than the large one.

Figure 4 shows the effect of acute inflammation on the rate of hemoglobin formation in iron-deficient pigs. It will be seen that 5 of the 6 pigs showed retarded hemopoiesis. Since the otherwise normal iron-deficient animal is capable of completely utilizing for hemoglobin synthesis much larger doses of Fe^{59} than those used in this experiment, retardation of the uptake of 10 μg. Fe^{59} per kgm. must be regarded as indicating severe depression of hemopoietic function. Pig 9–24, in Figure 2, is an example of the effect of a more chronic infection on the rate of uptake of Fe^{59}. This animal had been attacked by a dog and received severe lacerations on the legs which subsequently became chronically infected. It may be noted that in this pig a larger dose of Fe^{59} was utilized even more poorly than the smaller one.

Figure 5 illustrates the extent to which infection impairs the response to therapy with iron in iron-deficient pigs. Two iron-deficient pigs, one of which was receiving daily injections of a bacterial

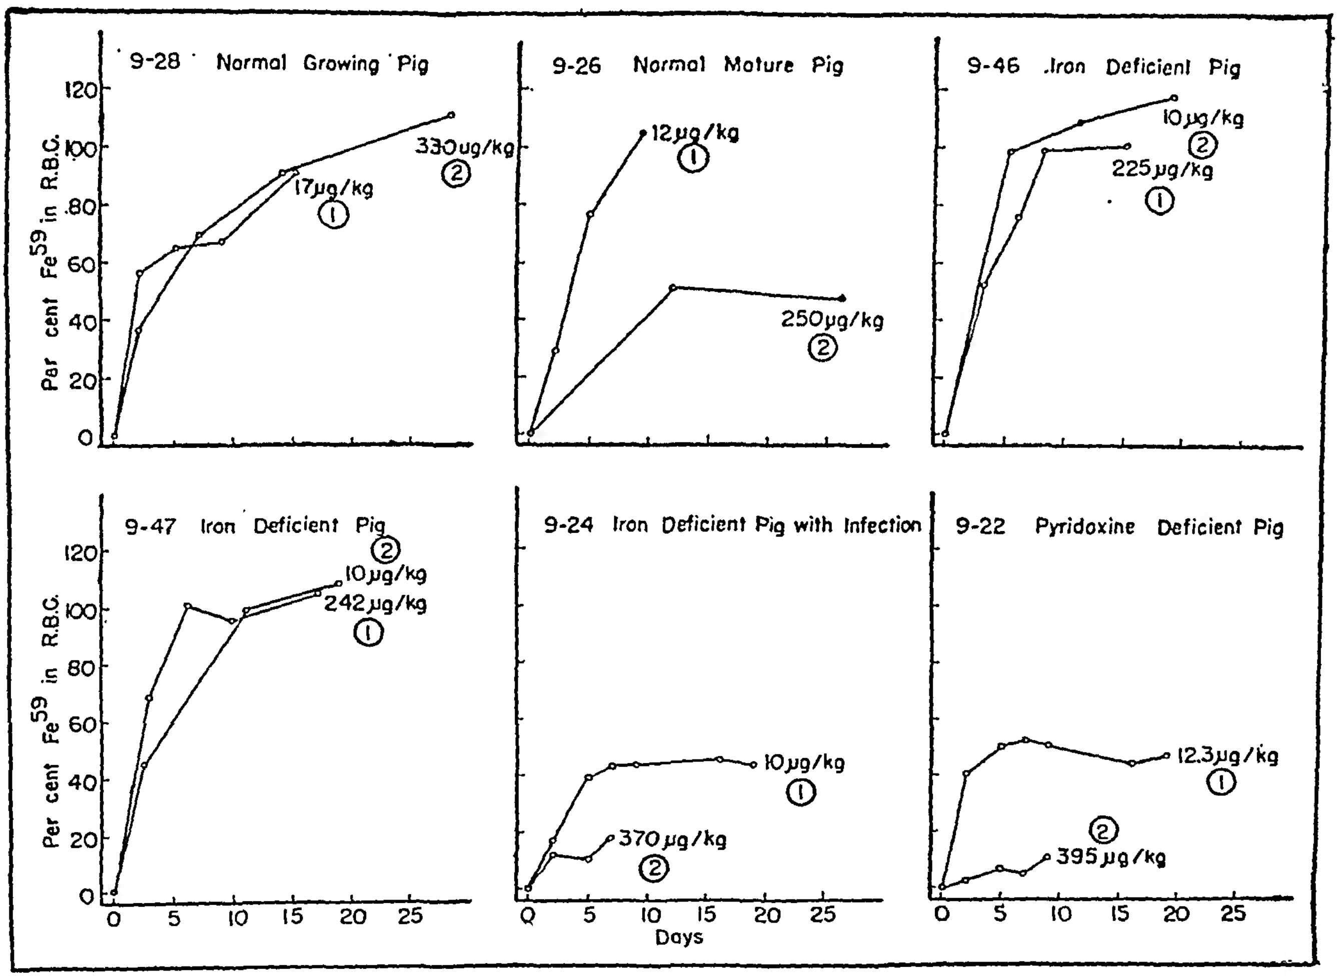

FIG. 2. UPTAKE OF INTRAVENOUSLY INJECTED RADIOACTIVE IRON (Fe^{59}) BY RED CELLS OF NORMAL GROWING AND MATURE PIGS AND IN PIGS WITH IRON DEFICIENCY OR PYRIDOXINE DEFICIENCY

A small and a large amount of iron was given in each instance. The order in which these were given is indicated as (*1*) and (*2*).

Note the more rapid uptakes of iron by the iron-deficient animals (9–46, 9–47) as compared with the normal ones, the less complete uptake of the large dose by the normal mature pig (9–26) as compared with the growing normal pig (9–28), and the poor uptake of iron by the pyridoxine-deficient pig (9–22).

The marked impairment of uptake of iron produced by infection in an iron-deficient pig (9–24) as compared with the uptake in a similar animal without infection (9–47), should be noted.

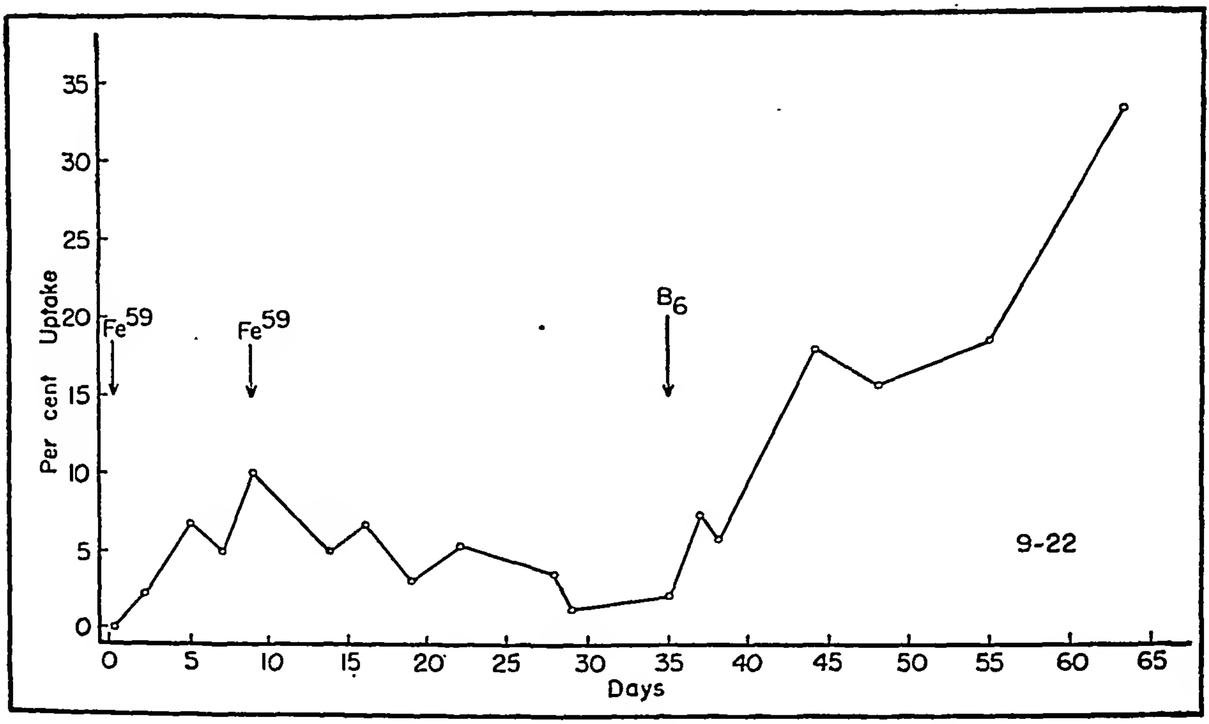

FIG. 3. UPTAKE OF INTRAVENOUSLY INJECTED RADIOACTIVE IRON (Fe^{59}) BY THE RED CELLS OF A PYRIDOXINE-DEFICIENT PIG BEFORE AND AFTER THE ADMINISTRATION OF PYRIDOXINE (B_6)

Two injections of Fe^{59}, each 250 μg. per kgm. body weight, were made. The percentage uptake has been calculated on the basis of the sum of the 2 doses.

That the iron which failed to enter the red cells before pyridoxine was given had been stored, is indicated by the appearance of the radioactive iron in the red cells after normal hemoglobin formation was made possible by the administration of pyridoxine.

mixture (*S. aureus* and *E. coli*), were both given intravenously 100 mgm. of iron per day for 4 days. The uninfected pig (9–49) showed prompt and rapid hemoglobin synthesis. From calculations of the total circulating hemoglobin before and after treatment, it is estimated that 83 per cent of the iron was utilized for hemoglobin formation. On the other hand, the animal receiving the bacterial mixture did not respond significantly to iron therapy until the bacterial injections were stopped and penicillin was used.

In Figure 6 is shown the effect of infection on the response of pyridoxine-deficient pigs to vitamin B_6. One pyridoxine-deficient pig (9–40) was given daily intramuscular injections of a bacterial mixture. Both were given pyridoxine intramuscularly. As will be seen, the animal receiving the bacterial mixture formed hemoglobin but slowly, even though large amounts of pyridoxine were given, whereas the non-infected pig synthesized hemoglobin promptly.

In Table V is presented evidence that Fe^{59} appearing in the blood cells is present as hemoglobin iron. The considerable variation in some instances, well beyond the usual error in the recovery and counting of Fe^{59} in a sample of blood (7), may be ascribed to the small quantity of hemin isolated and thus to the unusually small number of counts with which we were dealing. In spite of this technical difficulty, it will be noted that the average values for these animals showed approximately 100 per cent of the red cell Fe^{59} to be hemoglobin iron. The procedure employed for isolating and purifying the hemin could not possibly have carried through Fe^{59} which was not in the hemoglobin structure originally.

DISCUSSION

It is clear from the present studies that marked retardation of hemopoiesis occurs as a result of inflammation. This is in agreement with the findings of Robscheit-Robbins and Whipple (13)

who showed that a sterile abscess will diminish the production of new hemoglobin in the anemic dog when liver is being fed. That so powerful a stimulus as intravenous iron therapy for an iron- deficient animal, or pyridoxine for a B_6-deficient pig, cannot overcome the retardation or does so slowly and incompletely, attests to the severity of the effect of inflammation. Hemoglobin production normally has priority over other protein production (14). Any process which has precedence over hemoglobin formation can be expected to be important to the survival of the animal.

There is no reason to assume that the mechanism whereby hemoglobin formation is retarded by acute inflammation is different from that associated with chronic infection, even though anemia more commonly accompanies the latter than the former. That time is required for anemia to develop suggests that blood destruction is not a significant factor; instead, as red corpuscles wear out, they fail to be replaced. The "life cycle" of the red corpuscle is thought to be about 125 days (15).

It is of interest in connection with the pathogenesis of the anemia of infection that the pyridoxine-deficient pig which represents, in a sense, a state of supersaturation with iron, is incapable of synthesizing hemoglobin efficiently in the presence

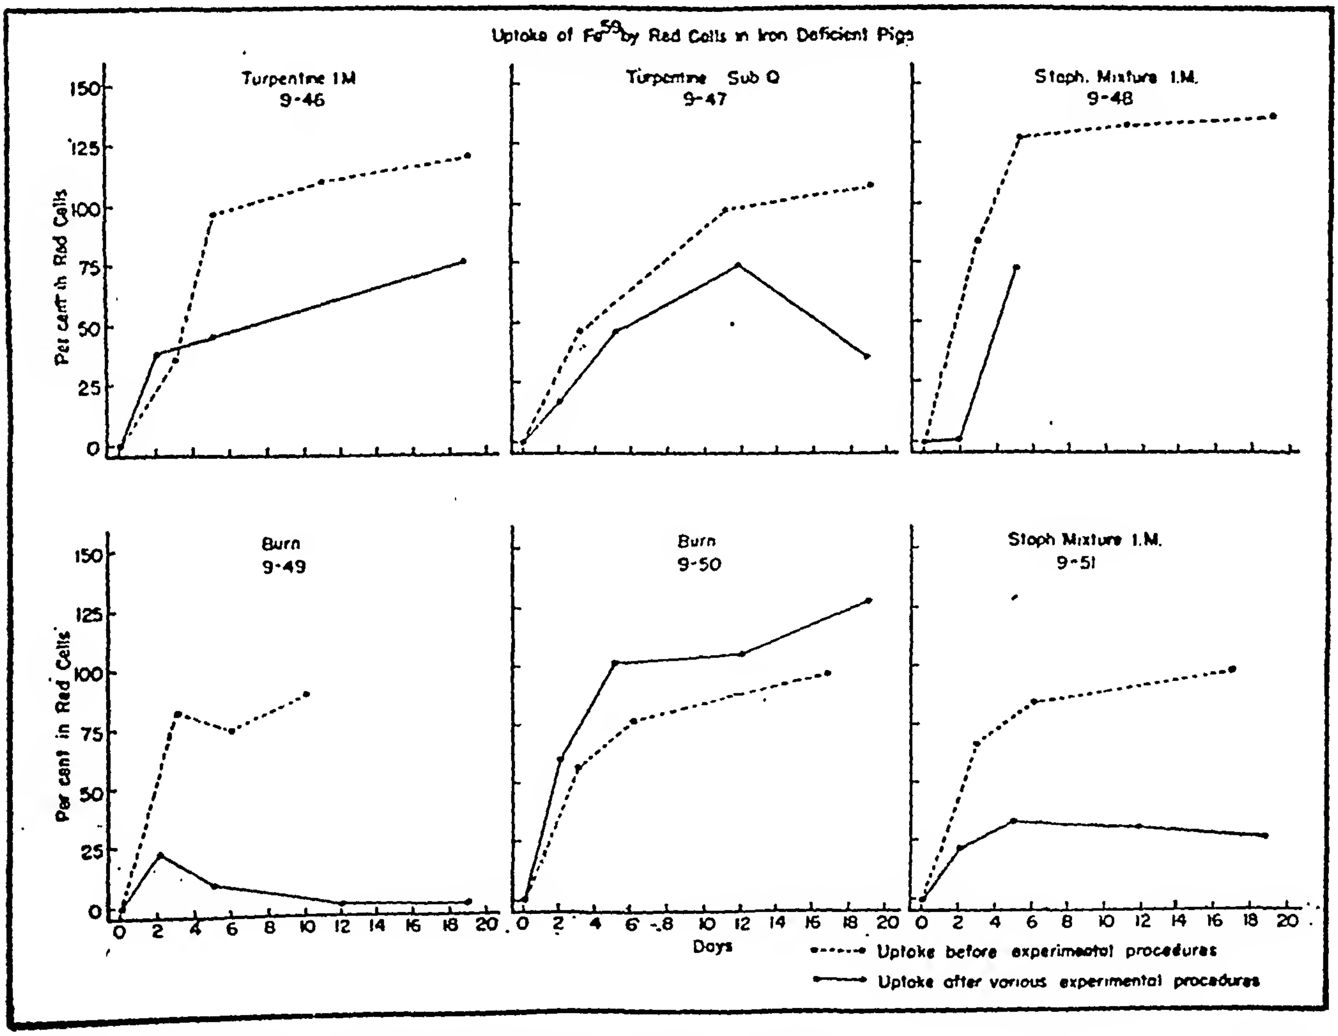

FIG. 4. THE INFLUENCE OF ACUTE INFLAMMATION ON THE UPTAKE OF INTRAVENOUSLY INJECTED RADIOACTIVE IRON BY THE RED CELLS OF IRON-DEFICIENT PIGS

In all instances small amounts of iron were given (10 μg. per kgm. body weight). The interrupted lines represent the uptake before the experimental procedure was carried out and the continuous line indicates the uptake after inflammation was produced.

Note that in every instance but one, a marked retardation of uptake occurred whether turpentine or a bacterial culture was injected, or a burn was produced.

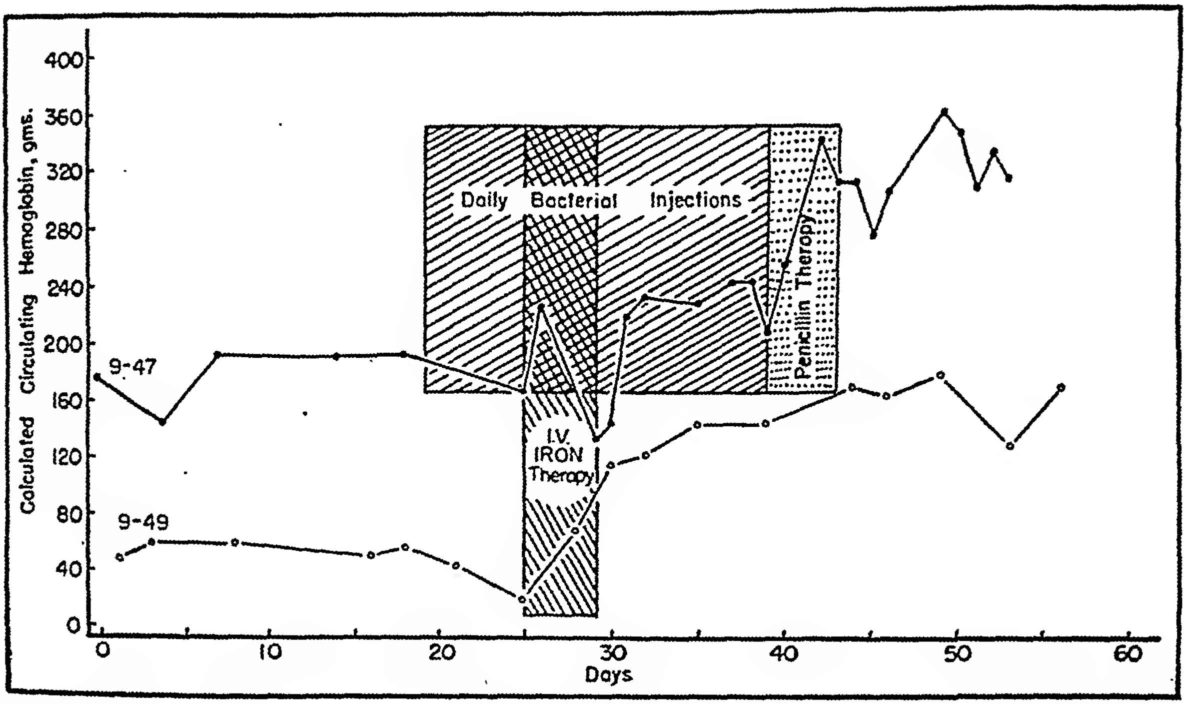

FIG. 5. THE EFFECT OF INFLAMMATION PRODUCED BY DAILY BACTERIAL INJECTIONS ON THE HEMOPOIETIC RESPONSE OF IRON-DEFICIENT PIGS TO THE ADMINISTRATION OF IRON

In the non-infected animal (9–49) the intravenous administration of 400 mgm. iron, given as ferric chloride reduced by ascorbic acid, and then brought to neutrality with alkali, was followed by a prompt and almost complete utilization of the iron for hemoglobin formation as estimated from the rise in calculated total circulating hemoglobin. In the infected animal, on the other hand, the rise above the average level preceding iron administration was comparatively small until the injections were discontinued, the abscesses were drained, and penicillin was given. Following such treatment the hemoglobin rose to the expected level.

of infection, even when pyridoxine is given. This suggests that a limitation of iron is not the primary cause of the anemia of infection. In the paper (16) which follows, additional evidence is presented which indicates that this anemia does not result from a lack of iron.

Comment may be made concerning the usefulness of the radioactive technic as a measure of retarded hematopoiesis. Observation of the rate and extent of the uptake of intravenously administered Fe^{59} is useful, particularly, in circumstances in which retarded hemoglobin formation is suspected but anemia is not present. Theoretically, at least, it should also be helpful in the study of cases where diminished red cell destruction exists to compensate for impaired hemoglobin formation. In using radioactive iron for such purposes, it is important to employ such amounts as will test the functional efficiency of the hemopoietic system, and yet will not be so great that the major portion of the iron given must necessarily be shunted into the iron stores.

SUMMARY

1. The uptake of radioactive iron, injected intravenously, has been studied in normal growing and mature pigs, in iron-deficient and in pyridoxine-deficient pigs, and in such animals when inflammation was produced by various means.

2. For this purpose, 2 different quantities of iron were used, one corresponding to the amount assumed to be absorbed daily from the diet, the other corresponding to the estimated amount derived from normal hemoglobin catabolism. These quantities have been selected in order to test the functional capacity of the hemopoietic system.

3. It has been shown by the isolation of hemin that the radioactive iron appearing in the blood is present in the hemoglobin moiety.

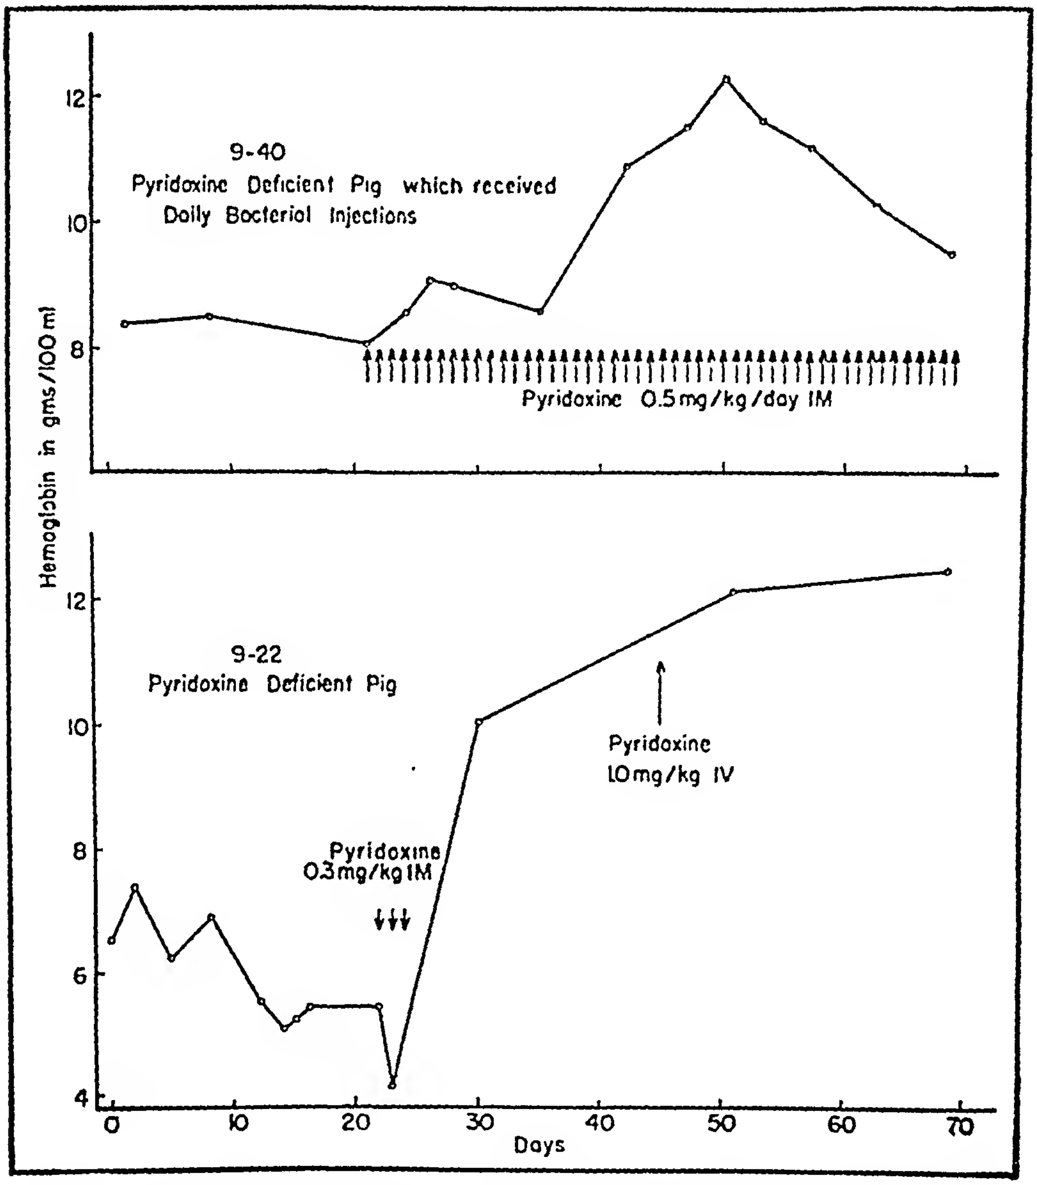

FIG. 6. THE EFFECT OF INFLAMMATION PRODUCED BY DAILY INTRAMUSCULAR INJECTIONS OF BACTERIAL CULTURES ON THE HEMOPOIETIC RESPONSE OF PYRIDOXINE-DEFICIENT PIGS TO THE ADMINISTRATION OF PYRIDOXINE

In the non-infected animal (9–22) the injection of pyridoxine was followed by a prompt and marked rise in hemoglobin, whereas in the pig in which infection was produced (9–40), the response was slow, small in amount, and was not maintained, even though much larger amounts of pyridoxine were given.

4. It has been demonstrated that the uptake of radioactive iron is rapid and complete in iron deficiency; slow, and even negligible, if large doses are used, in pyridoxine deficiency; and intermediate, between these extremes in normal animals.

5. In spite of the pronounced avidity of the iron-deficient animal for iron, in the presence of inflammation the uptake of iron is markedly impaired.

6. In pyridoxine deficiency the rapid and efficient uptake of iron which follows the administration of pyridoxine, is markedly reduced by the presence of infection.

7. It is concluded that the anemia of infection is caused by impaired hemoglobin production. Anemia does not appear at once, however, for it is only when outworn red corpuscles must be replaced that the defect is noticeable.

The radioactive iron used in these studies was obtained from the Massachusetts Institute of Technology through the courtesy of Dr. Robley D. Evans.

TABLE V

Conversion of intravenously injected Fe^{59} to hemoglobin iron in pigs

Animal no.	Status	Day following Fe^{59} injection	Percentage uptake of Fe^{59} by RBC	Percentage of RBC Fe^{59} which is hemoglobin iron
9-22	Pyridoxine deficient	5 7 9	50 53 51	101 101 116
9-24	Iron deficient + infection	7 9	43 43	106 119

THE ANEMIA OF INFECTION. IV. THE LACK OF RELATIONSHIP BETWEEN THE DIVERSION OF IRON FROM THE PLASMA AND THE ORIGIN OF THE ANEMIA[1]

By G. R. GREENBERG, HELEN ASHENBRUCKER, MARJORIE LAURITSEN, AND M. M. WINTROBE

(From the Department of Medicine, University of Utah Medical School, Salt Lake City)

(Received for publication September 21, 1946)

The pronounced and persistent hypoferremia which accompanies infection, and the rapidity with which intravenously injected iron is removed when given in such cases (1), have led to the suggestion that the anemia of chronic infection results from a local iron deficiency in the bone marrow. Since the quantity of free protoporphyrin in the erythrocytes has been found increased in association with the anemia of infection, the possibility exists that this anemia is the consequence of deficient formation of hemoglobin resulting from a lack of iron.

The studies to be described here were designed to test the validity of this hypothesis. Iron was infused continuously in patients with chronic infection in order to determine whether, by raising the iron level to the normal value, synthesis of hemoglobin could be induced. These observations have made it possible to study the rate and degree of diversion of iron from the plasma in infection. Several observations also have been made of the uptake of intravenously administered radioactive iron by the red cells of patients with acute and chronic infections. Evidence will be presented in this communication suggesting that while a rapid removal from the plasma of injected iron occurs in infection, another factor, rather than lack of iron, may be responsible for the development of anemia.

METHODS

Ferrous ascorbate was used for the continuous infusion studies. A 2 per cent aqueous solution was carried through a Seitz filter. With a syringe this was added to a bottle containing 500 ml. sterile 5 per cent glucose solution; thus, the final solution contained 4 mgm. of iron per 100 ml. Since ferrous ascorbate is a complex with varying amounts of iron (2), each lot had to be analyzed, and the amount used varied accordingly. To obtain quickly the elevated plasma iron level, a single dose of 10 mgm. of iron as the ascorbate was injected intravenously shortly after starting the infusion. Considerable difficulty was encountered because of the frequent development of phlebitis after prolonged infusion of iron. This may have been due to the fact that the solutions were too acid (the undiluted ferrous ascorbate solutions exhibited a pH of about 4), or it may have been caused by the continued exposure of the blood vessels to relatively high concentrations of iron. Later it was found that it is possible to raise the pH somewhat if an excess of ascorbic acid is added and the solution is titrated with alkali, as we have done in studies with radioactive iron (3). The radioactive iron for the uptake studies was prepared according to the procedure described in the preceding paper (3), but in patients pyrogen-free, water was used, and the final solution was heated at 70° C. for 3 hours.

The methods for preparing and electroplating Fe^{59} in the blood samples have been described elsewhere (4). In these studies, blood volume has been estimated by assuming a value of 80 ml. per kgm. body weight (5). A few determinations of hemin Fe^{59} have been made according to the technique described in the previous paper (3).

Plasma iron was estimated according to the method of Kitzes, Elvehjem and Shuette (6).

RESULTS

Diversion of intravenously injected iron:

In Figure 1 are presented the results of the continuous intravenous infusion of iron in patients with chronic infection and anemia. It will be seen that very great difficulty was experienced in maintaining an elevated plasma iron level in the presence of infection. In order to maintain the plasma concentration at the normal level, it was necessary to employ several times the quantity of iron that might have been expected on the basis of single intravenous injections of iron. When the quantity of iron infused per unit of time was doubled, the plasma iron level increased by much less than a factor of 2. On the other hand, it was relatively easy to produce a high plasma iron level in the iron-deficient patient shown in the same figure. It is known that the iron-deficient patient takes up iron rapidly for hemoglobin formation. Consequently the drain on the plasma iron in the pres-

[1] Aided by a grant for the study of the pathogenesis of the anemia of infection from the United States Public Health Service; and by grants for the study of hematology and nutrition from the Upjohn Company and Parke, Davis and Company.

ence of infection must be considerably greater than that associated with increased hemoglobin synthesis following the administration of iron in iron deficiency anemia.

That the forced elevation of the plasma iron level did not produce increased hemopoiesis is shown by the results in the case of C. S. (Figure 2). Although this patient's iron level was maintained at approximately the normal value for as much as 72 hours, and enough iron was infused in the 2 attempts to form 31 and 80 grams of hemoglobin, respectively, little increase in reticulocytes occurred, and no significant increase in hemoglobin per 100 ml. of blood took place.

Table I summarizes data presented in paper I of this series (1) on the rate of disappearance from the plasma of iron after a single intravenous injection. From these data it is possible to show that in both the normal subject and in the patient with infection, some mechanism acts to prevent the plasma iron level from rising to the expected values after the injection of iron. In the patient with

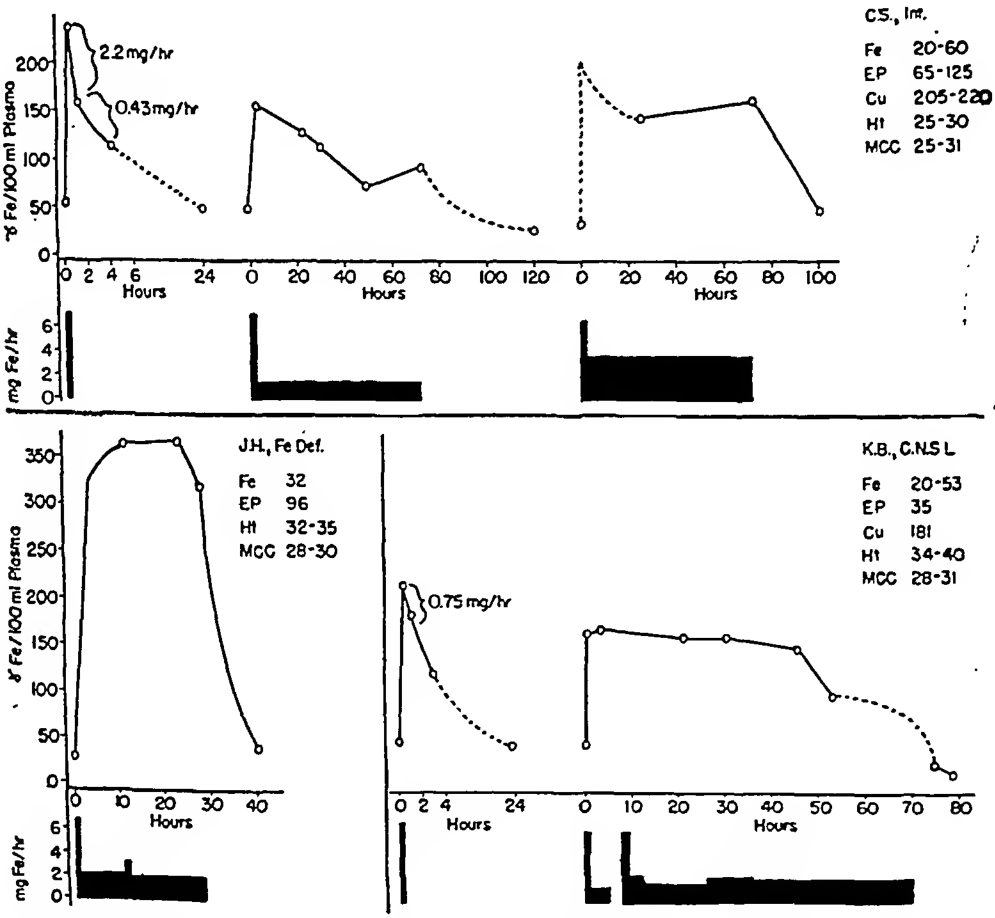

Fig. 1. The Effect on the Plasma Iron Content of Single and Continuous Injections of Iron Ascorbate in a Patient with Anemia Associated with Infection (C.S.), in a Patient with Iron Deficiency Anemia (J.H.), and in a Patient with Central Nervous System Syphilis (K.B.)

Under each patient's initials are given the plasma iron (Fe), the erythrocyte protoporphyrin (E.P.), the serum copper (Cu), the volume of packed red cells (Ht.), and the mean corpuscular hemoglobin concentration (MCC). [For normal values see (1).]

Note that in the cases of infection the plasma iron content could not be maintained at a level higher than normal, even though much larger quantities of iron were being injected intravenously than would be expected to be necessary from the rate of disappearance of single injections of iron. This was not true in the case of iron deficiency anemia, even though the need for iron was great.

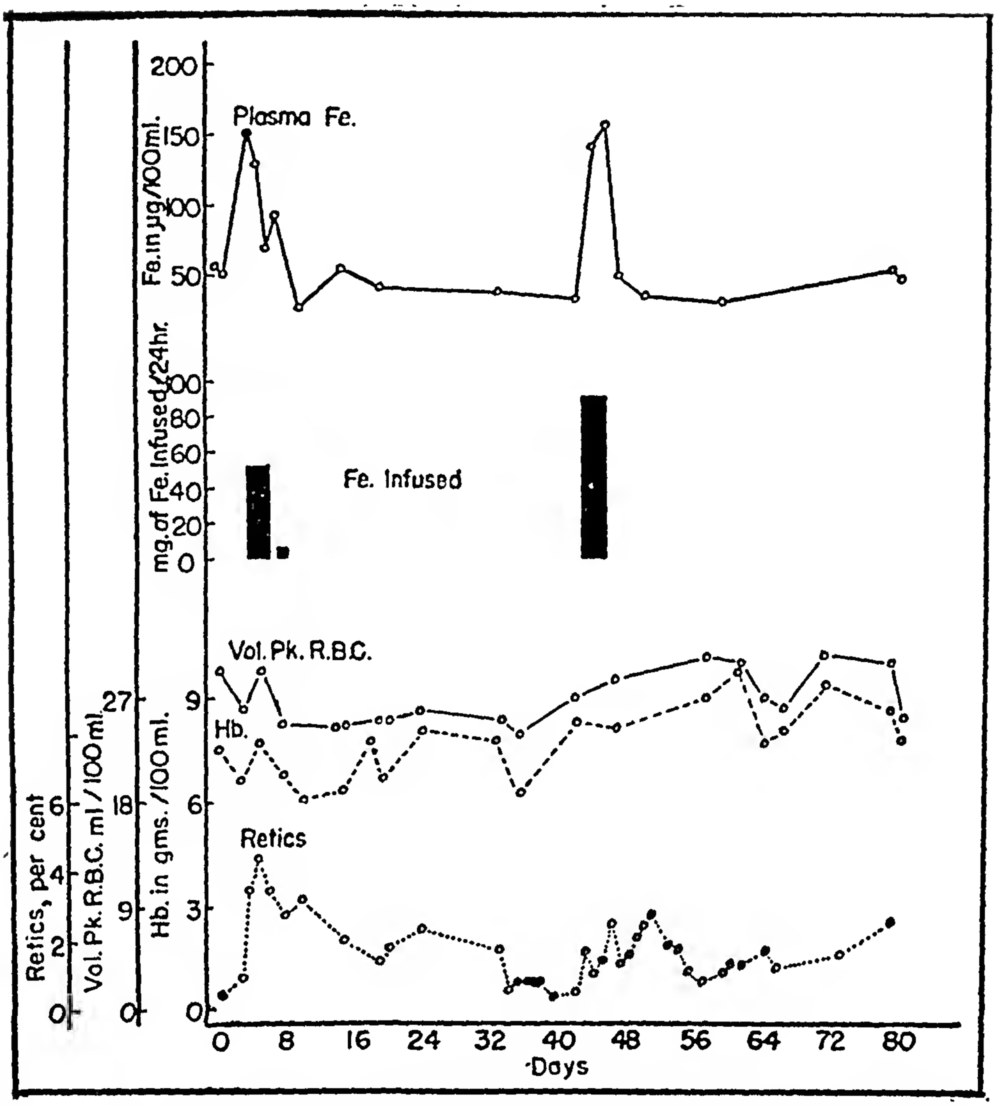

FIG. 2. FAILURE TO INDUCE BLOOD FORMATION OR TO PRODUCE A SIGNIFICANT RETICULOCYTE RESPONSE IN A PATIENT WITH A CHRONIC INFECTION, EVEN WHEN IRON WAS GIVEN CONTINUOUSLY BY VEIN AND THE PLASMA IRON WAS MAINTAINED AT A NORMAL LEVEL

Further details concerning this patient (C.S.) are presented in Figure 1.

infection this "brake" apparently acts at a lower level of iron. If it is assumed that the blood volume corresponds to 80 ml. per kgm. body weight, and that the patients and the normal subjects had average packed red cell volumes of 35 and 45 ml. per 100 ml., respectively, it is possible to calculate that, on the average, the plasma iron of the patients should have risen 250 µg. per 100 ml., and the plasma iron of the normal subjects should have increased 311 µg. per 100 ml. of plasma after the injection of 137 µg. and 130 µg. iron per kgm., respectively. Thus, in the patients, on the average, a maximum level of $43 + 250 = 293$ µg. per 100 ml. should have been attained, and in the normal subjects a peak value of $126 + 311 = 437$ µg. per 100 ml. should have been reached. The actu observed average levels were 196 and 315 µ respectively. Failure to observe higher values w not due to a failure to obtain the true peak, sin in one normal subject blood samples were drav each minute or two for 10 minutes after the i jection of iron; the peak rise was at approximate 5 minutes. Thus, the rate of loss of iron from t plasma in the first few minutes is approximate 100 times as rapid as in the succeeding hou The data indicate that the rate of disappearance iron from the plasma of a patient with infectio is about twice that seen in the normal subject the time following the initial few minutes aft the injection of iron (Table I).

TABLE I

Rate of disappearance of iron from the plasma following a single intravenous injection of iron in normal subjects and in patients with infection

In order to determine how rapidly the mechanism operating in infection can readjust to prevent a further rise in the plasma iron level, 3 injections of iron, 2 in a period of 1 hour, were given to a patient suffering from pneumonia. The results of this experiment are shown in Figure 3. It will be observed that the rise obtained after the third injection was only slightly higher than that obtained after the second injection given 1 hour before. On the basis of the peak rise after the second injection it might be expected that the level following the third injection would have been 334 µg. iron per 100 ml. The observed rise was to 266 µg. per 100 ml. Apparently the mechanism preventing the rise in plasma iron is able to readjust itself quickly in infection.

The uptake of Fe^{59}:

Figure 4 illustrates the results of preliminary studies on the rate of incorporation of intrave-

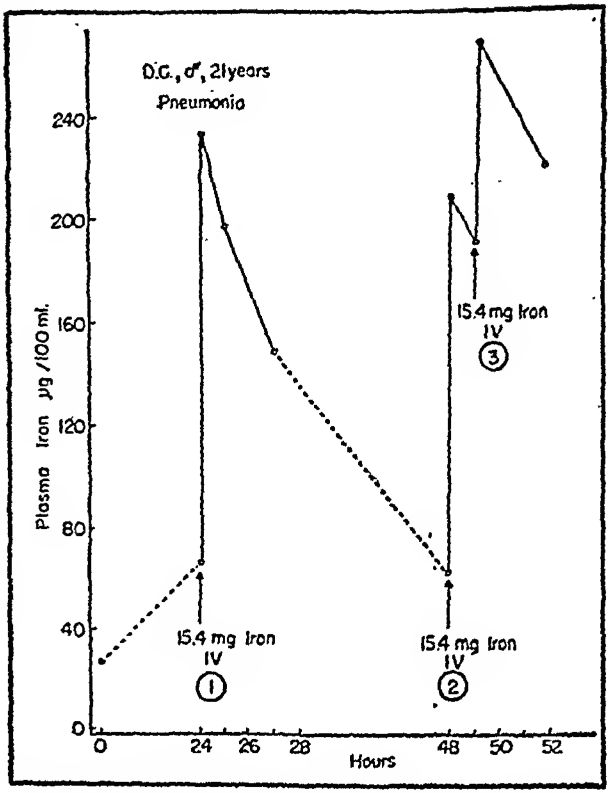

FIG. 3. THE EFFECT OF ATTEMPTS TO RAISE THE PLASMA IRON LEVEL BY THE INTRAVENOUS ADMINISTRATION OF REPEATED DOSES OF IRON IN THE PRESENCE OF INFECTION

It was difficult to maintain a high plasma iron level, even when a second injection was made before the plasma iron content had dropped. Note also that the rise following the third injection was relatively slight as compared with the rise following the previous injections. This suggests that a "braking" mechanism exists.

nously injected Fe^{59} into the erythrocytes as hemoglobin iron in patients with various infections, and in normal subjects. The dose of Fe^{59} employed in these studies ranged between 3 and 4 mgm., depending on the body weight. These data suggest that the degree of impairment of the uptake of Fe^{59} appears to be roughly proportional to the severity of the infection. It will be noticed that while there was an initial delay in the uptake of Fe^{59} by the patients with infection as compared to the normal subjects, in some of the patients after the first few days the rate of uptake approximated that of normal subjects, and the labelled iron was utilized almost completely. An example of this is seen in the case of T. G. who was suffering from a long-standing osteomyelitis. This pa-

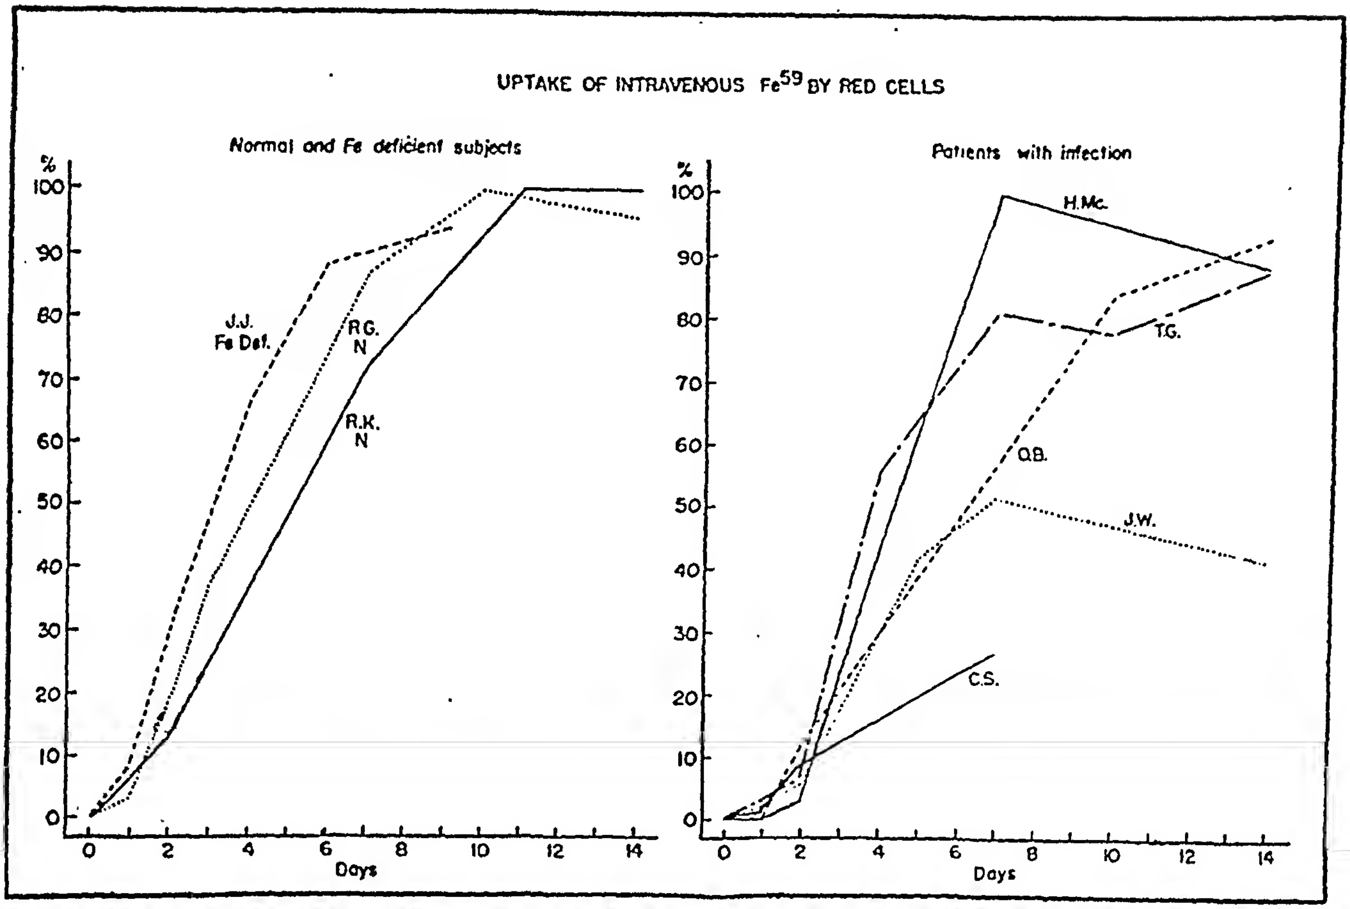

Fig. 4. Uptake of 3 to 5 mgm. Intravenously Injected Radioactive Iron (Fe^{59}) by the Red Cells of Normal (N) and Iron-Deficient (Fe Def.) Patients, and in Patients with Various Infections

In the patients with severe infections (C. S. and J. W.) there was not only a delay in uptake, but the uptake never was complete; whereas in those less ill, less difference was observed as compared with uptake in normal individuals. C. S. had chronic suppurative arthritis and chronic pyelonephritis. The volume of packed red cells (Ht.) was 28 ml. per 100 ml. blood. J. W. had subacute bacterial endocarditis, Ht. 30 ml. Both O. B. and T. G. had osteomyelitis and the volume of packed red cells was 39 and 40 ml., respectively. H. Mc. had rheumatic fever, Ht. 42 ml.

tient exhibited extremely low plasma iron concentration, rapid diversion from the plasma of intravenously injected iron, high erythrocyte protoporphyrin level and elevated serum copper, in addition to anemia. He was refractory to all forms of iron therapy (1). Yet approximately 100 per cent of the small dose of Fe^{59} which was given did enter his red cells. This was to be expected since, at a rate of hematopoiesis which maintains hemoglobin at 50 per cent of the normal, it can be calculated that about 12 mgm. of iron is being converted into hemoglobin in a man of average size (7).

Table II presents evidence that Fe^{59} appearing in the red cells after intravenous injection is present as hemoglobin iron. Hemin was isolated and its Fe^{59} content per mgm. of iron was compared with the Fe^{59} of the original blood per mgm. of hemoglobin iron. Such data have been presented for pigs in the preceding paper (3).

DISCUSSION

These observations indicate that in both normal subjects and in patients with infection, a mechanism operates which prevents the plasma iron level from increasing beyond certain limits. The major loss of injected iron occurs during the first few minutes when the rate of loss may be as much as 100 times as rapid as the loss in the ensuing hours. The initial loss of iron is approximately of the same absolute order of magnitude in both the normal subject and in the patient with infection, whereas the ensuing rate of loss is about twice as rapid in the presence of infection. This braking mechanism is so powerful that as more iron is given and the level is raised by repeated

TABLE II

Quantity of red cell Fe^{59} existing as hemoglobin iron

* The actual quantity of isolated hemin analyzed for Fe^{59} was determined by measuring the iron content of an aliquot part (13) and calculating from the known percentage of Fe in hemin.

** The quantity of isolated hemin analyzed for Fe^{59} was determined by weighing after drying at 100° C.

injections or by continuous intravenous infusion of iron, it becomes increasingly difficult to maintain the plasma iron concentration. In a study of the use of intravenous iron tolerance curves for the differentiation of anemias, Waldenström (8) likewise concluded that a braking mechanism exists which prevents the attainment of calculated peak plasma iron values.

In spite of the existence of such a mechanism, it was possible to raise the plasma iron level temporarily to normal values in anemic patients suffering from chronic infections; yet hemoglobin formation did not take place. The strongest argument against the hypothesis that iron is the limiting factor in the anemia of chronic infection is the fact that both intensive and prolonged therapy with iron, administered orally and intravenously, will not bring about increased hemoglobin formation (1). Actually, iron therapy has been given the most severe test of any employed thus far. Schaefer (9) was able by intensive iron therapy to raise the serum iron level of children with infection to approximately normal values without effecting a change in the anemia. Brøchner-Mortensen and Stein (10) treated patients with tuberculosis with iron by mouth for several months at a time. These patients showed a greater and more constant rise in the serum iron than was observed in those given no iron, but the average change in hemoglobin before and after treatment was less than one per cent.

It cannot be maintained that a normal plasma iron level must exist before iron can be used for hematopoiesis, for in such a case, in the face of persistent hypoferremia, the anemia of infection should be progressive and ultimately should become very severe. Yet it is well known that the anemia tends to become fixed usually at a moderate and, often thereafter, at a rather stable level. Furthermore, in the presence of active hematopoiesis we have observed, like others (11), that in pernicious anemia after liver therapy as well as in iron deficiency anemia, the plasma iron level tends to remain low until the anemia has wholly or largely disappeared. Very active hematopoiesis can, thus, take place when the plasma iron content is low. Finally, as has been shown here by the use of radioactive iron, if small amounts of iron are given they can be utilized for the formation of hemoglobin in spite of the existence of infection. That this should be found to be the case is to be expected, since otherwise no red corpuscles containing hemoglobin would be available to replace those which become worn out in the course of time.

As a consequence, it must be concluded that although diversion of iron from the plasma occurs in infection, the anemia itself does not result from a lack of iron. Some other factor may be deficient, or some enzyme system may be interfered with by some process associated with infection. In agreement with Brøchner-Mortensen and Stein (10) it appears that there is a lack of capacity on the part of the bone marrow to utilize iron for hemoglobin synthesis rather than unavailability of iron.

In spite of the evidence that the lack of iron does not cause the anemia, it is clear that in acute and chronic infection a very marked diversion of iron from the plasma occurs. The system taking up intravenously injected iron in infection apparently withdraws it from the plasma with more avidity than an iron-deficient subject uses iron for hemoglobin formation. The site of diversion of the iron is the subject of the paper which follows (12).

SUMMARY

1. Patients with anemia of chronic infection have been subjected to continuous intravenous infusions of iron for periods as long as 72 hours.

2. Considerably more iron was required to maintain a normal plasma iron level than would be expected from the results of a single intravenous in-

jection of iron. The higher the plasma iron value desired, the more inefficient was the infusion.

3. In neither case did the infusion of iron result in increased hemoglobin formation.

4. Calculations have been made suggesting that a braking mechanism exists which prevents the plasma iron from rising above a certain level.

5. Evidence has been presented from radioactive iron studies and observations of the nature of the anemia, that some iron is capable of entering the erythrocytes as hemoglobin in the anemia of chronic infection.

6. Since even very intensive iron therapy is ineffective, it follows that iron is not the limiting factor in the production of the anemia, even though diversion of iron from the plasma does occur.

THE ANEMIA OF INFECTION. V. FATE OF INJECTED RADIOACTIVE IRON IN THE PRESENCE OF INFLAMMATION[1]

By G. R. GREENBERG, HELEN ASHENBRUCKER, MARJORIE LAURITSEN, WANDA WORTH, S. R. HUMPHREYS, AND M. M. WINTROBE

(From the Department of Medicine, University of Utah Medical School, Salt Lake City)

(Received for publication September 21, 1946)

Since hypoferremia is so consistently associated with the anemia of infection (1), and since injected iron appears to be diverted from the plasma in infection (1, 2), it seemed desirable to determine the fate of the diverted iron.

In this study, radioactive iron was injected intravenously into normal rats and in rats with acute inflammation. The blood and tissues were then analyzed after a period of time for radioactivity. Preliminary studies were made in which only the blood and liver were analyzed in order to determine the appropriate amount of iron to employ. Radioactive iron was also injected intravenously into dogs, and analyses were carried out on a number of tissues, including the exudates.

METHODS

The radioactive iron used in these studies was injected as ferric chloride in physiological saline. For the rats, the concentration was adjusted so that about 0.2 ml. was injected for each 100 grams body weight. In all the rats the same tuberculin syringe was employed for this purpose. In order to be certain that the solution did not enter subcutaneously, the vein on the lateral aspect of the tail was exposed under nembutal anesthesia and the solution was injected intravenously. In one experiment Fe^{59} was injected intraperitoneally.

Inflammation was produced by the intramuscular injection of 0.5 ml. of turpentine. Robscheit-Robbins and Whipple (3) have shown that the resulting sterile abscess can be compared with a bacterial abscess. In some animals, 0.5 ml. of a mixed culture of *S. aureus* and *E. coli* was injected intramuscularly. Injections of bacteria or turpentine were made about 2 hours before Fe^{59} was administered.

The methods for preparing and electroplating the Fe^{59} from the biological samples have been described elsewhere (4). Blood volume was estimated by assuming that the normal mammal possesses 80 ml. blood per kgm. body weight. Hemoglobin was determined in a representative sample of the tissue to be analyzed for radioactivity by a modification of the method of Greenberg and Erickson (5). The radioactivity attributable to the tissue hemoglobin was then subtracted from the total radioactivity of the tissue.

Blood samples were taken in the rats from the abdominal aorta. Blood hemoglobin determinations were made by the photoelectric oxyhemoglobin method of Bell, Chambers and Waddell (6).

The white rats used for these studies were virgin females obtained from the Sprague-Dawley Company and from the Carworth Farms. The dogs were mongrels secured locally.

RESULTS

Table I summarizes the results of analyses of the blood and liver of rats which received Fe^{59} intravenously. It will be seen that usually the rats which had been subjected to acute inflammation showed more Fe^{59} in the liver than was the case in the control animals. On the other hand, the control rats showed better uptake into the red cells than those with inflammation. In general, the sum of the radioactivity in the blood and liver of the

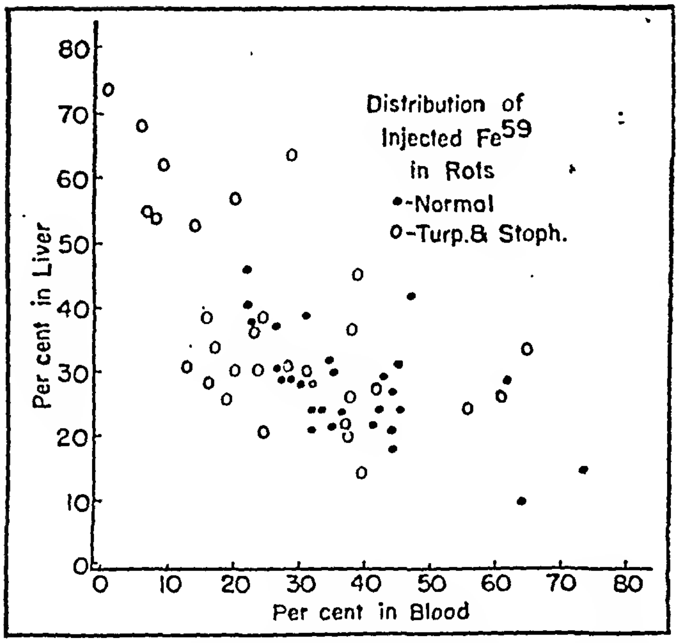

FIG. 1. TO ILLUSTRATE THE INVERSE CORRELATION OF THE QUANTITY OF RADIOACTIVE IRON IN THE BLOOD AND THAT IN THE LIVER FOLLOWING ITS INTRAVENOUS INJECTION BOTH IN NORMAL RATS AND IN RATS RECEIVING BACTERIAL OR TURPENTINE INJECTIONS

control animals was approximately equal to the same sum in the animals with inflammation. This is graphically illustrated in Figure 1.. In this figure the percentage of Fe^{59} in the liver of each animal is plotted against the corresponding Fe^{59} percentage in the blood. It may be observed that the points for the control animals and for those with inflammation fall along the same general line of correlation. When the iron was not found in the blood, it was in the liver. In no case, however, did the values for normal animals fall in the upper portion of the curve.

It should be pointed out that certain animals injected with turpentine apparently did not exhibit retardation of uptake of Fe^{59} by the red cells. The results in these animals together with their controls have been included in Figure 1. Sprague-Dawley rats were apparently considerably more sensitive to turpentine inflammation than were those of the Carworth Farm. Unfortunately, at the time these experiments were conducted it was very difficult to obtain the former animals. In these rats the liver and blood Fe^{59} percentages approached those of the normal animals. However, whether or not diversion to the liver occurred, the reciprocal relation of blood and liver Fe^{59} was maintained.

* Sample lost.
** Calculating by assuming lost sample to be equivalent of average finding in other animals.

In Table II are shown the results of an experiment in which Fe^{59} was injected intraperitoneally, rather than intravenously, in rats. Analyses of the blood, liver and spleen were made on ½ the animals at approximately 3 days, and on the other ½ approximately 4 days following the injection of Fe^{59}. It will be seen that the distribution of the Fe^{59} tended to follow the same pattern as that observed after intravenous injection, except that in the latter case more was recovered in the period of time the animals were studied. It cannot be said with any assurance that an increase occured in the relative percentage of Fe^{59} in the spleen in the animals with inflammation as compared with their controls.

Table III presents an experiment in rats in which analyses were made of the Fe^{59} content of normal and inflamed muscles together with analyses of the radioactivity of the livers and spleens. As will be observed, very little Fe^{59} could be accounted for in either the inflamed or normal muscle 48 hours following the turpentine injection. On the other hand, the liver and blood again ac-

counted for most of the Fe^{59}. Apparently a small increase in the proportion of Fe^{59} takes place in the inflamed muscle.

Table IV presents the results of an experiment in which Fe^{59} was injected into 2 dogs, one of which had received turpentine intramuscularly. The dose of iron employed was much larger than those used in the rat experiments. It will be seen that most of the Fe^{59} was found in the liver even in the normal dog. This is in agreement with the results of Hahn and coworkers (7) who noted that the major portion of a large dose of intravenously injected Fe^{59} is deposited in the liver, mainly as storage iron. It will be noticed that the percentage of Fe^{59} in the blood of the normal animal was more than twice that in the blood of the animal with inflammation. In addition it will be observed that more Fe^{59} was found in the spleen of the dog with inflammation than in the normal animal. The spleen is said not to enter into iron metabolism to the degree that the liver is concerned (8). It is of interest, finally, that no significant quantity of Fe^{59} was found in the inflamed muscle, in the exudate of the sterile abscess, or in the excreta. It should be mentioned that the analyses of the stools and bone marrows were made difficult by the presence of inorganic salts. The results are to be regarded only as approximate indices of the proportion of Fe^{59} carried to the stool and the bone marrow.

DISCUSSION

These results indicate that in infection a significant proportion of injected radioactive iron is not diverted away from the usual organs engaged in iron metabolism. Since the liver is the major iron-storing organ it is to be expected that most of the iron would be found there. It is of interest that Sandberg, Gross and Holly (9, 10) analyzed the spleen and liver from human autopsy specimens in chronic disease accompanied by anemia, and in various types of cancer with and without associated anemia. They found large accumulations of iron and copper in the liver and spleen, even when anemia was absent; and, in the presence of anemia, in amounts out of proportion to the degree of ane-

The inflammatory exudate in an animal given turpentine contained 0.1 per cent of the injected Fe^{59} per 100 ml.

mia. The present studies indicate that while more iron is found in the liver and spleen in infection, the increase in these tissues apparently corresponds to the quantity of iron not used for hemoglobin formation as a result of the retarded hemopoiesis. As has been shown in the preceding paper (2), the diversion which occurs, while very real, apparently is not the primary cause of the anemia of infection.

The greater quantity of iron found in the inflamed tissues as compared with that in the normal tissues was not of such an amount as to account for the persistent hypoferremia which accompanies infection. Menkin (11) found an accumulation of intravenously administered iron in the inflammatory tissues of rabbits. However, although his figures indicate that an average of 67 per cent more iron was present in the inflamed tissue after iron was injected than before, quantitatively the total amount of iron concerned was very small. He injected about 10 mgm. of iron and found 6.5 mgm. per 100 grams of dry inflamed tissue. From his description it seems unlikely, however, that more than 2 grams of dry tissue was inflamed; thus only 0.13 mgm. could be accounted for in this way. This represents but 1.3 per cent of the 10 mgm. of iron injected. This is of the same order of magnitude as was found in our studies.

It might be argued that this quantity of iron, if removed continuously, could produce hypoferremia in a patient with chronic infection. It does not seem plausible, however, that a comparatively small area of inflammation could take up sufficient iron to produce significant hypoferremia and impair hemoglobin synthesis. The data which have been presented suggest that it is the diversion of iron to the liver and spleen which is correlated with the hypoferremia.

With further reference to the fate of plasma iron diverted in the presence of inflammation, it may be pointed out that Hahn *et al* (12) showed that the urine and bile contain negligible quantities of iron injected intravenously in doses even larger than those used in the present study. In balance studies, Schaefer (13) found no evidence of increased excretion of iron in children with infection. It may be noted also that in a previous paper of this series (14), an iron-deficient pig with infection was described which was given large therapeutic doses of iron intravenously. This animal apparently did not excrete a significant quantity of iron, since on relief of the infection all of the injected iron could be accounted for as hemoglobin.

Our data offer no evidence as to the reason for the diversion of the iron from the plasma to the liver and, to a much smaller extent, to other tissues. It must be assumed that this diversion of iron is intimately related to some process related to infection. The present studies indicate that the lack of iron is not the fundamental factor in the pathogenesis of the anemia of infection. The presence of excess erythrocyte protoporphyrin and serum copper in cases of infection associated with anemia (1) suggests that no limitation exists in these substances. By elimination, the protein moiety of hemoglobin may be suspected as being involved. This view is tenable, furthermore, because it is well known that a disturbance in protein metabolism occurs in infections. It has been shown that in acute infections the urine nitrogen is very greatly increased (15), the same being true, though to a lesser extent, in chronic infections. It is generally recognized that the plasma albumin concentration is an index of protein reserves (16). Since globin is derived from these reserves (17), the fact that in chronic infection the plasma albumin concentration may be low (18) is probably significant in relation to the pathogenesis of the anemia of infection.

SUMMARY

1. Radioactive iron was injected intravenously in normal rats and dogs, and in animals with acute inflammation, in order to determine the fate of the iron.

2. A number of rats with inflammation showed retarded hemopoiesis and increased deposition of Fe^{59} in the liver and spleen as compared to the control animals.

3. There was good inverse correlation between the Fe^{59} in the liver and in the blood in both the normal rats and in the animals with inflammation.

4. Analyses of the inflamed tissues for Fe^{59} indicated that no significant quantity of iron is diverted to the inflamed area.

5. Insignificant percentages of large doses of intravenously injected iron were found in the exudate of a sterile abscess and in the excreta of a dog that had received turpentine intramuscularly.

6. It has been concluded that the major diversion of plasma iron in infection is to the ordinary storage tissues, mainly the liver.

7. This diversion is related to the hypoferremia.

THE CIRCULATING RED CELL AND PLASMA VOLUME AND THE DISTRIBUTION OF BLOOD IN LARGE AND MINUTE VESSELS IN EXPERIMENTAL SHOCK IN DOGS, MEASURED BY RADIOACTIVE ISOTOPES OF IRON AND IODINE[1]

By JOHN G. GIBSON, 2ND, ARNOLD M. SELIGMAN, WENDELL C. PEACOCK, JACOB FINE, JOSEPH C. AUB, AND ROBLEY D. EVANS

(From the Departments of Medicine and Surgery, Harvard Medical School, the Medical Clinics of the Peter Bent Brigham and the Massachusetts General Hospitals, and the Surgical Research Department of the Beth Israel Hospital, Boston; and the Radioactivity Center, Massachusetts Institute of Technology, Cambridge)

(Received for publication September 25, 1946)

During World War I a recently developed dye method of measuring plasma volume (1) was employed, to a limited extent, in the investigation of hemorrhagic and traumatic shock in wounded soldiers. Those studies (2 to 4) showed that shock was associated with varying degrees of reduction in the measurable total blood volume. It was assumed that this reduction resulted in a decreased venous return to the heart, which accounted for diminished blood flow and death in vascular collapse. It was also felt that severity of shock as judged clinically was proportional to the degree of blood volume reduction. Cannon (5) summarized the results of these investigations in 1923. There was little change in this conception of the fundamentals of shock for several years, and, as might be expected, little improvement in the therapy of shock.

Blalock (6) concluded that the decrease in blood pressure in experimental traumatic shock was due to loss of blood into damaged areas, or to hemorrhage into the intestinal tract (7). Moon (8) on the basis of pathological observations on dogs dying in prolonged shock (peritonitis) concluded that increase in capillary permeability permitting the leakage of plasma from the vascular bed was chiefly responsible for loss in blood volume.

As improvements in the original dye method of measuring plasma volume became available (9 to 11), attention was again concentrated on blood volume in shock. It was shown (12) that surgical operations may be accompanied by a loss of plasma and red cells greater than can be accounted for by measured blood loss. A reduction in blood volume severe enough to produce severe peripheral vascular collapse was found to be brought about by the excessive sweating accompanying artificially induced fever (13). It was observed for the first time that shock produced in dogs by thermal burns was *preceded* by great reductions in circulating plasma volume (14, 15).

Hemoconcentration of blood in large vessels has been associated with shock, and was thought to be characteristic. Scudder (16) suggested that the determination of the specific gravity of whole blood and plasma might be useful as a guide to therapy.

Interest in the hemodynamics of shock came into a renewed focus during the early years of World War II. An extensive historical review of our knowledge of shock was published by Harkins in 1941 (17) and a briefer summary of the known physiology of shock by Wiggers in 1942 (18).

The many blood volume studies in experimental shock in animals (19) and of traumatic shock in man (20 to 22) carried out during the war have amply confirmed the early conception that severe oligemia is a constant characteristic of the condition.

That significant leakage of plasma from capillaries whose permeability is increased in shock does not occur, has been clearly demonstrated by

[1] The work described in this paper was done under contracts recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts Institute of Technology, in collaboration with the Peter Bent Brigham Hospital, Harvard University, the Beth Israel Hospital, the Massachusetts General Hospital, and the Huntington Memorial Hospital.

Fine and Seligman (23 to 25). The opinion has been expressed by Noble and Gregersen that the reduction in blood volume is due to loss of whole blood at the site of injury (22). Since their subjects were accident cases, and the extent of blood loss suffered could be calculated only on the basis of blood volume measured after recovery, these observations do not indicate whether or not the entire reduction of blood volume as measured in shock could be accounted for by loss of blood into the various sites of injury.

Early in the course of our work we noted that the circulating red cell volume, as measured by the specific method of injecting red cells tagged with radioactive iron, was always some 15 per cent less than when measured by the dye plasma hematocrit method (26). This led us to question to some extent the reported changes in circulating red cell volume obtained by the latter method. Furthermore, our early studies in hemorrhagic shock in dogs, in which there was no evidence at autopsy of internal bleeding, consistently showed a reduction in *circulating* red cell volume greater than the cell volume removed, whereas dogs bled only moderately, and in whom shock symptoms did not occur, did not exhibit such a deficit in circulating red cells. This deficit was termed "trapping."

Root (27) and Chambers (28) made microscopic observations of capillary circulation in the mesentery of rats and dogs. Both observers noted that after severe hemorrhage, intestinal manipulation, and occlusion of blood flow in the leg, numerous plexi of capillaries contained closely packed erythrocytes at a complete standstill, the cells in circulation flowing through the larger arteriovenous shunts. This suggested that some portion of the red cells found to be "trapped" in our hemorrhaged dogs might still be within the vascular bed, and yet be temporarily isolated from the main course of the circulating blood. It was of interest to know where in the capillaries of the various organs such "trapping" might occur, and to what extent it might progress in relation to the clinical signs of impending, early or late shock.

Methods previously described (29) had enabled us to measure the quantity of red cells and plasma within the minute vessels of the organs in relation to the total circulating red cell and plasma volume. We concluded from these studies that (*1*) all erythrocytes were in active circulation at all times; (*2*) 17 per cent of the total blood volume was within the capillaries; (*3*) there are pronounced gradients in the hematocrit of whole blood as it flows from larger to smaller vessels; and (*4*) that there are no significant reserves of red cells in the body of the normal dog.

The purpose of the experiments herein reported was to (*1*) measure reductions in red cells and plasma volume in a variety of experimental shock conditions, (*2*) determine the degree of "trapping" of red cells in shock, (*3*) locate if possible the site of red cell trapping, and (*4*) determine the extent of disturbance in normal capillary flow in early, reversible and irreversible shock.

METHODS

Plasma volume was determined by the method of Gibson and Evelyn (30), red cell volume by the method of Gibson and Peacock (31). Intravascular measurements of hemoglobin (25) and of radioactive iodine (25) were made as described by Fine and Seligman.

MATERIAL STUDIED

Shock was experimentally induced in normal healthy (stray) dogs by hemorrhage, muscle trauma with and without hemorrhage (Blalock crusher) (32), muscle ligation (33), occlusion of blood flow in extremities (tourniquets) (34), burns (flame (14) and hot water) and toxins (Shiga (35) and Clostridium (36)). Morphine narcosis and, in a few cases, nembutal anesthesia were used. Clinical condition of animals was followed by changes in mean arterial pressure, obtained by cannulation of a femoral or carotid artery, registered with mercury manometer.

Four groups of experiments were completed, here classified by the type of blood volume measurements carried out.

Series I. Total plasma (dye) and circulating red cell volumes (radio-iron) in the normal state, and during periods of lowered arterial pressure (shock), were determined. Some of these animals received plasma or albumin therapeutically.

Series II. In addition to the observations made in Series I, the quantity of total (by hemoglobin or Fe^{59} measurements) and circulating (by Fe^{59}) red cells within the minute vessels of several organs was determined.

Series III. In addition to the observations made in Series I and II, the quantity of circulating plasma (by radio-iodo-protein) within the minute vessels was determined.

Series IV. Initial circulating cell and plasma volume was determined when the animals were in shock induced by tourniquets applied to both hind legs for 9 hours. These animals were treated with varying quantities of bovine albumin in 5 per cent and 25 per cent solution. A

repeat cell and a plasma volume were determined at varying intervals after the albumin infusion.

Series I. Gross volume studies.

Determinations were carried out in dogs in whom shock was experimentally induced as follows:

- Hemorrhage:
  - Controls—Bled for samples only—2 dogs.
  - Moderate bleeding but not to shock level—1 dog.
  - Severe bleeding to shock levels—10 dogs.
  - Severely bled, treated with dog plasma—2 dogs.
  - Severely bled, treated with bovine albumin—1 dog.
  - Severely bled, treated with whole dog blood transfusion—1 dog.
- Muscle trauma:
  - Blalock crusher—3 dogs.
  - Ligation of both gastrocnemii—1 dog.
  - Bilateral occlusion tourniquets—1 dog.
- Burns:
  - Flame, treated with bovine albumin—3 dogs.
  - Water (98° F.)—1 dog.
- Bacterial toxins:[2]
  - Shiga toxin—2 dogs.
  - Clostridium toxin—1 dog.

In all of these experiments, the plasma and red cell volumes were determined prior to the experimental procedure. The total quantity of blood withdrawn, in both sampling and intentional and accidental hemorrhage, and the hematocrit of that blood were measured. The net loss of plasma and cells was taken as the quantities of plasma and cells removed minus the quantities of plasma and tagged red cells given (as whole blood) for radio-iron cell volume measurements. The difference between initial and net loss of plasma and cells was termed the "expected volume." Repeat volume measurements, termed "found," were made in shock. If the found cell or plasma volume was less than the expected values, these discrepancies were termed "trapped"; if greater than the expected values, they were termed "mobilized." The quantity of trapped cells of plasma was expressed as a percentage of the expected volumes. Auricular, arterial, or venous hematocrits were measured directly. The average body hematocrit was calculated from total circulating plasma volume and red cell volume as measured by radio-iron.

Series II.

In 5 dogs the total and circulating red cells (but not plasma) within the minute vessels were measured, as described above. In addition, circulating red cell volume was measured in the normal and later in the shocked state.

Two animals were bled about ⅓ and ½ of their blood volume, and died in shock. One dog had both gastrocnemii ligated, was also bled and died in shock. Two dogs received Shiga toxin, and had moderate hemorrhages. Both were sacrificed, one before the onset of peripheral collapse and the other in deep shock.

[2] Experiments in collaboration with Freedberg, Haimovici and Blumgart (35).

Series III.

In 5 morphinized dogs, the total and circulating red cells, and the circulating plasma (by radio-iodo-protein) were measured, as described above, in addition to measurements of total circulating red cells and plasma in the normal and later in the shocked state.

Two animals were bled, one (25–128) moderately, and one (25–116) severely. Both were sacrificed before the onset of extreme peripheral collapse. Dog 25–129 was bled as previously described (37), a mean arterial pressure of below 30 mm. Hg being maintained for 3 hours; all of his own blood was then returned, and a large transfusion was given (800 ml.). The initial red cell and plasma volumes were determined *after* the transfusion. The blood transfusion was of no benefit, and the animal was sacrificed terminally. Dog 25–130 had both hind legs burned with water at 98° F. and was sacrificed *in extremis*. Occlusion tourniquets were applied to both hind legs of dog 25–132 for 9 hours, and the animal was in deep shock when sacrificed.

Series IV.

A series of 16 morphinized dogs, in whom deep shock was produced by the application of tourniquets to both legs for 9 hours, was treated with intravenous bovine albumin solutions (34). All of these animals had marked hemoconcentration, the hematocrits all being above 60, and mean arterial pressure fell to below 70 mm. Hg shortly after the release of the tourniquets. The auricular hematocrit was greatly lowered by the albumin, whether given in 5 per cent solution or 25 per cent solution, with or without additional fluid or salt. Circulating red cell volume was determined before and after the administration of albumin.

RESULTS

Series I.

The extent of trapping or mobilization of red cells or plasma, expressed as percentages of the expected final volume, found in all animals in this series is summarized in Table I.

In the control dogs, bled less than 10 per cent of total blood volume for sampling only, no trapping of cells or plasma was observed.

Of 11 dogs in hemorrhagic shock, bled a net of from 27 to 50 per cent of initial total blood volume, 10 showed trapping of red cells of from 4 to 48 per cent of the expected volume; 9 dogs showed trapping of plasma of from 8 to 43 per cent. One dog, excessively hydrated, showed mobilization of both red cells and plasma, and 1 animal treated with bovine albumin solution showed mobilization of plasma. The dog treated with a large whole blood transfusion (25–129) showed trapping of both red cells and plasma.

TABLE I

Trapping of red cells (by radio-iron and dye methods) and of plasma (dye method) in experimental shock in dogs

135–136	Clostridium toxin	20			10

* Vrr = Red cell volume by radio-iron method.
Vpd = Plasma volume by dye method.
** Experiments in collaboration with Freedberg *et al* (35).

Two animals injured with the Blalock crusher showed trapping, and 1 showed mobilization of cells and plasma. Trapping of both cells and plasma also was found in a dog both of whose gastrocnemii were ligated, and in a dog in whom the blood flow to both hind legs had been occluded by tourniquets. All 4 burned dogs had extensive trapping of red cells, and 2 had trapping of plasma. Three of these, burned by flame, received bovine albumin, and 2 of these mobilized plasma.

Minimal trapping of red cells with mobilization of plasma was observed in 1 dog (SA–2) receiving Shiga toxin (not in shock) but another dog in severe shock showed extensive trapping of whole blood. The animal receiving Clostridium toxin trapped cells, but mobilized plasma.

Series II.

The unit quantities (ml. per gram) of total and circulating red cells in the minute vessels of the organs, and the ratio of circulating to total cells, are shown in Table II . Also shown are the percentages of expected total red cell volume represented by total and circulating red cells in the minute vessels of the entire organ masses analyzed. In addition, the quantity of trapped red cells found by gross volume measurements and the quantities found trapped in the minute vessels of the organ samples analyzed are shown.

With certain minor exceptions, the findings in the animal sacrificed while not in shock (SA–2) were at the lower limit of the normal range. The quantity of total and circulating red cells in the spleen was about ⅔ the normal average, but within the normal range; and in the kidneys, about ⅓ of normal. The percentage of expected red cell volume found as total and circulating cells in all the minute vessels was about normal. Trapping of cells by gross volume measurements was within the accepted limit of error, and no trapping was found in the minute vessels, the ratio f2 being 1.00.

In all 4 dogs in shock, the red cell content of the spleen, both total and circulating, was below normal, and only about ⅓ to ⅔ of this reduced content of cells was in active circulation. The spleen had been emptied of about ⅓ of its normal red cell content.

Total red cell values were higher than normal in dog SA–3 (Shiga toxin), lower than normal in dog 25–120 (severe hemorrhage), but showed no marked deviation from normal in the other 2 dogs. The values for circulating red cells were definitely below normal (except in SA–3, in which they were high), and in virtually all instances were lower than the total cell values.

In all 4 dogs, the ratio of red cells actively circulating to those contained in the entire minute vessel bed was less than 1, ranging from 0.76 to 0.83, averaging 0.80. In only one instance out of 26 was the f2 value for an individual organ greater than one (1.03). Thus about ⅕ of the total cells in the minute vesels were not in measurable circulation.

Series III.

The total and circulating red cell content, and circulating plasma and whole blood content of all the organs are given in Table III. The ratio (f2) of rapidly circulating to total red cells for indi-

servations were made were striking. The total cell content was reduced by from 60 to 80 per cent, the plasma content remaining unchanged. Here again, as in Series II, the spleen had emptied about 20 per cent of the normal *total* minute vessel red cell content into the blood stream.

In both the untreated bled dogs, the total red cell content of minute vessels of all organs was well below normal. The lowest values were observed in the most severely bled animal, in whom circulating red cell contents were still lower.

Plasma content values were consistently about ⅔ of normal in all organs of the dog not in shock, but in the dog in early shock values for lung, liver and kidney were higher than normal, being elsewhere about normal. Whole blood values for all organs were below normal in both animals.

The animal receiving the large transfusion had higher than average normal total cell values in all organs, and higher than normal circulating cell values in liver, lungs and kidneys. Plasma values were at essentially normal levels. Whole blood values were above normal in liver and lungs, but otherwise were about normal.

The burned animal showed practically no deviation from average normal total cell content in the organs analyzed, but all values for circulating cells were low (no data were obtained on spleen, kidneys and bowel). Plasma values were on the low side, and whole blood values reflected the diminution in circulating cells and plasma.

In the animal with shock produced by tourniquets, total cell content values of all organs were consistently high, the circulating cell values approximating the normal range. Plasma values were low, to such an extent that the whole blood values were slightly below normal in spite of the high cell contents.

In this series, in 7 out of 28 instances f2 ratios greater than 1.0 were obtained. The weighted f2 value was 1.03 in the dog not in circulatory collapse, but in the 4 shocked animals values ranged from 0.60 to 0.82, averaging 0.74. In this series, as in Series II, about 20 per cent of the total cells within the minute vessels were not in active circulation.

Series IV.

In this series less than 10 per cent of the circulating red cell volume found in shock was removed in net sampling. In every case, the auricular hematocrit, markedly elevated after removal of tourniquets, was considerably lowered following the administration of albumin. The circulating red cell volume after albumin was higher than the expected volume (volume in shock less net loss in

sampling) in 10 dogs, showed no change in 4 dogs, and was lower in 2 dogs. Of the 10 showing an increase, the change was less than 10 per cent in 4, between 5 and 10 in 4, and over 10 per cent in 2 dogs.

Eight dogs survived more than 24 hours, after the removal of tourniquets (later to die of infection or be sacrificed), and 8 died within 24 hours. All of the 8 survivors showed increases over expected cell volume, but 2 that showed increases died. None of the animals that died showed an increase over expected volume, and 2 had decreases after therapy. Changes in circulating red cell volume, auricular hematocrit and mean arterial pressure are given in Table IV.

DISCUSSION

Virtually all of the animals in Series I, in which only gross red cell and plasma volume measurements were made, had reductions in total blood volume. In addition, they showed varying degrees of trapping of both red cells and plasma.

Considered by etiology of shock, the animals given bacterial toxins showed approximately 50 per cent trapping of red cells; those burned, 20 per cent; those whose muscles were injured, 15 per cent; those with severe or fatal hemorrhage, 25 per cent; and those whose blood loss was treated (without avail) with whole blood or protein solutions, 15 per cent. The majority of these animals underwent severe reductions in mean arterial and pulse pressure, and blood flow was markedly slowed, but, as far as the clinical condition of the animal could be judged by these observations, there was no obvious relationship between the degree of trapping and mean arterial pressure levels.

Some bled animals underwent hemodilution, as evidenced by a fall in auricular hematocrit, and some hemoconcentration, with a rise in auricular hematocrit. The burned animals (treated with albumin, and untreated) showed no marked change in hematocrit; those whose muscles were damaged showed considerable hemoconcentration, while those receiving toxins showed variable changes in hematocrit. There was no consistent relationship between the direction of, or degree of, change in hematocrit and the percentage of total red cell volume found to be trapped.

All of these animals underwent varying degrees of net loss of whole blood due to intentional bleeding or sampling. The findings cited above, however, indicate that characteristically, in shock,

Dogs 2 to 21 inclusive received 5 per cent albumin in 0.85 per cent NaCl.
Dogs 6, 8, 27, 38 and 41 received 25 per cent albumin with no additional fluid.
Dogs 31 and 33 received 25 per cent albumin plus saline by stomach tube.
Dogs 45 and 47 received 25 per cent albumin plus 0.5 gram NaCl per 100 ml. plus water by stomach tube.
S = Survived 24 hours or more after release of tourniquets.
D = Died within 24 hours of release of tourniquets.

there is a *greater reduction in circulating cells and plasma than can be accounted for by known external blood loss.*

This discrepancy may be accounted for in 2 ways: (*1*) loss of cells and plasma from the vascular tree through internal bleeding into damaged areas, serous cavities or hollow viscera, and (*2*) isolation from the moving blood stream of cells and plasma that remain within some portion of the vascular tree. Evidence of the former phenomenon should be obtained at necropsy. Evidence of the latter phenomenon was found in the experiments in Series II and III.

There were 2 dogs in these series not in shock (SA-2 and 25-128), and they served as controls for the shocked animals. Other than reductions in blood volume due to known blood loss, neither dog showed any significant deviation from the normal. The percentage of total red cell, plasma and whole blood volume found within the minute vessels of individual organs, the ratio of rapidly circulating to total red cells in minute vessels, and the ratio of the hematocrit of blood in minute and large vessels to the auricular hematocrit were all within normal limits.

The shocked animals in these 2 series represent 1 case of early shock (25-116), 1 fatal hemorrhage (25-118), 2 cases of severe hemorrhage in which volume replacement with bovine serum albumin (25-120) and whole blood (25-129) was ineffective, 1 case of severe muscle trauma (135-90), and 1 case of arterial and venous occlusion (25-132), both untreated and fatal in degree, 1 fatal burn (25-130), and 1 case in which death was due to an overwhelming toxin (SA-3).

Certain findings were common to all of these animals, although varying in degree, regardless of the etiology of their peripheral vascular collapse. Without exception, the unit values (ml. per gram) for total red cells in the spleen were well below normal values. In the other organs, values were above normal in the transfused dog (25-129) and the animal dying of Shiga toxin (SA-3). High values were chiefly in lungs and liver and kidneys. Low values were consistently found in all 3 animals that were bled. No significant change from normal was found in the other animals.

Unit values for plasma were below normal in the tourniquet dog (25-132), about normal in the bled dog not in shock, but above normal in the

burned dog (24–130), and in both the dog in early hemorrhagic shock (25–116) and the transfused dog (25–129). In all animals in shock, the unit value of circulating red cells tended to be less than that of total red cells. In both series, a total of 69 organ samples were analyzed for total and circulating red cells. In only 10 instances was the ratio (f2) of rapidly circulating to total red cells greater than unity. The weighted f2 for all organs was less than 1 in all 8 animals dying or sacrificed in shock. These values ranged from 0.60 to 0.83, averaging 0.76. The lowest ratio occurred in the burned dog, the highest in the bled dog in early shock and the bled dog treated with bovine albumin. The values for the other 5 dogs were from 0.73 to 0.79.

Thus from ⅓ to ⅕ of the red cells contained in the minute vessels throughout the body were not in active measurable circulation. This phenomenon was widespread, occurred in all the organs analyzed, and was not confined to sites of traumatic injury. The lowest f2 ratios were found in the muscles of the burned dog and the animal subject to occlusion tourniquets.

Since the techniques employed measure only red cells and plasma in active circulation, the findings reflect the state of blood flow through the minute vessel beds of the organs. It is apparent that in these shocked animals, the blood flow through all of the organs was reduced by from 20 to 40 per cent.

Thus another characteristic of shock is that, *regardless of etiology, there is a widespread stagnation of red cells within the minute vessels of all of the organs in the body.* The degree of this stagnation may be such as to indicate *a reduction in blood flow through minute vessels to from 60 to 80 per cent of normal.*

In Table V are listed for Series II and III (as percentages of initial volumes), the net amount of cells, plasma and whole blood removed by hemorrhage and sampling; the expected and found volumes; and the quantity of red cells, both total and actively circulating, measured as being within the vessels of the organs analyzed. These minute vessel red cell quantities are also expressed as percentages of the expected cell volume, and these in turn, as percentages of the fraction of total red cell volume normally found in circulation in the minute vessels. (See Table I for average normal values.) The percentage of expected cells, plasma and whole blood volume found trapped in the

vascular bed (by gross volume measurements) and in the minute vessels (by tissue analyses) are also shown. Finally, the red cells, plasma and whole blood not accounted for by measured trapping within minute vessels, are expressed as percentages of both initial and expected volumes.

The plasma content of minute vessels was not determined in Series II.

Dog SA-2 experienced a negligible net loss of whole blood (a slight net gain in red cells), and the fraction of total red cells found in the minute vessels was almost normal, 93 per cent. Only 2 per cent of gross trapping of red cells was found, and all of the cells in the minute vessels were in active circulation.

In both the dogs that were severely bled (25–118 and 120), the found volume of cells and plasma was less than expected. The fraction of the expected total red cell volume, found as total cells in the minute vessels, was below normal to a degree about equal to the net red cell loss, but the fraction found in active circulation was far lower than the percentage of cells lost. In both animals the gross volume trapping was far greater than that measured by organ analysis.

Dog SA-3 succumbed to the toxin and was in deep shock. Net blood loss was little, but the found cell and plasma volume was much less than expected. The minute vessels contained only 85 and 66 per cent of the expected total and circulating cell volume. Only a fraction of the total trapping was found in the minute vessels. The gut contained a large quantity of bloody fluid at necropsy.

Dog 135–90 experienced moderate blood loss in addition to trauma, and again the found red cell and plasma volume was considerably lower than the expected. The reduction from normal in fraction of expected total cells in the minute vessels was greater than the percentage of initial red cell volume removed, and the reduction of circulating cells was even greater. Again, gross trapping far exceeded that measured by organ analysis. There was evidence of a large loss of red cells and plasma into the the ligated muscles at necropsy.

Thus, all 4 dogs in shock experienced a greater reduction in total circulating cell volume than could be accounted for by net blood loss. In addition the proportion of total cells, both expected and found, in the minute vessels was less than normal, and the proportion in active circulation considerably less than normal.

In dog 25–118, 21.0 per cent of the initial cell volume was unaccounted for, but only 1.3 per cent was accounted for by measured trapping in minute vessels. Since the tagged cells for final red cell volume were given with the animal in a dying state, they may not have become completely mixed, and the final total red cell volume calculation may therefore have been falsely low.

In Series III (Table III), dog 25–128, not in shock, showed no gross or minute vessel trapping of either cells or plasma, and the found volumes equalled the expected volumes, but the percentages of total and circulating cells and circulating plasma in the minute vessels were about 15 per cent below normal. There was slight gross trapping but none by organ analysis.

Dog 25–116, in early shock, showed reduction in red cell volume greater than accounted for by hemorrhage; and reductions in the normal fraction of total and circulating cells in minute vessels. Considerable plasma had been mobilized so that, although total whole blood volume was reduced, the fraction of whole blood in minute vessels was higher than normal. There was evidence of slight trapping in the minute vessels, and of 10 per cent gross trapping.

None of the other 3 dogs experienced any net blood loss. In the animal transfused, 25–129, the found blood volume was about equal to the expected; the quantity of total cells and of plasma in the minute vessels was above normal, and the quantity of circulating cells in minute vessels only slightly below normal. Five per cent of the initial cell volume was found trapped in the minute vessels, by tissue analysis, and 4 per cent by gross volume measurements. The quantity of trapped cells was 27 per cent of the total cells in the minute vessels. About 7 per cent of the expected plasma volume was unaccounted for.

Similar but more severe changes were found in the tourniquet dog (25–132). Found circulating cell volume was 90 per cent of expected; plasma volume, 42 per cent; and whole blood volume, 60 per cent of expected. The portion of total cells in the minute vessels was normal, but only 32 per cent of the normal fraction was in active circulation. The minute vessels contained only 63 per cent of the normal complement of circulating

plasma, and as a result only 74 per cent of the normal quantity of whole blood was flowing through the minute vessels. Five per cent of the initial cell volume and 56 and 38 per cent of the initial plasma and whole blood volume were unaccounted for.

Thus in only 2 of the above experiments (25–118 and 120) was the amount of trapped cells unaccounted for by organ analysis greater than could be explained by whole blood loss into damaged areas or intestinal hemorrhage.

The actual quantities of red cells trapped within the minute vessels is a very small fraction of both the expected and found red cell volumes. *These quantities of trapped red cells, however, represent a very large percentage of the total cells within the minute vessels.*

The quantity of all the cells and plasma in the body, as determined by gross plasma (dye) and circulating red cell (radio-iron) measurements; and of the cells and plasma in the minute vessels (by analyses of tissue samples for radioactive iron and radioactive iodine) were measured for dogs in Series III. The arithmetic difference between whole body and minute vessel blood may be termed "large vessel blood." These radioactivity data permit of calculating the hematocrits of (*1*) the blood in minute vessels of individual organs, and hence the average weighted hematocrit of all the blood in the minute vessels of the organ analyzed, (*2*) the hematocrit of all the blood in the body, and (*3*) the hematocrit of that portion of blood contained only in the large vessels. These values are shown in Table VI, in comparison with corresponding values found in 5 normal dogs. They serve to bring out another characteristic disturbance in the circulation in shock, illustrated in Figure 1. The upper left-hand figure represents the normal percentage, in terms of degrees, of total blood volume contained within the large and minute vessels, the hematocrit of the blood being indicated by the cross-hatched inner circles. The other figures represent the degree of change from the normal relationship in the 5 dogs in Series III. In each case the entire circle represents the *final* found total blood volume; the larger angular section, the percentage of whole blood in the larger vessels; and the smaller section, the percentage of whole blood in the minute vessels. The cross-hatched sections again represent the hematocrit of the blood in the 2 compartments. The black sections in the centers of the circles represent the percentage of total minute vessel cells trapped out of circulation. Thus the graphs portray changes in distribution of cells and plasma within the vascular bed.

Dog 25–128 was not in shock; the percentage of final total blood volume in the minute vessels was normal, and the hematocrit of that blood was

TABLE VI

Hematocrits of blood in right auricle, large vessels, the whole body, and minute vessels; and the ratio of these hematocrits to the auricular hematocrit

	Normal dogs											
	25–131		25–127		25–114		25–113		25–111		Average

only slightly elevated. The hematocrit of large vessel blood was definitely below normal. There was no trapping. Arterial hematocrit was 35.1.

Dog 25–116 was in early shock. The percentage of whole blood in the minute vessels was increased, the hematocrit of that blood was below normal, and there was slight trapping. The hematocrit of large vessel blood was subnormal, and the arterial hematocrit was 43.1.

Dog 25–129 died in shock after a large trans-

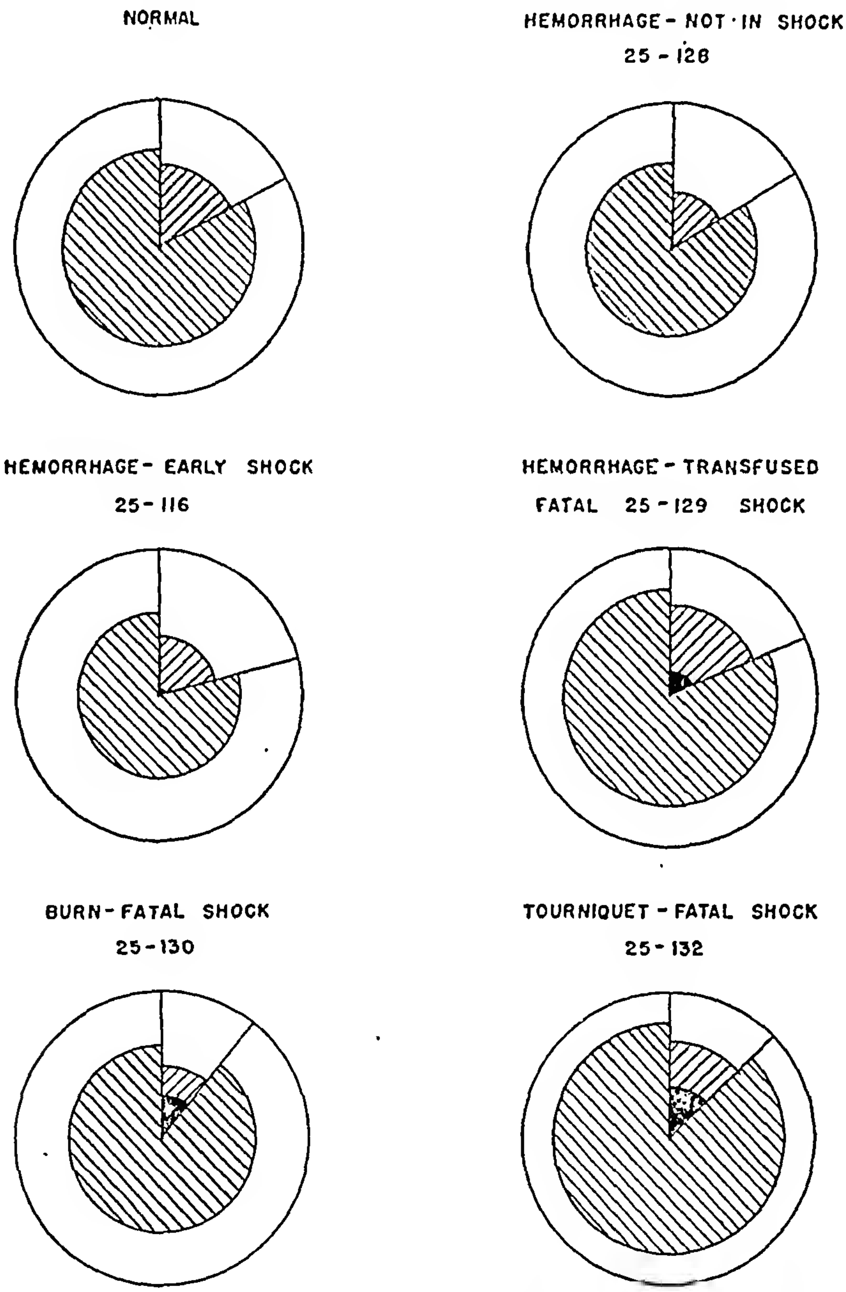

FIG. 1. REDISTRIBUTION OF CELLS AND PLASMA BETWEEN LARGE AND MINUTE VESSELS IN SHOCK

The whole circles represent the total whole blood volume as finally determined by dye plasma, radio-iodo-plasma, and radio-iron red cell volume measurements. The larger segments represent whole blood in all the large vessels; the smaller, whole blood in all the minute vessels. In both segments, the cross-hatched areas represent the red cell fraction of whole blood. The inner black segments represent the fraction of total cells trapped in all the minute vessels. For discussion of changes in the several types of shock, see text.

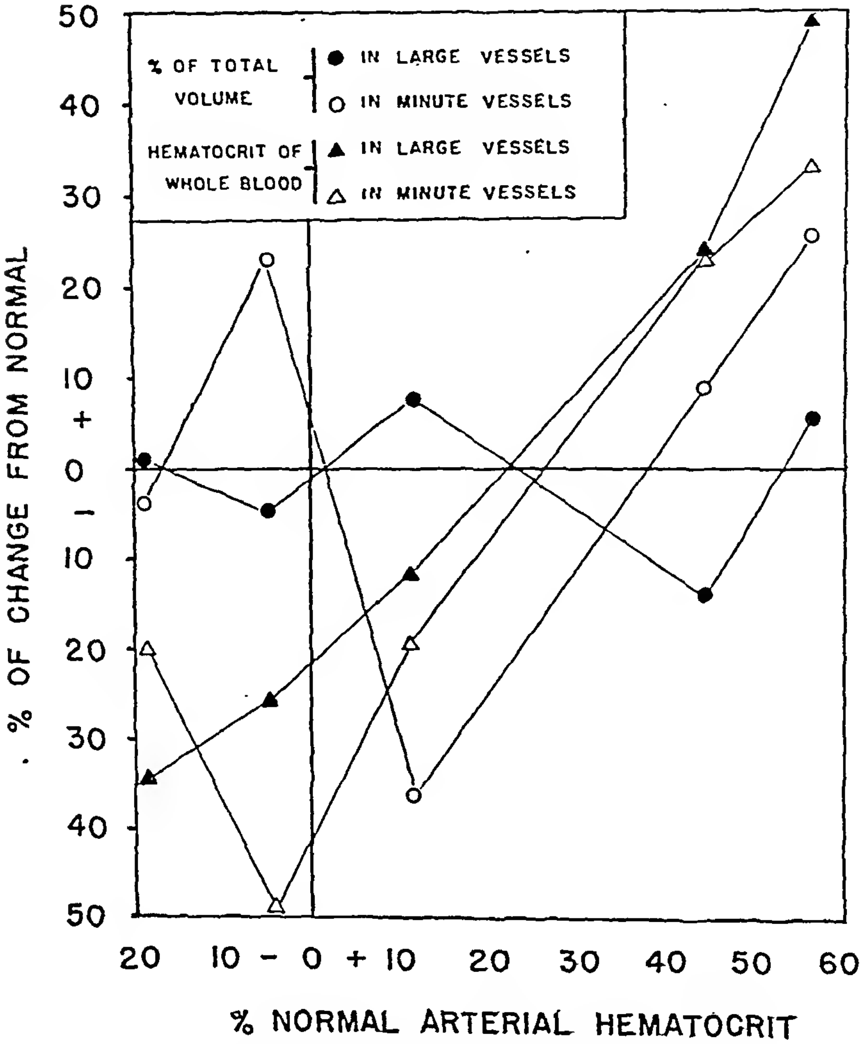

FIG. 2. REDISTRIBUTION OF BLOOD IN LARGE AND MINUTE VESSELS IN RELATION TO ARTERIAL HEMATOCRIT LEVEL IN SHOCK

The change from the normal proportion of whole blood in all the large and minute vessels in shock bears no relation to hemodilution or hemoconcentration. The change from the normal hematocrit of blood in both the large and minute vessels is related to arterial hematocrit level, the hematocrits being low in hemodilution (due here to hemorrhage) and rising progressively with increasing hemoconcentration (here due to plasma loss).

fusion. The percentage of total final blood volume in the minute vessels was well above normal, as was also the hematocrit, and extensive trapping occurred. The hematocrit of large vessel blood was considerably higher than normal. The arterial hematocrit was 62.5.

Dog 25–130 died in shock of severe burns. The minute vessel whole blood percentage was reduced, the hematocrit was normal, but 40 per cent of the cells were trapped. The large vessel hematocrit was normal and the arterial hematocrit was 48.4.

Finally, Dog 25–132 succumbed to tourniquet shock. The minute vessel whole blood percentage was reduced, the hematocrit of this blood was high, and there was considerable trapping. The large vessel hematocrit was extremely high, and the arterial hematocrit was 67.5.

Thus in the 4 animals in recognizable clinical shock *there was not only a reduction in total vol-*

ume, with varying degrees of trapping, but an abnormal distribution of whole blood between large and small vessels, and a resulting distortion of the hematocrit of large and minute vessel blood.

The graphs also emphasize the extremely small fraction of total red cell volume that need be trapped in minute vessels to bring about the reduction in capillary flow associated with irreversible shock.

The degree of abnormal distribution of blood and the distortion in large and minute vessel hematocrit are shown in relation to the level of arterial hematocrit in Figure 2, expressed as percentage deviation from average normal values. Fluctuations in either large or minute vessel whole blood content bore no relationship to arterial hematocrit level. There was, however, a definite direct linear relationship between arterial hematocrit and both large and small vessel hematocrits.

The degree of trapping found in the minute vessels of the organs analyzed did not appear to be related to the amount of external blood loss, as shown in Figure 3. The lowest ratio of circulating to total red cells was found in the burned dog which was bled only 14 per cent of its total volume; the highest, in an animal bled 48 per cent of its volume. The phenomenon is, however, apparently related to the fall in mean arterial pressure, as is also shown in Figure 3. Four dogs with ratios higher than 0.80 had a decline in mean arterial pressure of less than 30 mm. Hg. The remaining 6 dogs, with ratios lower than 0.80, experienced declines of greater than 65 mm. Hg in mean arterial pressure. It has been pointed out (38) that the blood pressure may be a misleading guide to the state of the animal when the blood viscosity is abnormally high due to a high hematocrit. In such event, the blood flow, as indicated by cardiac output, is very poor in spite of nearly normal blood pressure.

Thus, 2 observations appear to be of value in the clinical diagnosis of the presence of, and appraisal of, the severity of capillary trapping in shock: hemoconcentration and arterial hypotension.

It appears probable that while reduction in total volume may be the precipitating cause of peripheral vascular collapse, this simple oligemia alone does not bring about the changes usually classified as "irreversible." It seems far more probable that the reduced flow of whole blood through the nutrient capillaries of all the organs results in anoxia, and starvation of parenchymal cells. If sufficient in degree and duration, impairment of cellular function and eventually death are inevitable sequelae.

If this conception be true, then effective therapy should be directed not only at restoration of re-

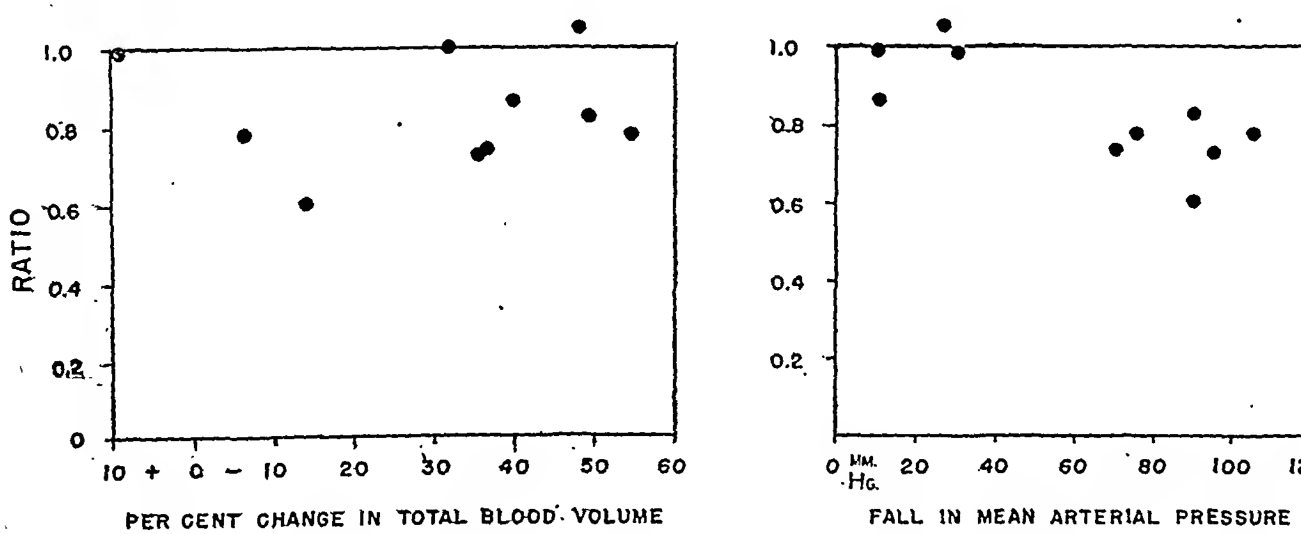

FIG. 3. THE RATIO OF CIRCULATING TO TOTAL RED CELLS IN MINUTE VESSELS IN RELATION TO REDUCTION IN TOTAL BLOOD VOLUME AND FALL IN MEAN ARTERIAL PRESSURE

Reduction in total blood volume alone does not appear to be a causative factor in bringing about trapping of red cells in minute vessels. The degree of trapping does, however, become increasingly severe with progressive fall in mean arterial pressure.

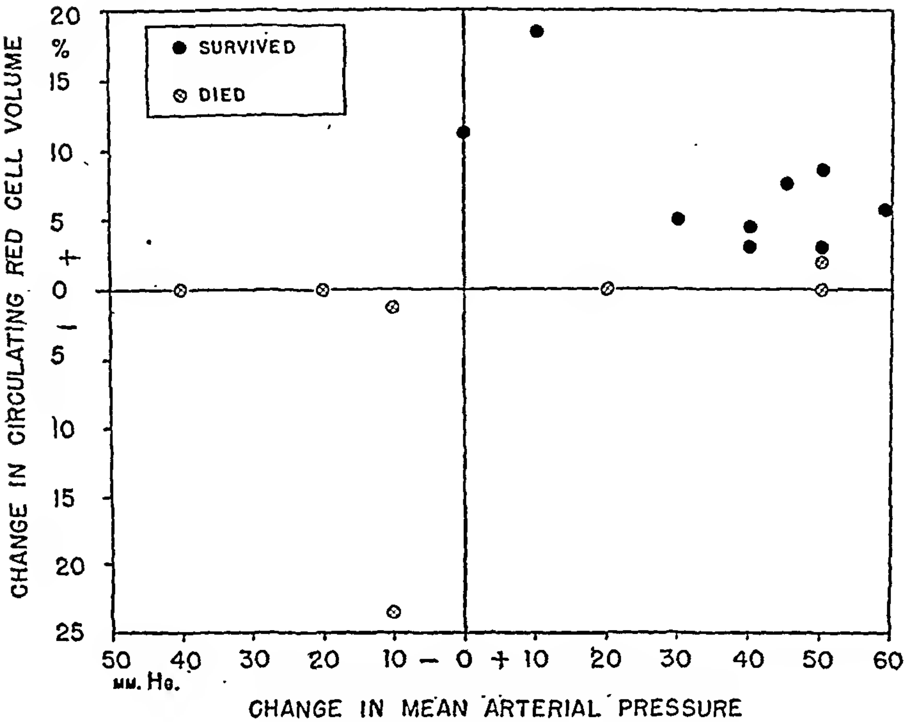

FIG. 4. CHANGE IN TOTAL CIRCULATING RED CELL VOLUME IN RELATION TO CHANGE IN MEAN ARTERIAL PRESSURE IN TOURNIQUET SHOCK AFTER ALBUMIN THERAPY

All of the 8 surviving dogs mobilized red cells, as evidenced by increases in circulating red cell volume, and 7 had sustained rises in mean arterial pressure. Slight increases in red cell volume occurred in only 2 of the 8 dogs that succumbed, although 4 had sustained rises in pressure.

duced total cell and plasma volume, but in restoration of *normal* flow through the entire vascular bed. Following the treatment of shock with protein solutions, there should be an increase, over shock levels, not only in plasma volume but in *circulating red cell volume* if therapy were to be considered successful.

Data obtained in Series IV are of interest. Most of the animals showed increases in mean arterial pressure immediately after the administration of albumin. These pressure rises were fairly well maintained in the survivors but were transient in those that died. There was no relationship between degree of fall in auricular hematocrit and the percentage change from expected circulating red cell volume. The fall in hematocrit in the dogs that died was as great as in the dogs that survived. The improvement in circulating red cell volume was however related to the change in mean arterial pressure. All of the 8 surviving dogs had increases in red cell volume. In 1 the pressure was unchanged but in the other 7, a rise of from 10 to 60 mm. Hg was sustained. Of the 8 dogs that died, 4 had increases in pressure of from 20 to 50 mm. Hg, and 4 had decreases of from 10 to 40 mm. Hg. Three dogs had elevations in pressure of 50 mm. Hg, accompanied by slight increases in red cell volume, but died.

Most of the survivors showed percentage increases in red cell volume that were within the limit of error of the technique of cell volume measurement used. However, the percentage increases are of the same order of magnitude as the percentages of red cells found trapped in minute vessels in Series II and III. The consistent finding of an augmented circulating cell volume after therapy in all the surviving animals is in keeping with the possibility that one effect of successful treatment was to restore the circulation through

the minute vessels to normal, with the resultant flushing back into circulation of trapped cells. Failure of this in the animals that died is of almost equal significance.

In a previous communication (26) it was noted that in the normal dog, the hematocrits of the blood in large vessels and in all the body are approximately equal, but less than the auricular and greater than the minute vessel hematocrits. It was stated above that the ratios of these hematocrits to the auricular hematocrit explained satisfactorily why the dye plasma hematocrit technique always gives a value of the red cell volume some 20 per cent higher than does the radio-iron technique.

In the shocked dogs, the ratios of the large and minute vessel hematocrit to the auricular hematocrit were changed, that of the large vessel hematocrit being 0.83, and that of the minute vessel hematocrit being 0.61.

In the 5 dogs in Series III, the percentage of total circulating whole blood in the minute vessels averaged 16 per cent. Then

$$\begin{aligned} 0.84 \times 0.83 &= 0.697 \\ 0.16 \times 0.61 &= \underline{0.097} \\ 0.794 &= \frac{\text{Vrr}}{\text{Vrpd}} \quad \text{or} \quad \frac{\text{Vrpd}}{\text{Vrr}} = 1.26. \end{aligned}$$

Since here again Vrpd is based on the plasma volume and auricular hematocrit, it follows that Vrr will be about 20 per cent lower than Vrpd. In other words, the red cell volume as measured by the dye technique will be about 26 per cent higher than by the radio-iron technique.

In a series of 28 simultaneous measurements of cell volume by both techniques in dogs in varying degrees of shock, in which auricular hemaocrits ranged from 19 to 69, averaging 43.7, the average ratio of $\frac{\text{Vrpd}}{\text{Vrr}}$ was found to be 1.32.

Thus, the former technique not only over-estimates circulating red cell volume in the normal state, but gives an even higher degree of error in peripheral vascular collapse, regardless of the presence of hemodilution or hemoconcentration.

COMMENT

These studies are in keeping with the findings of several authors on the circulatory changes in shock. The gross volume studies confirm the conclusions of Noble and Gregersen (22) that reduction in blood volume is due to loss of both cells and plasma: whole blood. In these controlled experiments the loss of whole blood was always more than the measured external blood loss. In certain types of insult (burns, tourniquet and toxins), some of this whole blood was undoubtedly lost in damaged areas or in the intestinal tract. The other site of whole blood "loss" lies within the capillary bed. Chambers *et al* (39) found cessation of blood flow in the capillaries in the mesentery of dogs in shock. The studies herein reported indicate that this phenomenon is not confined to sites of injury, or to abdominal viscera, but that it is a widespread phenomenon occurring in all organs throughout the body.

Since the methods of volume measurement used are dynamic, they reveal changes in total blood flow through capillary beds of all the organs. The net effect of trapping is a reduction of flow through vital areas. The resulting anoxia, failure in nutrition and waste disposal, if continued for long periods, is not compatible with the continued existence of certain parenchymal cells. For instance, it has been shown (37) that liver cells in dogs in hemorrhagic shock may be the earliest to show the effects of the reduced blood flow characteristic of peripheral vascular collapse.

Since the capillaries of organs normally contain less than $\frac{1}{5}$ of all the total circulating cells and plasma, the trapping of only $\frac{1}{20}$ of the total blood volume may bring about a reduction in flow to $\frac{1}{4}$ or $\frac{1}{3}$ of normal. Extensive trapping may be present in the absence of measurable hemoconcentration or hemodilution, or with a normal hematocrit.

Effective therapy should be directed not only towards restoration of total blood volume, but to the resumption of normal capillary flow. Objective evidence of effective therapy lies in the restoration and maintenance of normal hematocrit and normal arterial pressure.

CONCLUSIONS

1. Measurements of the total circulating red cell and plasma volume, and of the distribution of blood in large and minute vessels were made in dogs in experimental shock, by means of tech-

niques employing Evans blue, 2 isotopes of radioactive iron, and radioactive iodine. The following characteristics of the circulation in shock have been demonstrated.

2. There is always a greater reduction in circulating red cells and plasma than can be accounted for by measured external blood loss.

3. A part of this discrepancy in blood volume may be lost into damaged areas or by intestinal bleeding in certain types of shock.

4. Regardless of etiology, there is a widespread trapping of red cells within the minute vessels of all the organs in the body.

5. The effect of this trapping is a reduction in capillary blood flow through all organs.

6. Since the normal capillary blood content is less than 20 per cent of the total volume, the trapping of even a small portion thereof may result in a fatal reduction in capillary flow.

7. There is an abnormal distribution of whole blood between large and minute vessels which is not reflected by changes in the arterial hematocrit.

8. There are marked deviations from normal in the hematocrit of large and small vessel blood, and these are directly related to changes in the arterial hematocrit.

9. The degree of red cell trapping present does not parallel the reduction in total blood volume, but is related to the reduction in mean arterial pressure. However, this correlation between trapping and arterial pressure may not apply when the hematocrit is abnormally high.

10. The findings indicate that the therapy of shock should be directed not only towards restoration of total blood volume, but also towards the resumption and maintenance of normal capillary flow.

A STUDY OF THE RESIDUAL EFFECTS OF PHOSGENE POISONING IN HUMAN SUBJECTS. I. AFTER ACUTE EXPOSURE

BY MORTON GALDSTON,[1] JOHN A. LUETSCHER, JR., WARFIELD T. LONGCOPE, AND NICHOLAS L. BALLICH, WITH THE ASSISTANCE OF VIRGINIA L. KREMER, GILES L. FILLEY, AND JOHN L. HOPSON

(From the Clinical Research Section, Medical Division, Chemical Warfare Service, Edgewood Arsenal, Maryland, and The Department of Medicine, Johns Hopkins Hospital, Baltimore, Maryland[2]*)*

(Received for publication March 4, 1946)

INTRODUCTION

During World War I the British Chemical Warfare Medical Committee (1 to 8) recognized a distinctive syndrome which resulted most often from exposure to phosgene and which resembled in symptomatology the "Irritable Heart" or "Effort Syndrome." The patients presented scant physical evidence of structural disease of the lungs. Haldane and his co-workers emphasized that these symptoms were associated with rapid, shallow breathing (3). Although no measurements of the oxygen of the blood were reported, the cyanosis, polycythemia, and relief after inhalation of oxygen suggested that anoxemia was an important factor (2, 6). Furthermore, it was suggested that rapid, shallow breathing alone might produce anoxemia (5). Haldane, Meakins, and Priestley (5) state that "as soon as the exaggerated Hering-Breuer reflex has been produced by gassing or any other cause, the resulting slight anoxemia produces a general nervous upset in which various reflexes tend to be abnormal or exaggerated. The exaggeration of the Hering-Breuer reflex itself may thus be kept up and with it the anoxemia." The patients were treated with oxygen inhalation. They were encouraged to take gradually increasing exercise. The majority of patients improved, but a considerable number were unable to return to duty (1 to 8).

The British Ministry of Pensions maintained that serious structural after-effects did not occur, provided the lungs were healthy before gassing. Only a few casualties suffered from chronic bronchitic attacks (9, 10). On the other hand, numerous reports in the French and American literature have presented clinical evidence of residual damage to the lungs among phosgene and other types of chemical warfare casualties in the form of one or more of the following: chronic bronchitis, pulmonary emphysema, obliterative bronchiolitis, peribronchiolitis, bronchiectasis and suppuration of the lungs (11 to 18).

In spite of these valuable observations, there are too few objective measurements to indicate whether such patients have structural damage to the lungs, or simply a reflex or psychological disturbance. With the development of more precise methods for the evaluation of the ventilation of the lungs and the aeration of the blood, it is possible to study in greater detail these aspects in patients after exposure to phosgene. The cardiovascular system and the patients' psychological reactions also warrant more detailed study.

EXPERIMENTAL

Six patients, who are known to have been exposed to phosgene and who developed symptoms of acute poisoning, volunteered for the studies here reported.

METHODS

1. PULMONARY FUNCTION TESTS. These consisted of ventilatory function tests which are concerned with movement of air into and out of the lungs and respiratory function tests which are concerned with exchange of oxygen and carbon dioxide in the lungs.

A. Ventilatory function tests.

a. Lung volume measurements. Vital capacity, complementary air, tidal air, and reserve air were measured from graphic tracings of a spirometer. All volumes are expressed as gas saturated with water vapor at 37° C. and prevailing barometric pressure.

b. Mid-capacity (functional residual air). This was measured by the method of Darling, Cournand, and

[1] Captain, MC, A.U.S.

[2] Study carried out at the Johns Hopkins Hospital, Baltimore, Maryland, under a contract with the OEMcmr and a Medical Division, OC, CWS, Work Project Specification.

Richards (19). The mid-capacity minus the reserve air represents residual air.[3]

c. Respiratory dead space. This was calculated according to Bohr's formula (23). It included an instrumental dead space of 100 ml.

d. Intrapulmonary mixing of gases. This was studied by the method of Darling, Cournand, and Richards (24). The presentation of the mixing curves has been changed by reversing the axes of the semi-logarithmic scale. This changes the sigmoid curve used by Darling and his coworkers (24) to a much simpler form consisting chiefly of two straight lines, the falling line of nitrogen dilution and the final level reached when the only remaining nitrogen is that eliminated from the blood. This curve is easier to construct, only two points being needed to define its form. It has the additional advantage that all deviations from the predicted values are represented in proportion to their significance, regardless of the level of alveolar nitrogen.

e. Completeness of emptying of lung nitrogen. This was measured as described by Cournand *et al.* (20).

f. Rate and depth of respiration. These were measured in a recording spirometer at rest, during exercise, and on recovery from exercise.

g. Voluntary breathing capacity (maximum breathing capacity). This was measured according to Cournand and Richards (25). These investigators kindly sent us the formulae for prediction of maximum breathing capacity.

h. Breath-holding. This was performed in moderate inspiration. At the end, a sample of alveolar air was collected and analyzed for oxygen and carbon dioxide content. Observations were also made on the effect of hyperventilation, for one minute, and oxygen breathing for two or three minutes, singly or combined on the duration of breath-holding. A breath-holding time of less than 25–30 seconds when breathing room air was considered limited.

B. Respiratory function tests.

a. Oxygen content and capacity of arterial blood. These were each measured in 1 ml. of blood (26).

b. Tension of oxygen and carbon dioxide in arterial blood. These were measured according to the method of Riley (27). In most instances duplicate samples of blood were drawn a few minutes apart. The post exercise arterial blood samples were usually obtained at ½ to 1 minute and 3 to 5 minutes after exercise. Alveolar air was collected at the end of withdrawal of blood. At rest, the air was collected at the end of expiration; after exercise, at the height of inspiration. The range of oxygen tension values of arterial blood for each observation listed in the tables is in most instances based on three analyses, occasionally on two, four or five.[4]

c. pH, carbon dioxide content, and tension of plasma. Arterial blood was drawn anaerobically into a syringe wet with heparin. The pH determination was made at room temperature with a sealed glass electrode which was standardized empirically with plasma equilibrated at 37° C. with gas of known partial pressure of carbon dioxide. The carbon dioxide content of the plasma was measured (26) and its carbon dioxide tension was calculated from Peters' chart (31).

d. The oxygen extraction and carbon dioxide output per volume of air breathed at rest, during exercise and recovery. These were measured on expired air collected in a spirometer. At various times, a bicycle ergometer, a flight of steps, and single step (25) were used depending upon the degree of exercise desired. In the oxygen tension studies, exercise was continued for 30 seconds beyond the time the patient experienced marked shortness of breath. The rate, depth, and minute volume of respiration was recorded at the start of the exercise and during the last 30 seconds. Expired air was collected until the alveolar air sample was taken. The range of normal values for the step test (25) based on unpublished data was kindly sent to us by Drs. Cournand and Richards.

2. CIRCULATORY FUNCTION STUDIES.

a. Postural tests. The patient lay on a tilt table while observations of pulse and arterial blood pressure and recordings of rate and depth of breathing were made. When a steady base line had been established the patient was shifted from the horizontal to the 90° vertical position. When the circulation and breathing reached a constant level, the patient was returned to the horizontal position where similar observations were made.

b. Ballistocardiographic studies of cardiac output. These were performed by Dr. Giles F. Filley on an instrument designed by Dr. Dugald S. Brown (32) and calibrated to correspond with Starr's instrument. Calculations were based on the area formula (33).

[3] The published data on the per cent of the total lung volume comprised of residual air in normal individuals show a wide range of variation (20, 21, 22). Moreover there has been some variation in results with the same method in different laboratories (21, 22) (Figure 1). This may be due to the fact that the number of individuals studied in each age group has not been comparable. Furthermore, differences in method may lead to some divergence of results, particularly in instances of pulmonary disease (20). There are enough data with each method to reach a general idea of the mean and range, but not enough to be completely satisfactory. It is necessary, therefore, to withhold final judgment on borderline abnormalities until more data can be obtained on normal individuals of comparable age with the same technique as used on the patients in this study (Figure 1).

[4] In 21 comparisons performed in 17 healthy resting subjects, the alveolar air pO_2 range was 89 to 103 mm. Hg, average 99 mm. Hg and the arterial blood pO_2 range was 87 to 101 mm. Hg, average 98 mm. Hg. These agree essentially with similar studies recently reported (28, 29). In 11 comparisons in 9 healthy subjects, post exercise, the alveolar air pO_2 range was 98 to 118 mm. Hg, average 115 mm. Hg and the arterial blood pO_2 range was 92 to 114 mm. Hg, average 110 mm. Hg. The post-exercise studies were carried out in subjects who had volunteered for the studies at rest (30).

3. PSYCHIATRIC EXAMINATIONS.

These were performed in all 6 patients and in patients 2, 3, 4, 5, of the chronically exposed group (34) by Dr. Nicholas L. Ballich. The psychiatric summaries are presented in the Appendix.

4. OTHER STUDIES.

In all patients roentgenograms of the chest and electrocardiograms were taken. Blood counts, blood chemical studies, urine examinations, and other studies were performed as indicated.

RESULTS

The results are presented in detail in the Appendix and are summarized in Table I.

TABLE I

Summary of clinical observations and data on studies performed

* Listed in order of severity of exposure.
** Applies to all special studies except arterial blood and alveolar air oxygen and carbon dioxide tensions and cardiac output which were performed 4 to 8 months later. Symptoms, physical and roentgenographic findings were unchanged on re-examination of all available patients (All except 5) 4 to 8 months later.

DISCUSSION

This small group of patients presents symptoms very similar to those observed after phosgene poisoning in World War I (1 to 8). These symptoms are similar from patient to patient, but some individuals appear to suffer much more than others. The patients complained regularly of shortness of breath, tightness of the chest, and precordial pain at rest or after slight exertion. Cough was disturbing, particularly on exertion and at night, but only a little mucoid sputum was produced. Sleep was often disturbed by anxiety, terrifying dreams, dyspnea, and cough. Nausea, vomiting, and diarrhea were occasionally present. Several patients complained of nervousness and fatigue.

The most impressive feature of the physical examination was the rapid, generally shallow breathing, previously described by Haldane *et al.* (5). This pattern of respiration was present during sleep. Breathing was regular and not interrupted by sighs, which have been observed in respiratory neuroses (35, 36, 37). The patients with complaints looked anxious. The hands were often cold and clammy. Otherwise, the physical examination presented no significant abnormality.

There was no tendency to polycythemia such as was observed during World War I (2). The red blood cell count, hemoglobin, and hematocrit were within the normal range or slightly below normal. Arterial and venous pressures were normal. Roentgenograms of the chest did not exhibit any abnormality of the lungs or heart, except for a healed tuberculous focus in two patients.

The studies of pulmonary function revealed a number of borderline changes and frank abnormalities in lung volume, intrapulmonary mixing of gases, and transfer of oxygen to the arterial blood. Some abnormality was observed in every patient, but there was no consistent pattern and the severity of the changes could not be correlated with the patients' symptoms.

The most striking and consistent abnormalities brought out by these studies were concerned with the rapid and usually shallow pattern of respiration. This pattern was present both at rest and during exercise and was accompanied by a low extraction of oxygen and a low output of carbon dioxide per unit of air breathed. These abnormalities are closely related and have been described after phosgene poisoning (3, 5). In contrast to Haldane's findings (3), however, the unusual pattern of respiration was not altered by breathing pure oxygen, and could be voluntarily slowed and deepened to a normal level. The limitation of breath-holding to a few seconds, described by Haldane *et al.* (5), was not observed in our patients, who could generally hold a breath for a

normal time and who responded to hyperventilation or breathing oxygen with a prolongation of breath-holding time. Voluntary breathing capacity was significantly reduced in three of the six patients (cases 2, 3, 5). It is of interest that these three patients had a normal vital capacity.

The alveolar air oxygen tension was normal or high in this group of patients. Haldane and his co-workers (3) made a similar observation and remarked upon the paradox of a normal alveolar air and apparent anoxemia without obvious anatomical disease of the lungs. They postulated unequal ventilation during shallow breathing in which certain alveoli were poorly ventilated and contributed little to the alveolar air specimen, which came primarily from well-ventilated alveoli. This inefficient pulmonary ventilation resulted in anoxemia. Certain indirect evidence was brought forward to support this view (38). Some observations on our patients do not substantiate certain of Haldane's postulates.

Anoxemia was present in only one of the six patients (case 5). In this patient, intrapulmonary mixing of gases was normal as measured by the nitrogen dilution method. In one other patient (case 2) who did not exhibit anoxemia, a disturbance in the transfer of oxygen to arterial blood existed without demonstrably impaired intrapulmonary mixing of gases. It is therefore apparent that in our group of patients, anoxemia is infrequent and is not necessarily dependent on impaired mixing of gases in the lung. A well-marked defect of intrapulmonary mixing of gases was not associated with anoxemia, even with shallow breathing, in three patients chronically exposed to phosgene (34).

Electroencephalograms and conditioned reflex studies, designed to detect possible diffuse cortical damage resulting from anoxemia, showed minimal changes in the acute stage and essentially normal patterns when repeated several weeks later. On the basis of these tests, it was not possible to demonstrate any clear-cut, irreversible, organic involvement of the cerebral cortex.

Although the nitrogen-dilution method does not show a consistent abnormality of intrapulmonary mixing of gases during shallow breathing, a tendency toward impaired mixing during shallow breathing is apparent when all observations on patients exposed to phosgene are charted (Figure 2).

Exercise to the point of dyspnea, then maintained for a half minute, did not produce anoxemia in any patient and actually abolished the anoxemia in one patient (case 5).

Postural tests indicated that there was no instability of vascular control nor any accompanying respiratory change. The ballistocardiographic tracings indicated a subnormal cardiac output in one patient (case 2). No case showed the changes described by Starr in a large proportion of his cases of neurocirculatory asthenia (39).

The results of these studies demonstrate certain disturbances of pulmonary function which were not recognized on clinical examination. The changes were probably not serious enough to account for the disabling symptoms present in some of the patients. There was no obvious change in symptoms, physical findings, or roentgenograms for as long as a year and a half after exposure, but a detailed reexamination of the patients after a number of years would be necessary to decide whether the disease would recede or progress.

The correlation of the psychiatric abnormalities with the severity of symptoms was quite obvious. The timid and apprehensive patients developed disabling hypochondriacal and anxiety reactions. Pre-existing maladjustments and insecurity helped to perpetuate the symptoms. Socio-economic factors and previous personality trends were outstandingly important. Visible emotional support in the form of substantial personal contacts tended to stabilize the patient's reactions. Hospitalization and sympathy resulted in minimal improvement of symptoms and an increasing tendency toward chronic invalidism. Although compensation was rarely mentioned, the potential financial and psychological gains of invalidism loomed large to the insecure patients.

Three important points may be drawn from these data. Definite abnormalities in pulmonary function may persist for at least a year after exposure to phosgene. A characteristic change in the pattern of breathing accompanies these changes in the lungs. Symptoms are quite uniform in type, but the severity of symptoms and the ensuing disability are much more closely related to the patient's psychological reactions than to any demonstrable physical or physiological abnormality.

The disturbances in pulmonary function are almost certainly a reflection of organic changes in the lungs as a result of exposure to phosgene. The disturbances are generally suggestive of damage to the bronchioles and surrounding parenchyma as seen in beginning pulmonary emphysema.

The rapid, shallow breathing is probably also a consequence of pulmonary injury. This is perhaps due to a disturbance in the nerve-endings concerned with the stretch reflex of the lungs (Hering-Breuer). The same pattern of breathing occurs in men chronically exposed to phosgene (34). The persistence of this pattern of breathing during sleep and its occurrence in patients without complaints point strongly to a physiologic rather than a neurotic basis. Furthermore, the graphic respiratory records of our patients after recovery from phosgene poisoning show none of the features of a respiratory neurosis (35, 36, 37). The results of our studies also indicate that anoxemia is not necessarily a consequence of shallow breathing and is not an essential factor for its persistence as suggested by Haldane and his co-workers (5).

Disability in the group of patients is apparently caused by symptoms rather than by any serious inability of the lungs or cardiovascular system to perform adequately. There is a large neurotic component in the symptoms of the disabled patients. Mild symptoms referable to the lungs occur, however, even in stable individuals who have returned to full activity after exposure to phosgene. Even in the absence of serious injury to the lungs, the conscious or unconscious awareness of a disturbance in the pattern of breathing may be responsible for these complaints. In the patients with a suitable psychological predisposition, many of the neurotic complaints are focused on the pulmonary symptoms, which are magnified and extended to the point of complete disability, since the patients are unwilling to attempt any activity for fear of precipitating the very disturbing and even terrifying symptoms. The symptoms in such patients may be partly those of an anxiety neurosis, but still resemble closely the symptoms produced by exposure to phosgene.

Sudden grave exposure to phosgene obviously resulted in great psychic trauma and was very demoralizing. It led to a considerable degree of personality disorganization and to the exaggeration of latent neurotic trends, brought out by this personal stress, which also highlighted socio-economic factors. As the acute anxiety subsided with understanding interviewing and management, there was a shift of emphasis from concern about the physiological manifestations of anxiety to personal issues and themes in the lives of these patients. It may be said that this transition, when accomplished, was of considerable therapeutic value.

CONCLUSIONS

1. Objective studies of pulmonary function have been carried out in six patients from 3 to 14 months after exposure to phosgene, which in 4 patients resulted in acute pulmonary edema and emphysema.

2. After 3 weeks following exposure, physical examinations and roentgenograms revealed no definite evidence of disease of the lungs, but the patients complained of symptoms like those reported in phosgene casualities during World War I.

3. The rapid, shallow breathing, described by Haldane, Meakins, and Priestley, was regularly observed but was not associated with a disturbance of intrapulmonary mixing of gases sufficient to lead to anoxemia.

4. Breathing oxygen did not alter the pattern of respiration and did not afford consistent relief of symptoms.

5. Objective changes of pulmonary function were consistently observed but varied in type and severity, and could not be correlated with the seriousness of initial injury or chronic symptoms.

6. The severity of chronic symptoms and the associated disability were closely related to the patients' psychological reactions.

7. A possible explanation of these observations would be that the injury initiated changes in the lungs and a uniform pattern of symptoms, which in certain individuals were sufficiently disturbing to produce disability.

APPENDIX

Clinical summaries and data on pulmonary and circulatory function studies. Case histories of patients 1 through 6 are given below. The clinical course and laboratory findings of cases 1, 2,

3, 4 and 5 are summarized in Figures 1A through 5A.

The results of the pulmonary function studies on each patient are presented in Figures 1B, 1C, 1D through 5C, 6A, 6B and in Tables IA, IB through IVB, VA, VB, VC through VIC.

The number of each figure and table corresponds to the case number listed in Table I.

Legends for figures on intrapulmonary mixing of gases. The data on each patient are presented in two ways (see Methods).

(a) Figures 1C, 2C, 3C, 4C, 5B, 6A. These figures present the difference between predicted nitrogen concentrations and observed nitrogen concentrations, and between predicted nitrogen concentrations and calculated nitrogen concentrations for each number of breaths. The ordinates represent differences in nitrogen concentration

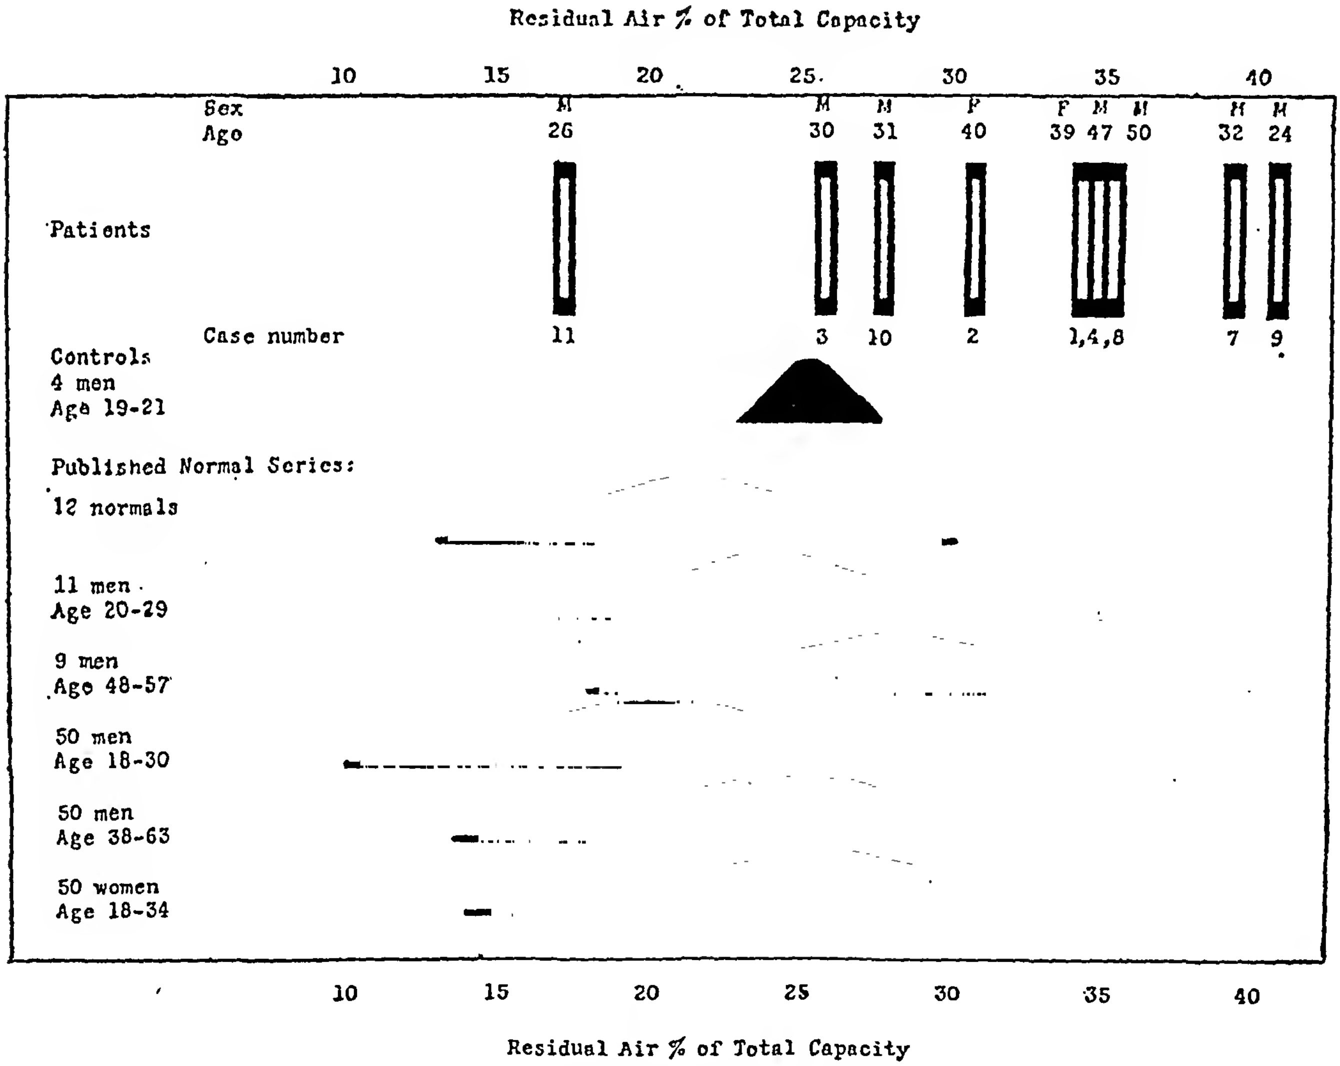

FIG. 1. RESIDUAL AIR AS PER CENT OF TOTAL LUNG CAPACITY IN PATIENTS EXPOSED TO PHOSGENE AND IN NORMAL MEN AND WOMEN

Each block at the top of the chart represents a patient exposed to phosgene. The number under each block designates the patient as referred to in the case history, with the exception that numbers 7, 8, 9, 10, 11 refer to cases 1, 2, 3, 4, 5 in the group of patients with chronic exposure to phosgene (34).

In descending order are curves which represent the mean and range of variation observed in different laboratories: 4 men, 19–21 years, present study, open circuit method of Darling *et al* (19); 12 normals, age not specified, open circuit method of Darling *et al,* by Cournand *et al* (20); 11 men (20–29 years) and 9 men (48–57 years), modified Christie method (closed circuit), by Robinson (23); last three curves, modified Christie method (closed circuit), by Kaltreider *et al* (21).

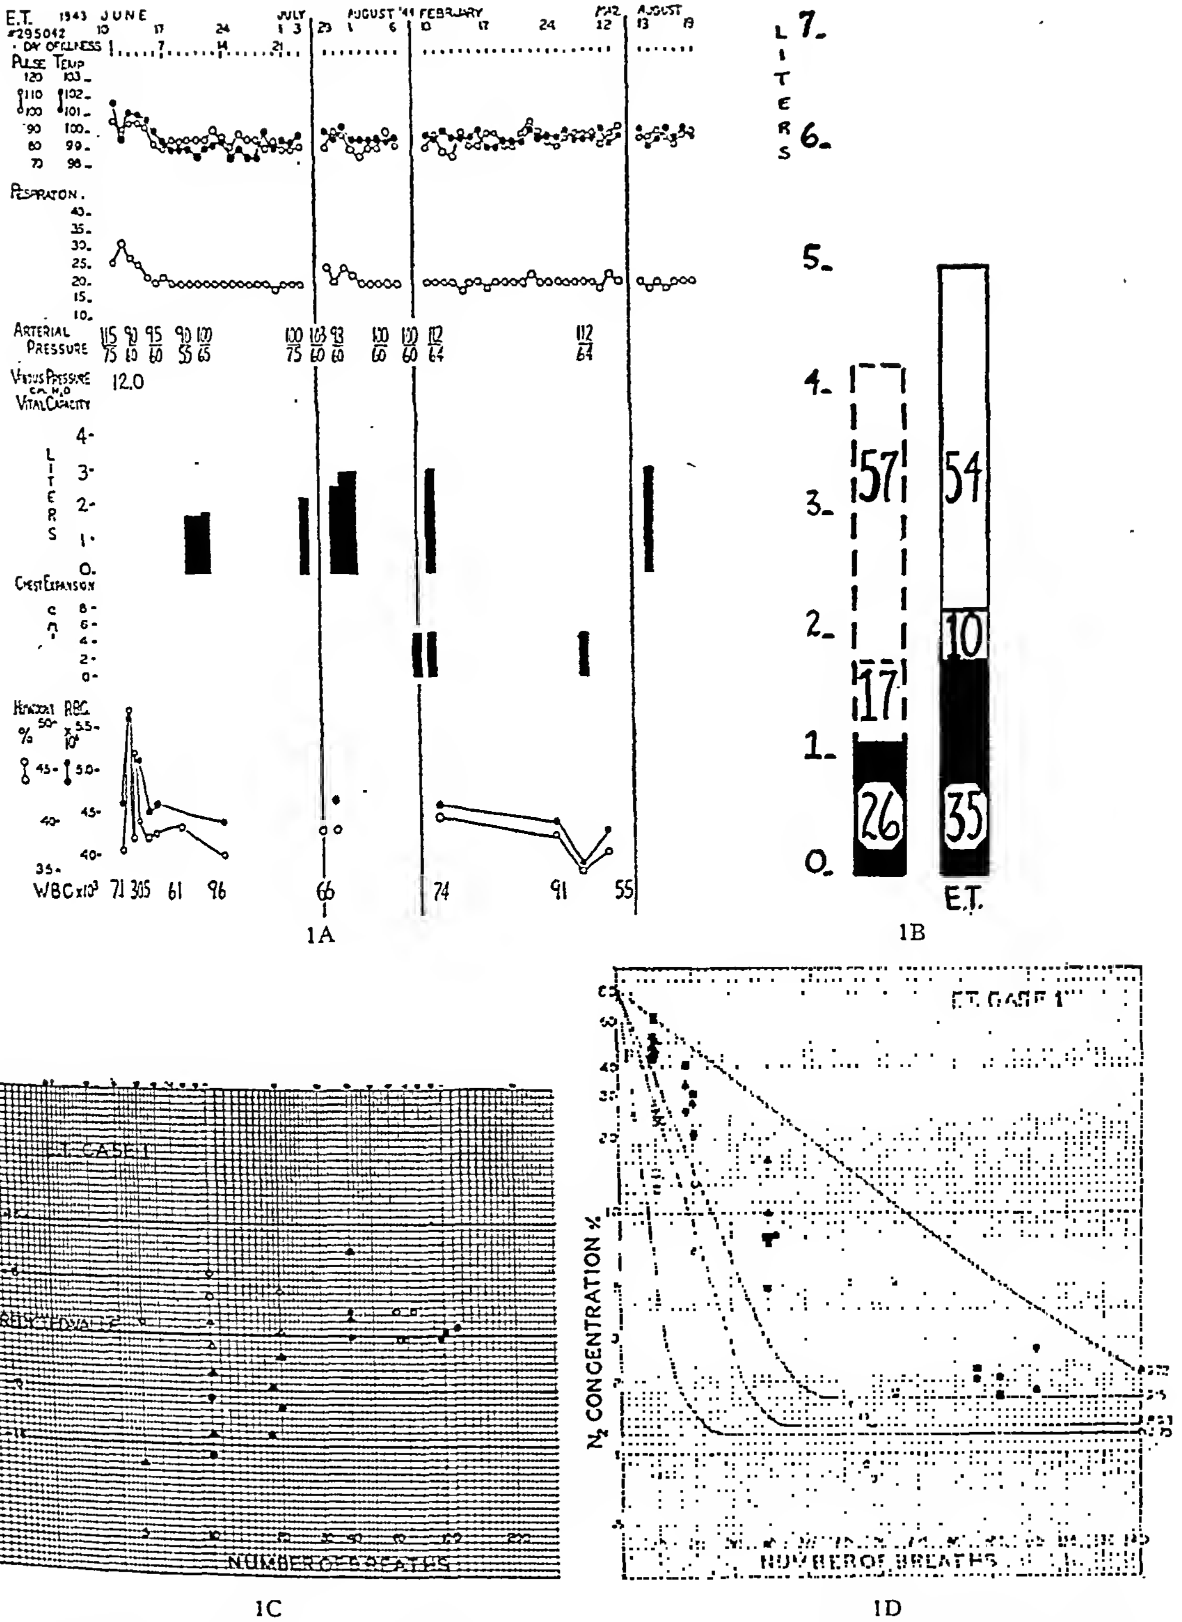

FIG. 1A. CLINICAL COURSE; 1B. SUBDIVISIONS OF LUNG VOLUME; 1C AND 1D. INTRAPULMONARY MIXING OF GASES—TIDAL AIR: 220–440 ml. generally 325 ml.) voluntarily deepened: 480–810 ml. (generally 600 ml.). DEAD SPACE: 182 ml. (Tidal Air below 400 ml.), 224 ml. (Tidal Air above 400 ml.).

from the predicted value which is represented by the line passing through the zero point. The abscissae represent the number of breaths.

Solid circle ● = observed alveolar nitrogen − predicted nitrogen concentration.

Solid triangle ▲ = calculated nitrogen − predicted nitrogen concentration. Open circle ○ and open triangle △ represent similar nitrogen concentration differences during voluntary deep breathing.[5]

[5] Comparisons between predicted, observed, and calculated levels of nitrogen remaining in the lungs after a measured number of breaths of 100 per cent oxygen may be made. Predicted nitrogen concentration is the level which would exist in the alveolar air in the presence of theoretically perfect intrapulmonary mixing of gases. This is based on the formula derived by Darling *et al.*

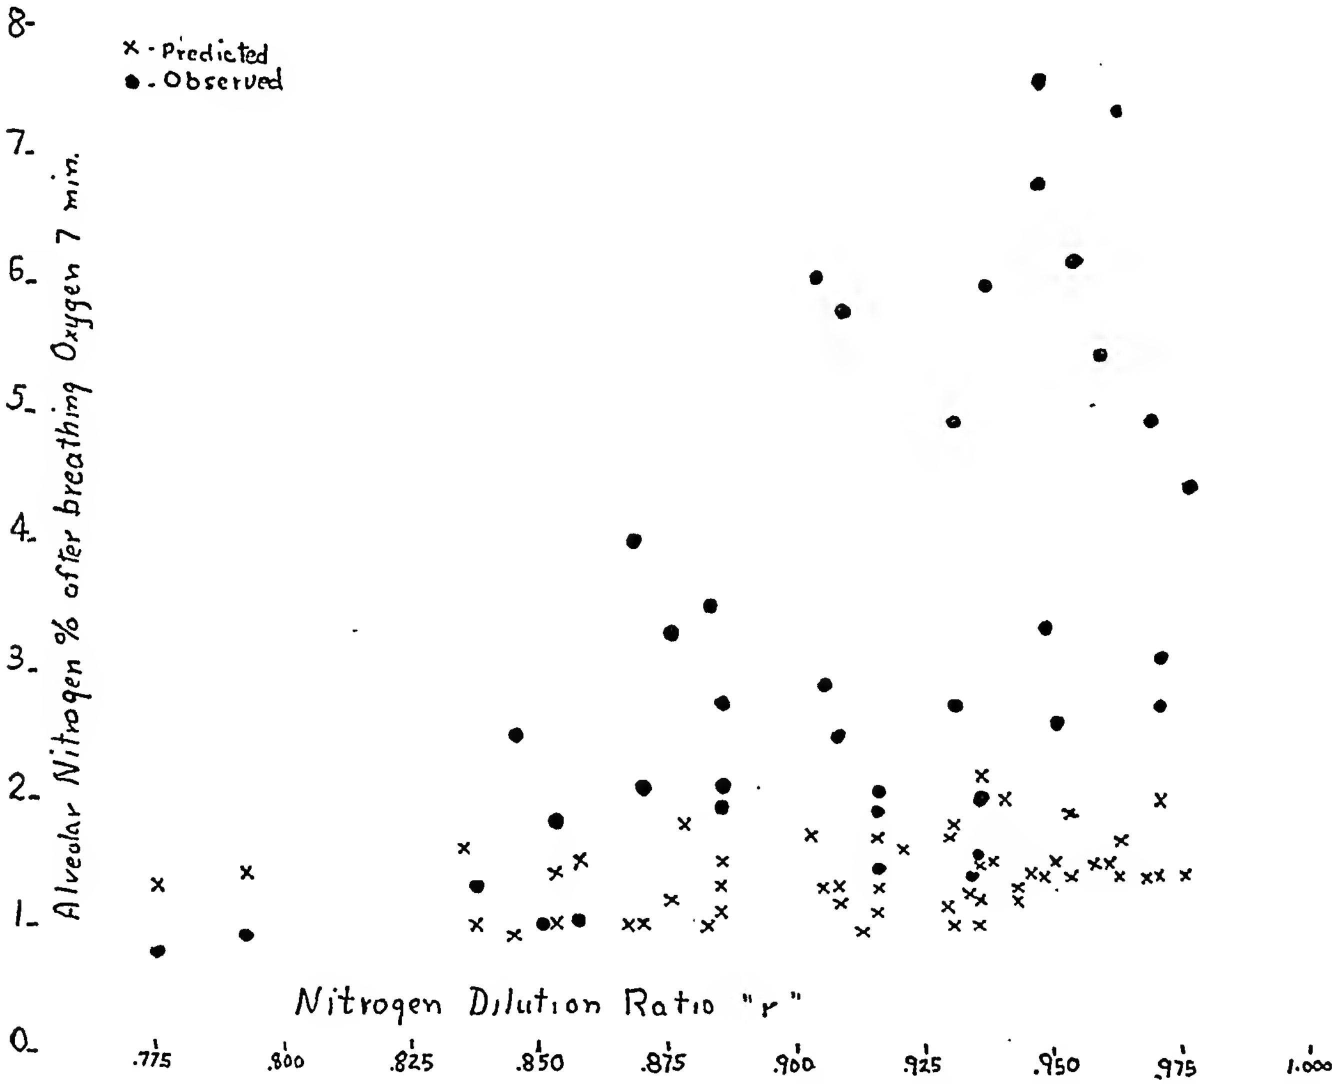

FIG. 2. THE NITROGEN CONCENTRATION OF ALVEOLAR AIR AFTER SEVEN MINUTES OF BREATHING OXYGEN,[6] PLOTTED AGAINST THE RATIO OF DILUTION OF FUNCTIONAL RESIDUAL AIR WITH EACH BREATH ("r") IN PATIENTS EXPOSED TO PHOSGENE

The observed values are indicated by solid circles and the predicted values by crosses. During shallow breathing (large "r"), there are more frequent and larger deviations from the predicted concentration than during deep breathing. This figure includes observations on the patients who had been acutely exposed to phosgene and also on the patients who had been chronically exposed to phosgene (34).

[6] The concentration of alveolar air nitrogen after 7 minutes of breathing oxygen is another index of effectiveness of intrapulmonary mixing of gases. 2.5 volumes per cent is considered the upper limit of normal in the presence of a normal tidal air volume (20).

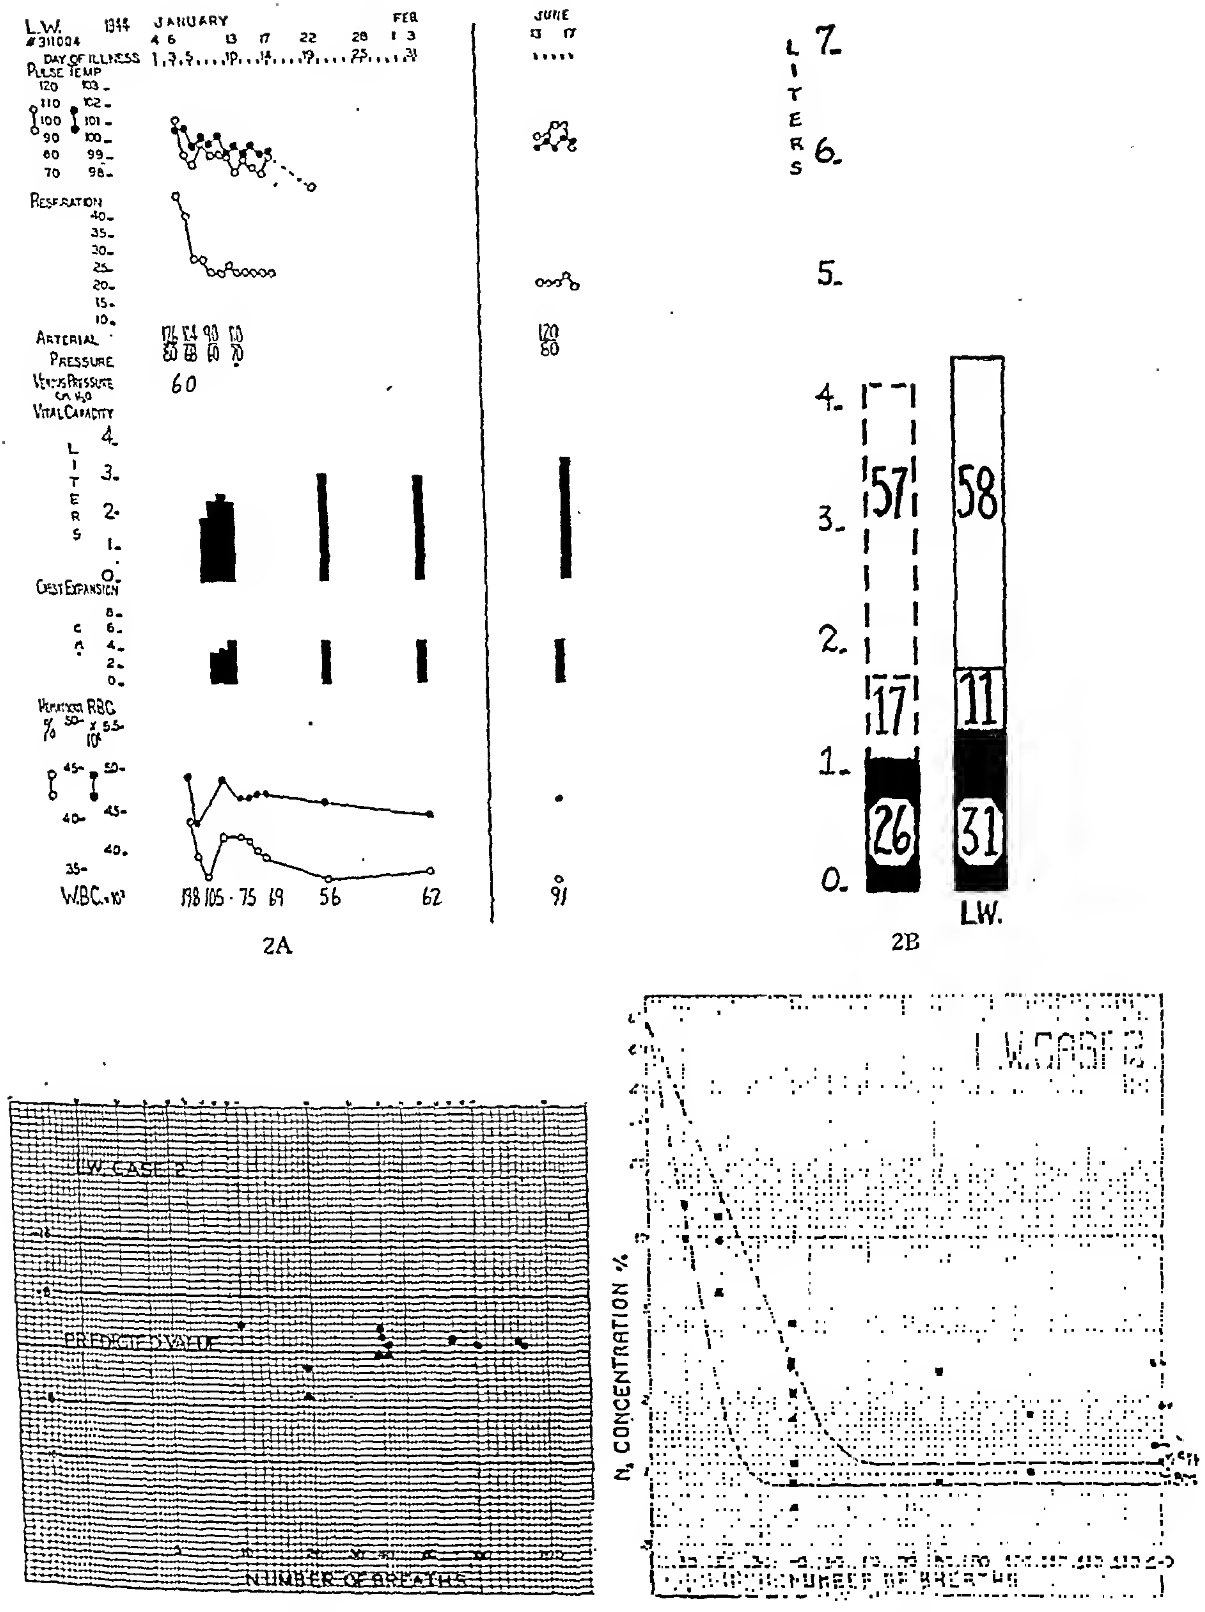

FIG. 2A. CLINICAL COURSE; 2B. SUBDIVISIONS OF LUNG VOLUME; 2C AND 2D. INTRAPULMONARY MIXING OF GASES—TIDAL AIR: 403–610 ml. (generally 475 ml.). DEAD SPACE: 227 ml.

When there is a disturbance in mixing, elimination of nitrogen from the lungs will be delayed, and calculated and observed alveolar nitrogen concentrations should exceed predicted alveolar nitrogen concentration. If there are large areas in the lungs where mixing is very poor and which contribute little or not at all to the alveolar air specimen, the calculated alveolar air nitrogen value should be greatly increased and the observed value may agree closely with the predicted value. Deviations of about 8 per cent or more in the above directions are considered indications of impaired intrapulmonary mixing of gases.

(b) Figures 1D, 2D, 3D, 4D, 5C, 6B. In these figures, the curves represent the range of values of the observed dilution ratios, *r*. When there are four curves on a figure, the two with the lowest *r* values represent the range during voluntary deep breathing; the other two, during normal quiet breathing.

Solid squares ■ represent predicted nitrogen concentrations; solid circles ●, observed nitrogen concentrations; and solid triangles ▲, calculated nitrogen concentrations. The open circles ○, squares □, and triangles △ represent similar ni-

(24) which includes the following factors: effective tidal air (tidal air minus respiratory dead space), functional residual air, amount of nitrogen released from the blood during the experiment, and number of breaths. Observed nitrogen concentration is the level obtained by analysis of an end-expiratory alveolar air sample. Calculated nitrogen concentration is the level which remains in the lungs. This is arrived at by subtracting the nitrogen in the expired air from the nitrogen in the functional residual air. The volume of nitrogen released from the blood during the measured number of breaths is taken into account.

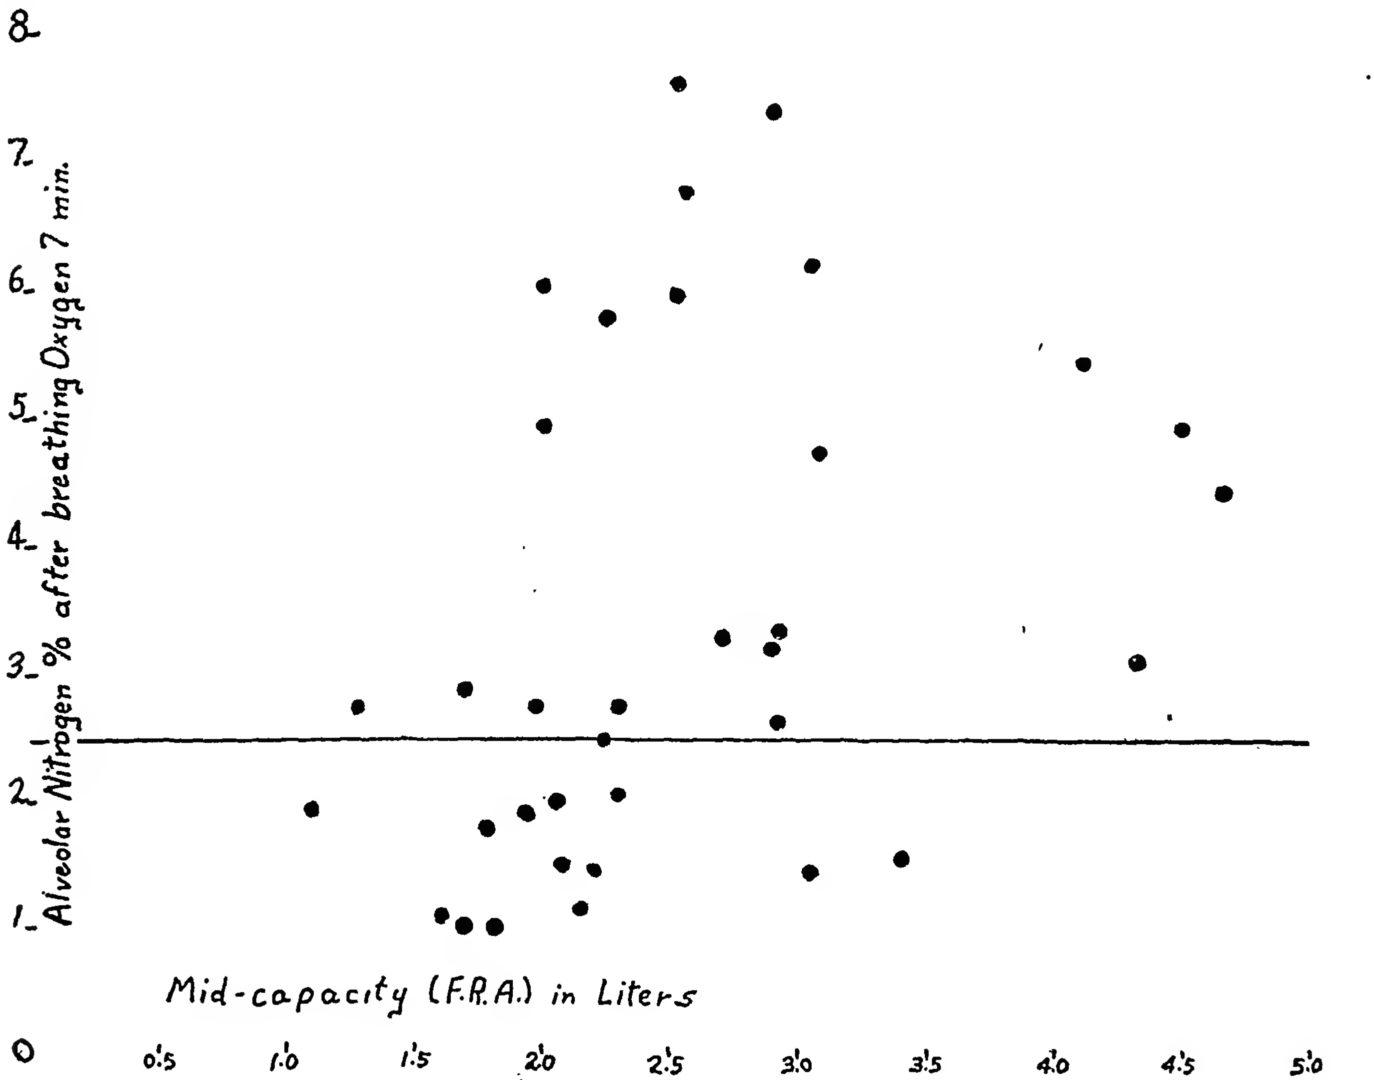

FIG. 3.

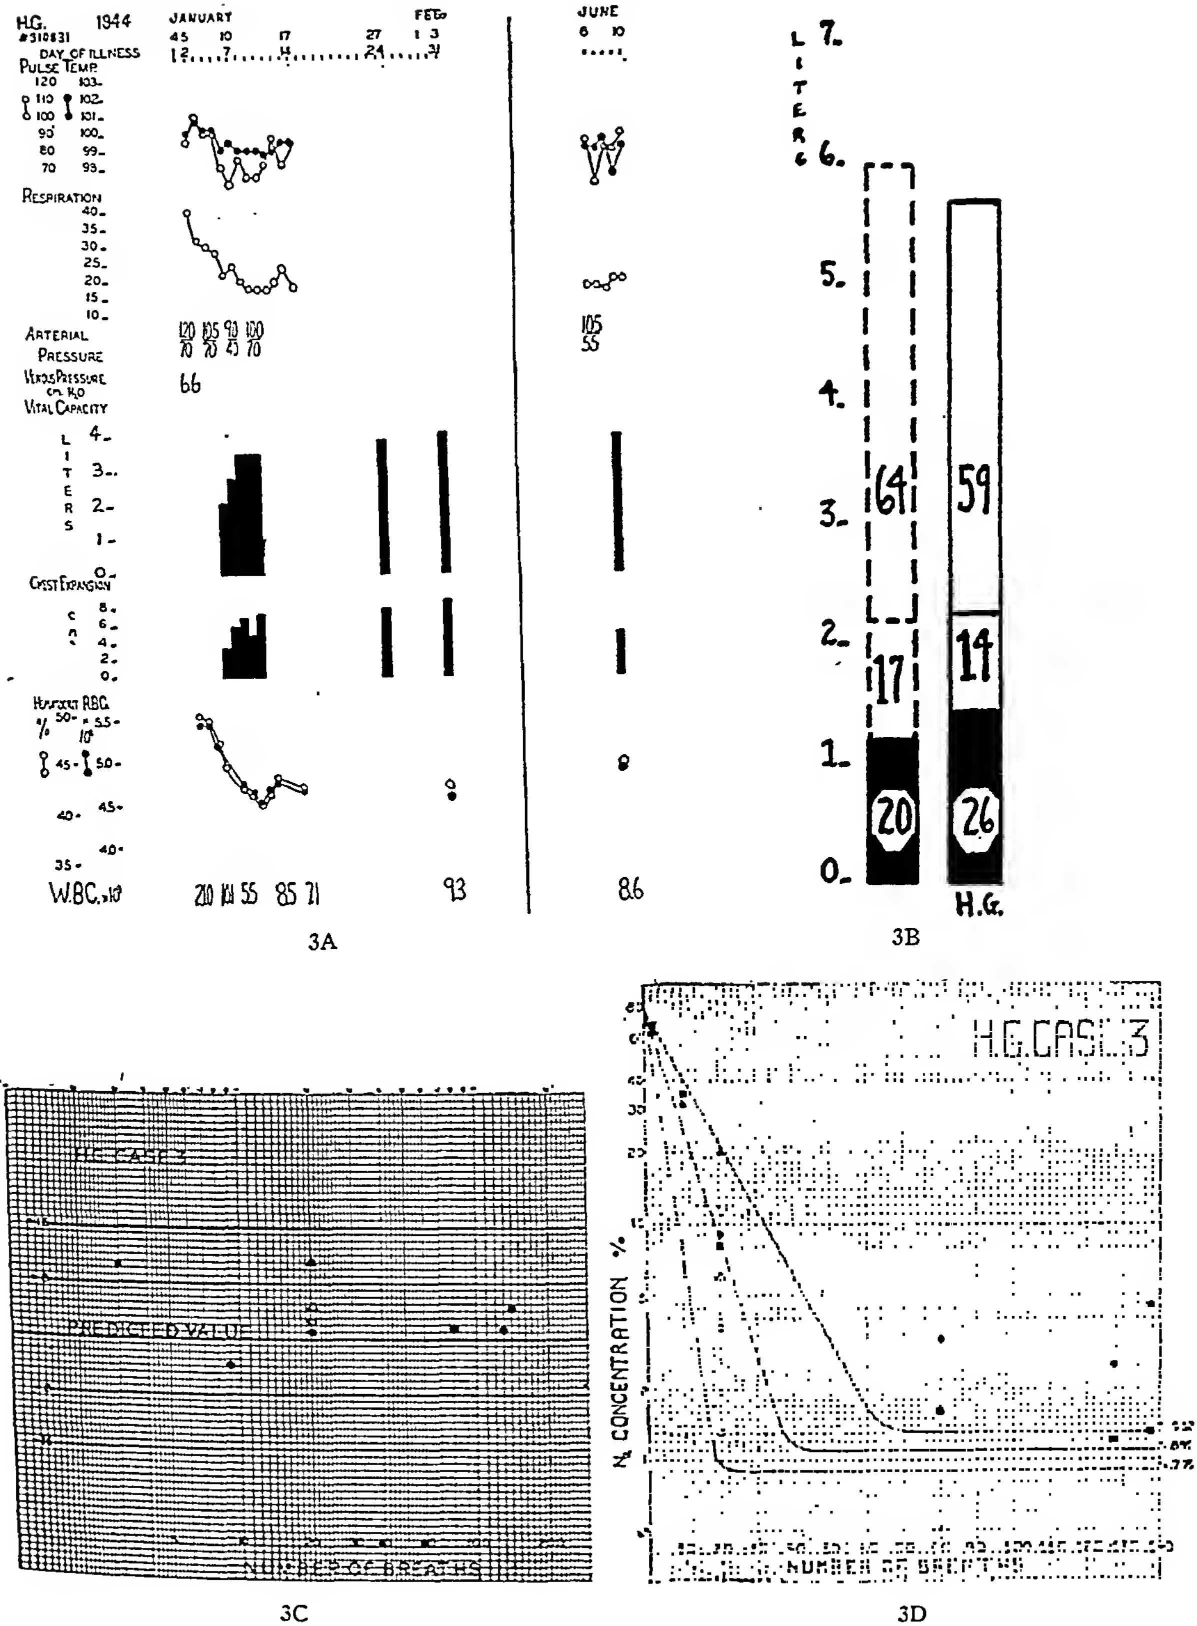

FIG. 3A. CLINICAL COURSE; 3B. SUBDIVISIONS OF LUNG VOLUME; 3C AND 3D. INTRAPULMONARY MIXING OF GASES—TIDAL AIR: 386 ml.–510 ml. (generally 400 ml.), voluntarily deepened 910 ml. DEAD SPACE: 220 ml.

trogen concentrations during voluntary deep breathing. $r =$ with a number following it, at the lower right end of each curve, represents the dilution ratio.[7]

The nitrogen concentrations marked by an arrow represent values for numbers of breaths greater than 140.

Legend for figures on subdivisions of lung volume (Figures 1B, 2B, 3B, 4B). The values obtained for each patient are compared with the normal values of Kaltrieder *et al* for individuals of the same age and sex (21) expressed in absolute volumes.

The column with initials below it represents the observed total lung volume for each patient. The column drawn in broken lines represents the predicted values for the individual (21). Each column is divided into segments which represent the per cent of the total lung volume which each subdivision comprises. The white area indicates the residual air, and the black area above it, the vital capacity. The lower segment of the vital capacity indicates the reserve air; the upper segment, the complementary air.

Legends for tables IA through VIC. In the tables dealing with exercise studies, work is expressed both as foot pounds (ft.–lb.) and kilogram meters (kgm.–m.).

In the tables dealing with arterial blood oxygen tension studies the values in parentheses under arterial blood oxygen tension represent the range of generally three, occasionally two, four, or five determinations by the direct method on the same sample of blood. The value preceding the parentheses is the average of these determinations.

Carbon dioxide tension mm. Hg arterial blood direct indicates the level of carbon dioxide tension in millimeters of mercury by the direct method (27).

Case 1 (E. T., Female, Age 38, Record No. 295042). Height 160 cm., Weight 46.3 kgm., Surface Area 1.44 M².

The patient had been working in the phosgene plant for about six months when her face was accidentally sprayed with liquid phosgene at about 10:15 a.m., June 11, 1943. Within a few hours she had developed signs of bilateral pulmonary edema and acute emphysema (Figure 1A). She was treated with oxygen inhalation under atmospheric and also positive expiratory pressure. By the third day, June 13, she had definitely improved. On the fourth day, June 14, a roentgenogram of the lungs still exhibited diffuse mottling throughout both upper lobes and the right lower lobe. On the seventh day, June 17, the lungs were clear on physical examination and a roentgenogram of the lungs appeared normal on the twelfth day, June 22.

Convalescence was complicated by complaints of aching pain in the left chest and shortness of breath on walking a few steps. In spite of these symptoms her physical condition improved and she was discharged to her home on July 3, 22 days after the accident.

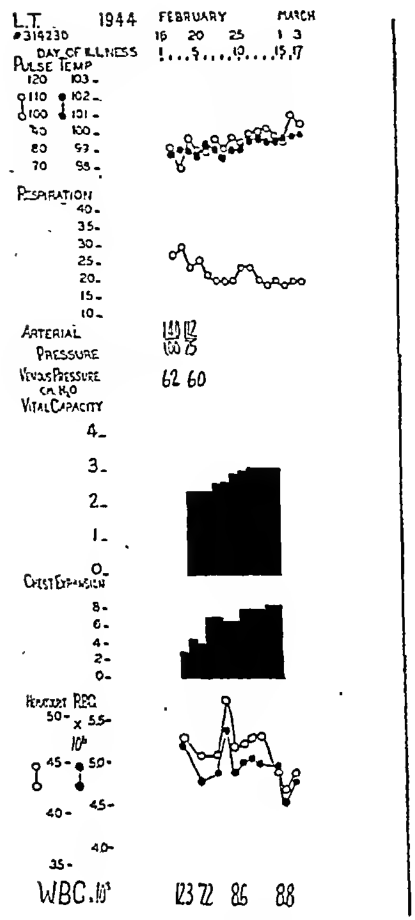
COURSE FOLLOWING FIRST ADMISSION TO THE HOSPITAL: During the nineteen months since the patient inhaled phosgene she has entered the hospital for observation on four occasions (Figure 1A).

She has complained of tiredness, weakness, marked shortness of breath, and palpitation on climbing one flight of steps, accompanied by sensation of a tight band around the lower part of the chest, weakness of the left side of the body with hyperesthesia and hyperalgesia, nervousness when amongst people, and nightmares. There has frequently been noted tenderness of the trapezius, pectoral, biceps and shoulder muscles, and over the cardiac impulse. Tolerance for moderate exercise has improved with practice. The lungs have been clear in serial teleoroentgenogram though increased aeration of the lower ⅓ of the lung fields has appeared to develop.

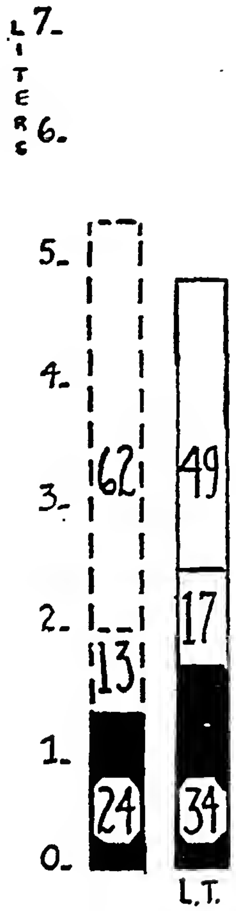
PSYCHIATRIC SUMMARY: E. T. is a rather timid, insecure, apprehensive, and not too well adjusted married white woman, who, following exposure and a rather critically sick period, developed persistent bodily aches and pains, weakness, tiredness, and palpitation, which may well have a substantial basis physically. She does have, though, a definite neurotic background, which is highlighted by interpersonal conflicts involving especially a very difficult relationship with her husband. Their sexual adjustment is quite unsatisfactory, the family relationships are not too good, and the patient finds herself annoyed and irritated by the activities of her children. Since the accident she has found it impossible to continue with her regular program of activity, she has been unable to resume work, and there has been a definite tendency toward the development of a chronic invalid reaction, which might be characterized clinically as a psychoneurosis— an anxiety state with hypochondriacal and neurasthenic features. The emotional factors have continued to assume increasing importance, and, though not recognized consciously by the patient, compensation issues are significant.

PULMONARY FUNCTION STUDIES: The ratio of residual air to total capacity is close to the upper limit of normal variation. The absolute volume of vital capacity is normal, but, because of the high residual air, the ratio of vital capacity to total capacity is reduced to the lower range of normal variation (Figure 1B).

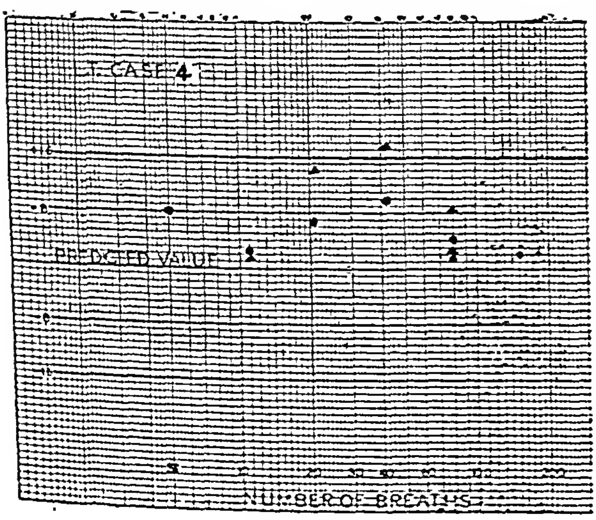
[7] The dilution ratio, r, represents the rate of dilution of nitrogen in the functional residual air per effective breath (tidal air minus respiratory dead space) of 100 per cent oxygen.



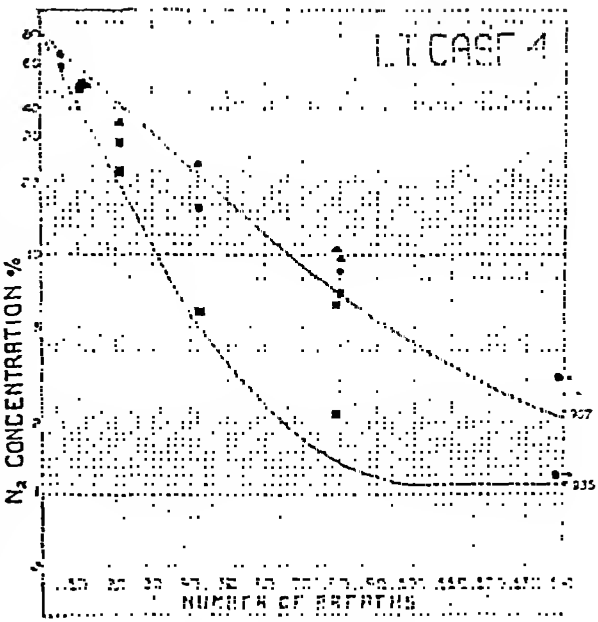
4A



4B



4C



4D

Fig. 4A. Clinical Course; 4B. Subdivisions of Lung Volume; 4C and 4D. Intrapulmonary Mixing of Gases—Tidal Air: 356–457 ml. (generally 425 ml.). Dead Space: 280 ml.

Respiratory rate and depth at rest are normal. The pattern of respiration is not altered by breathing oxygen. The minute respiratory volume during exercise increases primarily by an increase in the depth of tidal air. The alveolar air oxygen and carbon dioxide tensions are normal except for a high carbon dioxide tension occasionally (Table IA).

The nitrogen dilution rate is slow. The intrapulmonary mixing of gases is not impaired. The pulmonary emptying rate is normal (Figures 1C, 1D).

The oxygen extraction per volume of air breathed at rest is at the lower limit of normal. It rises slightly during exercise (step test) and to a greater degree during recovery. The rate of elimination of carbon dioxide is normal at rest and does not change significantly during exercise but like the oxygen uptake continues to increase during recovery (Table IA).

The arterial blood and alveolar air studies indicate that there is no disturbance in oxygen and carbon dioxide exchange in the lungs at rest and during exercise (Table IB).

The voluntary breathing capacity is 72 liters (94.0 per cent of the predicted value) when standing and 70 liters

(101.7 per cent of the predicted value) when recumbent. Breath-holding time is normal. The results of postural tests on a tilt table are normal. The cardiac output is 1.54 liters per minute per square meter body surface area. This is a normal value.

SUMMARY: A relative decrease in vital capacity and a relative increase in residual air are suggestive of early pulmonary emphysema. Ventilatory and respiratory functions of the lungs are normal.

Case 2 (L. W., Female, Age 39, Record No. 311004). Height 160 cm., Weight 61 kgm., Surface Area 1.61 M^2.

The patient had been working in the phosgene plant for about 1½ years when she accidentally inhaled phosgene at about 6:00 p.m., January 4, 1944, by placing her head under a hood in which there was a cracked glass ampule containing 40 ml. of phosgene. There were no immediate disabling symptoms and the patient worked the remainder of the shift.

There was no history of previous inhalation of phosgene. Shortness of breath developed 6 to 8 hours after inhalation of phosgene. This symptom along with cough and expectoration of thick, yellow sputum became progressively worse during the next 1½ days.

The patient was brought to the Johns Hopkins Hospital at 12:30 p.m., January 6, 1944, approximately 41 hours after exposure to phosgene. By then there were severe pulmonary edema, acute emphysema, partial col-

lapse of the left lower lobe, marked anoxemia (arterial blood oxygen saturation 54 per cent), fever and leukocytosis (Figure 2A). Treatment consisted of continuous inhalations of 60 per cent oxygen combined with 20-minute periods of 100 per cent oxygen under 6 to 12 cm. of water expiratory pressure.

By the morning of the third day of hospitalization the patient was comfortable and without oxygen, and abnormal lung signs were practically all gone by clinical and roentgenographic examinations.

Convalescence was rapid and without complications. At the time of discharge, January 17, 11 days after admission to the hospital, the patient experienced only slight shortness of breath and no undue fatigue after moderately severe exercise.

COURSE FOLLOWING FIRST ADMISSION TO THE HOSPITAL (Figure 2A): A roentgenogram of the lungs taken one week following discharge from the hospital appeared normal. The patient returned to work one month following discharge from the hospital. Shortness of breath was no longer present at that time.

When last seen in June, 1945, approximately 17 months after the inhalation of phosgene, the patient was working, had no complaints, and did not exhibit any abnormalities on physical examination.

PSYCHIATRIC SUMMARY: L. W. is a 40-year-old widow who returns to the hospital for a checkup at this time (January 25, 1945) and says she feels perfectly all right. She had her exposure in January, 1944, and after 11 days in the hospital she took 5 weeks of rest at the suggestion of Dr. Longcope. Her course since then has been quite uneventful as far as complications are concerned, and her personal adjustment has been excellent. Her previous personality structure was that of a stable, conscientious, hard-working woman. Her attitude at present is excellent and her emotional reaction quite good. She has been able to work regularly and, although she occasionally has pain in the left side of her chest, she does not get particularly distressed by it, and actually handles it quite well without any pronounced neurotic exaggeration. She has had periods of despondency, which have not been severe or particularly incapacitating. Since her husband's death some 8 years ago, she has devoted her life to the raising of her son and has been working hard enough to provide for him adequately. She is proud of her contribution to the war effort and national emergency through her work, the buying of bonds, and giving of blood. There is very little recreation in her life because her work takes up so much of her time, but she seems to thrive on it and derives a great deal of satisfaction from this work. In addition, she gets a substantial amount of satisfaction and emotional support from the good relationship with her son. She says, "I have no alternative —I have to work to support my son."

In general, she seems a quite stable individual who has made a very good personal adjustment to her traumatic experience, showing no particularly untoward emotional response, and being able to maintain a very sensible attitude.

PULMONARY FUNCTION STUDIES: The vital capacity and the relative values of the subdivisions of the total lung volume are normal (Figure 2B).

Respiratory rate at rest is rapid, tidal air is normal, and minute respiratory volume consistently high. Breathing oxygen does not alter the pattern of respiration. During exercise, hyperventilation is even more marked than at rest because of a large increase in tidal air (Table IIA).

The nitrogen dilution rate, intrapulmonary mixing of gases, and pulmonary emptying time are normal (Figures 2C, 2D).

The maximum breathing capacity in the erect posture is reduced. It is 67.5 liters, which is 80.5 per cent of the predicted volume.

The oxygen extraction at rest per volume of air breathed falls below the normal range. The corresponding rate of carbon dioxide output is at the lower limit of normal. During exercise they both rise to well within the normal range (Table IIA).

The alveolar air oxygen tension is consistently high and the carbon dioxide tension low. This is probably due to persistent hyperventilation and is reflected by a low resting arterial blood carbon dioxide content and tension and a relatively high pH (Table IIB).

The arterial blood oxygen tension is considerably lower than that of the alveolar air at rest and after exercise (Table IIB). The air samples are representative of alveolar air since there is close agreement between the carbon dioxide tension of the alveolar air and arterial blood. There is no anoxemia. Breath-holding time is normal.

The results of postural tests on a tilt table are normal. The cardiac output is 1.05 liters per minute per square meter body surface area. This is low according to the standards used.

	5 min.	116	109(107–110)	31	29	30	47.0	7.45

* Alveolar air sample taken while sitting in bed.

SUMMARY: Ventilatory function is normal except for hyperventilation characterized by a rapid respiratory rate and a normal tidal air and a reduced voluntary breathing capacity. The low oxygen uptake and carbon dioxide output per volume of air breathed in the presence of a normal tidal air, together with the significantly higher oxygen tension in the alveolar air than in the arterial blood indicate a disturbance in respiratory function.

Case 3 (H. G., Male, Age 30, Record No. 310831). Height 177 cm., Weight 69.7 kgm., Surface Area 1.84 M².

The patient worked as a munitions handler at Edgewood Arsenal for approximately 2 years prior to the time he was incapacitated by phosgene. During that time he had two seemingly insignificant inhalations of phosgene. There was no history of lung disease.

On January 4, 1944, at 2:30 p.m., the patient accidentally took at least two full breaths of phosgene while filling shells with phosgene. He promptly experienced marked tightness in the chest, became nauseated, and vomited. There was prompt subjective improvement from oxygen and the patient returned to work in half an hour. He worked the remainder of the day though he experienced tightness in the chest, cough with expectoration of thick yellow sputum, and dizziness. These symptoms along with respiratory distress progressed during the night.

The patient entered the Johns Hopkins Hospital on January 5, almost 24 hours following the accident (Fig-

** Dyspnea.

ure 3A). By then there were pulmonary edema, acute emphysema, marked anoxemia (arterial blood oxygen saturation 53 per cent). The level of arterial blood pressure was 120/70. There were no signs of heart failure. Treatment consisted of continuous inhalations of 60 per cent oxygen under atmospheric pressure with 20-minute periods of 100 per cent oxygen under 6 to 12 cm. of water expiratory resistance.

By the morning of the third day, January 7th, the patient had definitely improved. On the fifth day, January 9th, he no longer required oxygen and on the sixth day, the lungs were clear. Convalescence was rapid and he was discharged on the thirteenth day, January 17, capable of performing moderately heavy work without any difficulty.

COURSE FOLLOWING FIRST ADMISSION TO THE HOSPITAL (Figure 3A): The patient returned to work as a painter at Edgewood Arsenal three weeks after discharge. He did not experience any limitation of physical ability.

When last seen in January, 1945, approximately one year after accidental exposure to phosgene, he was working steadily, was in good health, and did not exhibit any new physical findings.

PSYCHIATRIC SUMMARY: H. G. is a likeable, friendly, but very simple person. He is stable, has a good work record which he points to with pride, and he is conscientious. Though his exposure was followed by quite definite bodily distress, he experienced a very satisfactory emotional reaction and, largely as a result of his feeble-mindedness, which may well have prevented his being able to appreciate fully the seriousness of the situation, he was able to make a very good personal adjustment characterized by an agreeable, enthusiastic attitude, and an anxiousness to return to his former work to prove that he could take it.

PULMONARY FUNCTION STUDIES: The vital capacity is normal. The ratio of residual air to total capacity is normal (Figure 3B).

The rate of breathing is rapid; tidal air is at the lower limit of the normal range. The minute volume is high. The expired air carbon dioxide content is low and oxygen content high. The composition of the alveolar air is normal. During moderate exercise, depth of breathing increases and the carbon dioxide output and oxygen extraction rise (Table IIIA).

The rate of dilution of lung nitrogen is normal. The data concerning intrapulmonary mixing of gases are insufficient to draw definite conclusions, but several points are suggestive of impaired mixing (Figures 3C, 3D).

The oxygen saturation of the arterial blood at rest is 96.4 per cent (Table IIIB). Oxygen and carbon dioxide tension studies in arterial blood and alveolar air indicate that there is no disturbance in gaseous exchange in the lungs at rest and during exercise.

The voluntary breathing capacity in the erect posture is impaired. It is 81.8 liters which is only 62.7 per cent of the predicted value. Breath-holding is normal in duration.

Postural change on a tilt table produces no abnormal circulatory or respiratory response. The cardiac output is 1.41 liters per minute per square meter body surface area. This is a normal value.

SUMMARY: There is a disturbance in the ventilation as indicated by a low voluntary breathing capacity, a rapid respiratory rate, and suggestive evidence of impaired intrapulmonary mixing of gases. Respiratory function of the lungs is normal.

Case 4 (L. T., Male, Age 48, Record No. 314230). Height 174 cm., Weight 68.1 kgm., Surface Area 1.81 M².

The patient has been under the care of his private physician since 1938 because of inconstant aching pain in the left anterior chest, not related to breathing or exertion. Cause for the pain has not been found.

He worked in the chlorine and phosgene plants of Edgewood Arsenal for nearly two years before he was admitted to the Johns Hopkins Hospital following accidental inhalation of phosgene.

On November 15, 1942, the patient had a non-disabling exposure to chlorine. On December 23, 1943, he accidentally took a short breath of phosgene while loading shells in a box car. He soon had a choking sensation, coughed frequently, expectorated tenacious white phlegm, became nauseated, vomited, and felt dizzy. He did not seek medical attention and rested at home for the next 10 days. On returning to work there still were some cough, expectoration, and a sensation of tightness in the chest.

On February 16, 1944, he again accidentally took one or two breaths of phosgene. The immediate symptoms were similar to those following the first exposure but more intense. He sought medical attention for the symptoms. The next morning on reporting to work he was referred to Johns Hopkins Hospital (Figure 4A).

Here it was noted that the patient had acute pulmonary emphysema, edema of the base of each lung, and edema of the pharynx. There was no heart failure.

Treatment consisted of continuous inhalation of 60 per cent oxygen at atmospheric pressure and frequent 20-minute periods of 100 per cent oxygen with 5 cm. of water expiratory resistance.

Improvement was rapid. Graded exercises were begun on February 23rd, 6 days after admission. On discharge, March 3rd, 19 days after admission, he was able to perform moderately heavy work without respiratory distress or fatigue.

A roentgenogram of the chest taken on the day of admission exhibited slight clouding in the cardiohepatic angle. On the seventh day, roentgenograms of the lungs and sinuses appeared normal.

COURSE FOLLOWING FIRST ADMISSION TO THE HOSPITAL: The patient returned to work but was able to do only light labor because of pain over the left chest, similar to that which he had experienced for the past 6 years, tenderness to touch over the precordium, and shortness of breath on moderate exertion. These symptoms were still present when he was readmitted to the hospital on May 28, 1944, more than 3 months after the last inhalation of phosgene and again on January 10, 1945, approximately 6 months later. The only disturbance noted on physical examination was rapid, shallow abdominal breathing. The chest remained immobile except during deep inspiration when it expanded 7 cm. He was taught breathing exercises to encourage the use of his chest muscles in respiration. His symptoms did not improve during the period of hospitalization. His capacity for work appeared to be limited moderately.

PSYCHIATRIC SUMMARY: L. T. is a stable, well-adjusted colored male, who seems to have lived a very satisfactory life with a good work record and a well-rounded program of activities. In a conscientious sort of way, he has maintained wholesome personal contacts with relatives and friends which afforded him a considerable amount of emotional support and security. His reaction to the exposure was not accompanied by any remarkable emotional reaction, and his subsequent personal adjustment has remained good, though he continues to have some symptoms which he finds not too disturbing and to which he is able to adjust quite well, so that he has been able to resume work and live reasonably comfortably. Largely, it would appear, as a result of his previous excellent personality synthesis, he has been able to overcome the difficulties and to maintain a very reasonable attitude, with little tendency toward the development of an invalid reaction.

PULMONARY FUNCTION STUDIES: Vital capacity is abnormally low. The relationship of the residual air to the total lung volume is at the extreme upper limit of the normal range (Figure 4B).

The respiratory rate at rest is rapid, the tidal air, at the lower limit of the normal range, and the minute volume of respiration, abnormally high. Breathing oxygen does not alter the pattern of respiration. During exercise, the minute volume increases through depth of respiration. The rate becomes slower but is still rapid. The rate of oxygen extraction at rest is generally below the limit of normal variation, and the rate of carbon dioxide output

is below or close to the lowest extreme of the normal range (Table IVA).

The dilution rate of nitrogen when oxygen is breathed is slow. Intrapulmonary mixing is impaired and the pulmonary emptying rate is slow (Figures 4B, 4C).

The oxygen saturation of arterial blood at rest is normal (Table IVB). The arterial blood and alveolar air oxygen and carbon dioxide tension studies indicate that there is no disturbance in gaseous exchange in the lungs (Table IVB).

The voluntary breathing capacity when erect is 111.6 liters or 99.5 per cent of the predicted value. The breath-holding time in room air was 20 seconds in three efforts. The alveolar air carbon dioxide tension was 47 mm. Hg, and the oxygen tension, 65.8 mm. Hg at the breaking point.

Passive change in posture on a tilt table is accompanied by no unusual respiratory or circulatory response. The cardiac output is 1.37 liters per minute per square meter body surface area. This is a normal value.

SUMMARY: Pulmonary ventilation is impaired as indicated by a relatively reduced vital capacity and complementary air, and a relatively increased residual air and mid-capacity, impaired intrapulmonary mixing, and slow pulmonary emptying rate. These changes are consistent with pulmonary emphysema.

There is hyperventilation characterized by rapid and relatively shallow breathing. Respiratory function at rest and during exercise is adequate.

Case 5 (S. O., Female, Age 43, Record No. 313427). Height 156 cm., Weight 58.6 kgm., Surface Area 1.57 M².

The patient worked in the phosgene plant, Edgewood Arsenal, for approximately 2 months prior to accidental inhalation of a low concentration of phosgene for about 10 minutes on January 22, 1944.

She was promptly admitted to the Station Hospital, Edgewood Arsenal, where she complained of sneezing, watering of the eyes, substernal distress, and nausea and vomiting.

Her conjunctivae and pharynx were injected. The thorax was symmetrical, expansion shallow and equal. The lungs were clear throughout. The level of arterial pressure was 116/70. There were no signs of heart failure.

COURSE IN STATION HOSPITAL: Injection of the pharynx and conjunctivae cleared in a few days. Pulmonary edema did not develop. She frequently complained of shortness of breath on moderate exertion, cough, weakness, and pain over the heart. She was afebrile.

A teleoroentgenogram was interpreted as exhibiting old obliteration of the right costophrenic sulcus, chronic diffuse emphysema, and a partially calcified nodule in the right upper lobe. The heart appeared normal. When the patient was discharged on February 1, after 16 days of hospitalization, she still had the previously mentioned complaints.

SUBSEQUENT COURSE (Figure 5A): The patient was admitted to the Johns Hopkins Hospital 1 week later because of persistence of symptoms. There was a non-productive cough, obliteration of cardiac flatness by pulmonary resonance. The lungs were clear throughout.

The cough gradually diminished but her tolerance for exercise remained limited at the time of discharge, after 20 days of hospitalization.

She was readmitted to the hospital on March 21, 1944, for 19 days and again on May 29, 1944, for 11 days because of symptoms which were the same as on the first admission.

On each admission, no abnormalities were found on physical examination. She had numerous minor complaints and there often was slight tenderness to the touch in the 4th and 5th interspaces about the mid-clavicular line on the left.

Treatment with 60 per cent oxygen sometimes gave symptomatic relief. Breathing exercises and encouragement seemed the most effective treatment.

When last observed in June, 1944, approximately 6 months after the accident, there was no change in symptoms, tolerance for work and physical findings.

PSYCHIATRIC SUMMARY: S. O. is a somewhat timid, ineffectual, but conscientious person, who has reacted to her exposure by developing considerable anxiety with depressive manifestations. Her past life has been rather unhappy, she is an immature person, and depended on her family for emotional support, though she experienced very little real satisfaction in life. Through her work she hoped to emancipate and find some comfort in her more independent adjustment, but things did not turn out

as anticipated. The social transplantation, with the severing of old friendships and wholesome interpersonal contacts, did not work out so well. As a result there was a fertile field for the development of neurotic trends which developed following her psychologically traumatic experience and tended to exaggerate the bodily complaints and anxiety-like manifestations commonly seen in these people. Compensation issues, more or less unconsciously motivated, provided an impetus for the development of an invalid reaction with anxiety, hypochondriacal, and reactive depressive trends. Unfortunately, this illness has permitted the patient to develop a martyr-like attitude which serves a useful purpose as far as her personal needs are concerned so that it seems doubtful if she will be able to develop easily any real incentive to get better.

PULMONARY FUNCTION STUDIES: The components of the total lung volume are within the normal range. The data do not allow a calculation of the exact proportions (Table VA).

The rate of breathing is rapid, the depth is variable from test to test, although relatively constant during any one test. The tidal air is generally very low. The minute volume is higher than normal, especially when the tidal is larger than usual, as the patient does not compensate with a slower rate. During exercise, the depth is greatly increased and the minute volume becomes excessive even with mild exercise. Hyperventilation continues for at least 5 minutes after exercise. The expired air at rest contains little carbon dioxide and an abnormally high oxygen concentration, and a similar trend is observed during and following exercise. The alveolar air is of approximately normal composition (Table VB).

On oxygen breathing, the rate of dilution of lung nitrogen is slow, but no disturbance of mixing of gases is demonstrated (Figures 5B, 5C).

The arterial oxygen saturation is abnormally low at rest and rises during exercise and when breathing 100 per cent oxygen (Table VC).

The voluntary breathing capacity measured while standing is abnormally low. It is 55.5 liters or 69.5 per cent of the predicted value. Breath-holding is limited to 23 to 26 seconds and is not influenced by hyperventilation or oxygen breathing.

Passive change in posture on a tilt table is not accompanied by any abnormal circulatory response. There is a moderate increase in the rate of respiration in the horizontal position and mild hyperventilation occurs after tilting in either direction.

SUMMARY: The relationship among the components of the total lung volume is normal. The abnormally low arterial blood oxygen saturation, in the absence of impaired intrapulmonary mixing of gases, indicates that the disturbed respiratory function is not related primarily to the rapid, shallow breathing.

Case 6 (M. P., Female, Age 49, Record No. 317296). Height 159 cm., Weight 56 kgm., Surface Area 1.55 M².

The patient worked in the chlorine plant, Edgewood Arsenal, during the summer of 1941. On July 15, 1941,

she accidentally inhaled several breaths of chlorine. She soon felt faint, short of breath on moderate exertion, became nauseated, vomited, and her throat felt sore. When she continued to feel "sick" the next day she was admitted to the Station Hospital, Edgewood Arsenal. She was discharged after a few hours. The symptoms persisted for the next 3 months.

She worked in the phosgene plant from January, 1942 to January 22, 1944.

During two weeks in December, 1943, she had several short exposures to phosgene which caused her to cough and vomit.

The patient was admitted to the Station Hospital, Edgewood Arsenal, on January 22, 1944, 1½ hours after she accidentally inhaled several breaths of phosgene which had escaped from leaking shells.

The patient was coughing violently, was nauseated, vomited, and had a nasal and lachrymal discharge.

She appeared ill. Respirations were 24 a minute, shallow. There was no cyanosis, orthopnea or dyspnea. The lungs were clear throughout; the pulse 96 per minute, regular. The level of arterial pressure was 120/80.

When discharged from the hospital after 5 days, January 26, she complained of soreness over the left side of the anterior aspect of the chest, slight shortness of breath on moderate exertion, and a non-productive cough. The lungs were clear and there was no limitation of excursion of the chest.

Roentgenograms of the lungs on admission and on the following day appeared normal. There was no leukocytosis, there was a moderate degree of normocytic anemia.

SUBSEQUENT COURSE: The patient has been unable to work steadily even at light clerical work because of precordial pain not necessarily related to effort, shortness of breath on moderate exertion, cough, and nausea and vomiting after meals.

She was observed in the hospital for 6½ weeks in March and April, 1944 and in January, 1945 for 2 days.

There have been no new physical findings. Roentgenograms of the gastrointestinal tract were normal. Electrocardiograms were normal. The anemia improved. Urine examinations were normal.

Treatment consisted of frequent massage to the legs and deep breathing exercises.

PSYCHIATRIC SUMMARY: M. P. is a modestly endowed individual with a simple social background, few outside interests, and limited interpersonal contacts upon which she can lean for emotional support. She is a conscientious, well-meaning person, with a good work record from which she obtains some additional satisfaction by being able to contribute to the national effort during the wartime emergency. Though she has the usual multiple somatic complaints and anxiety-like manifestations seen in these patients, she seems earnestly interested in trying to overcome her difficulties and in making a better personal adjustment. Emotionally she displays some instability with mild depressive trends, and some tearfulness. Clinically, the description might be that of a reactive depression with hypochondriacal and anxiety features found in a modestly endowed, conscientious woman, who probably has some more or less definite physiological bases for her symptoms which are, however, exaggerated by emotional factors; she has a strong tendency to flirt with a chronic invalid reaction with its potential gains. This attitude has been fostered to a certain extent by the numerous repeated examinations that had to be done for research reasons, and was enhanced in a way by the contacts with other patients who under similar circumstances seemed sicker, more incapacitated, and consequently standing a better chance for compensation, though it is doubtful if the patient was consciously aware of this aspect of her illness.

PULMONARY FUNCTION STUDIES: The vital capacity and the mid-capacity of the lungs are within the normal range (Table VIA).

The tidal air at rest is usually shallow, the respiratory rate is variable, and the minute volume, moderately high. The alveolar air carbon dioxide tension is generally slightly increased. During moderate exercise, the breathing becomes very rapid with only slight increase in tidal air (Table VIB).

TABLE VIC

Arterial blood studies

Date 1944	State	O_2 content	O_2 capacity	Saturation
		vol. per cent	*vol. per cent*	*per cent*
5/3	Resting	16.7	16.7	100.0

Date 1945	State	Oxygen tension		Carbon dioxide tension			CO_2 content	Serum pH
		Alv. air	Art. blood	Alv. air	Arterial blood, Direct	Arterial blood, Calculated		
		mm. Hg		*mm. Hg*			*vol. per cent*	
1/9	Resting	103	104	45	44	47	60.0	7.35
	Resting	95	96(92–99)	—	—	—	—	—
	Deep breathing	101	99(94–104)	40	—	45	58.0	7.36

During oxygen breathing, the rate of dilution of alveolar nitrogen is slow. With shallow breathing, the observed nitrogen exceeds the predicted concentration especially at about 100 breaths. When the patient's breathing is slow and deep (5 per cent carbon dioxide added and voluntary control), the observed nitrogen concentration agrees closely with the predicted value. Apparently there are portions of the lungs which are poorly ventilated during *shallow breathing* but which react quite normally when depth is increased (Figures 6A, 6B).

The oxygen saturation of arterial blood at rest is normal. The arterial blood and alveolar air oxygen tension studies indicate that there is no disturbance in exchange of these gases in the lungs (Table VIC).

The voluntary breathing capacity in the erect posture is normal. It is 68.8 liters or 92.3 per cent of the expected value. Breath-holding time is normal.

The response to passive change in posture is normal. The cardiac output is 1.36 liters per minute per square meter body surface area. This is a normal value.

SUMMARY: The outstanding feature in this patient is the shallow breathing accompanied by moderately impaired intrapulmonary mixing of gases. This does not lead to anoxemia. Intrapulmonary mixing of gases is not impaired when respirations are deepened. Respiratory function of the lungs is not impaired.

A STUDY OF THE RESIDUAL EFFECTS OF PHOSGENE POISONING IN HUMAN SUBJECTS. II. AFTER CHRONIC EXPOSURE

By MORTON GALDSTON,[1] JOHN A. LUETSCHER, JR., WARFIELD T. LONGCOPE, AND NICHOLAS L. BALLICH WITH THE ASSISTANCE OF VIRGINIA L. KREMER, GILES L. FILLEY, AND JOHN L. HOPSON

(From the Clinical Research Section, Medical Division, Chemical Warfare Service, Edgewood Arsenal, Maryland, and the Department of Medicine, Johns Hopkins Hospital, Baltimore, Maryland [2])

(Received for publication March 4, 1946)

INTRODUCTION

In contrast to the serious consequences of a single, heavy exposure to phosgene, distressing symptoms and disability are uncommon among workers repeatedly exposed to small amounts of phosgene over a period of years. Physical and roentgenographic examinations of such workers have revealed a relatively low incidence of disease of the lungs (1). There are no reports, as far as we are aware, of detailed studies of the function of the lungs in such individuals.

EXPERIMENTAL

Five workers, who had repeated exposures to small amounts of phosgene during the course of 1½ to 3½ years, were studied with particular emphasis on pulmonary function and cardiovascular and psychiatric status. The methods employed have been previously described (2).

RESULTS

Clinical summaries and data on pulmonary and cardiovascular function studies are presented in detail in the Appendix and summarized in Table I.

DISCUSSION

Most of the patients had experienced on several occasions transitory symptoms from inhalation of phosgene. Over a period of several months, all of these patients developed cough, shortness of breath on exertion, and pain or tightness of the chest, in varying degrees of severity. Sputum was scanty and mucoid. Symptoms improved on removal of the worker from exposure for several weeks.

Two of the patients (cases 2 and 3) exhibited well-marked physical and roentgenographic evidence of emphysema of the lungs, which was confirmed by an increased proportion of residual air, a definite impairment of intrapulmonary mixing of gases, prolonged pulmonary emptying of nitrogen, a limited voluntary breathing capacity, and a discrepancy between the tension of oxygen in alveolar air and arterial blood.

Anoxemia was not observed in these patients despite the well-marked ventilatory abnormalities.

One of these patients (case 3) had a history of attacks suggestive of bronchial asthma, and it is impossible to evaluate the effect of the repeated exposures to phosgene.

Two other patients (cases 1 and 4), who presented no clinical evidence of disease of the lungs, showed abnormalities of lung volume and intrapulmonary mixing of gases. Case 4 also had an arterial blood oxygen tension considerably below the alveolar air oxygen tension during exercise. These patients' objective abnormalities are equally as severe as those found in the presence of clinical signs of emphysema (cases 2 and 3).

One patient (case 5), whose chief complaint was shortness of breath on exertion, showed a reduction in voluntary breathing capacity without any clinical or other functional evidence of pulmonary disease.

The pattern of breathing in three patients (cases 2, 3, 4) was similar to that observed after acute exposure to phosgene (2). The rapid, shallow breathing was present at rest and after exercise and was associated with a subnormal extraction of oxygen per volume of air breathed.

The patients were generally seen by the psychiatrist on only one or two occasions. They appeared to be stable and not unduly disturbed about their symptoms. One patient (case 4) was under

[1] Captain, MC, A.U.S.

[2] Study carried out at the Johns Hopkins Hospital, Baltimore, Maryland, under a contract with the OEMcmr and a Medical Division, OC, CWS, Work Project Specification.

stress from a difficult situation at home, but this did not reflect itself in a tendency to exaggerate his symptoms.

Psychological factors appear to be of little consequence in their symptoms. This is in contrast to the patients studied following acute exposure to phosgene (2). This difference between the acutely and chronically exposed patients may be related to the stability of these latter patients, the lack of an isolated severe traumatic episode, or the less disturbing character of their symptoms. The previous personality structure and sources of emotional support in the form of wholesome personal contacts and secure environments seem to be significant factors.

CONCLUSIONS

1. Emphysema of the lungs may develop after chronic exposure to phosgene.
2. The measurable disturbances of the lungs are more striking after chronic exposure to phosgene than after recovery from a serious acute exposure.

TABLE I

Cardiac output	N	A	N	N	—

A = Definitely abnormal. B = Borderline abnormal.
N = Normal. — = Not done.

* Listed in order studied.

** Arterial blood oxygen and alveolar air oxygen and carbon dioxide tension studies at rest and after exercise were performed 4 to 8 months after all other studies were completed. Symptoms, physical and roentgenographic findings were unchanged on re-examination of all available patients (all except 5) at that time.

3. The symptoms of chronic exposure to phosgene have not been disabling, in contrast to the frequent prolonged disability seen after acute exposure.

APPENDIX

Clinical summaries and data on pulmonary and circulatory function studies. Case histories of patients 1 through 5 are given below. The results of the pulmonary function studies are presented in Figures 1A, 1B, 1C through 5C and in Tables IA, IB through IVB and Table VA. The number of each figure and table corresponds to the case number listed in Table I.

Legend for figures on intrapulmonary mixing of gases. The data are presented in Figures 1B through 5B and 1C through 5C. The method of presentation is the same as previously described (2).

Legend for figures on subdivisions of lung volume (Figures 1A through 5A). Standards for comparison and manner of presentation are the same as described under methods (2).

Legend for Tables IA through VA, VB, VC, are the same as for Tables IA through VIC of Appendix in previous report (2).

Case 1 (W. L., Male, Age 32, Record No. 325055). Height 164 cm., Weight 80.7 kgm., Surface Area 1.78 M².

The patient voluntarily entered the Johns Hopkins Hospital on June 26, 1944, for study of his pulmonary function.

His past history is non-contributory.

Since January 2, 1944, he has been working as a supervisor in gas warfare agent production plants of Edgewood Arsenal. He has been supervising phosgene production most of the time.

He experienced moderate conjunctivitis during the early part of 1941 and conjunctivitis and laryngitis in the fall of 1943 when he worked with mustard.

From March 6 through March 9, 1941, he accidentally inhaled small amounts of phosgene on several different occasions. This caused a sense of constriction in the chest, dizziness, mental confusion, blurred vision, and severe headaches.

On July 15, 1941, he experienced severe irritation of the throat from inhaling chlorine.

He worked steadily in the phosgene plant from October, 1943, until he entered the hospital on January 26, 1944. During the 10 days prior to entering the hospital he experienced a sensation of tightness in the chest, slight shortness of breath on exertion, and nervous twitchings in different muscles which he ascribed to recent minor exposures to phosgene.

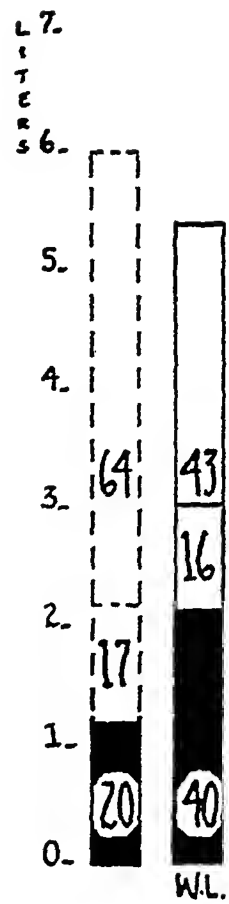
1C



1A

FIG. 1A. SUBDIVISIONS OF LUNG VOLUME. 1B AND 1C. INTRAPULMONARY MIXING OF GASES—TIDAL AIR: 348–700 ml. (generally 500 ml.). DEAD SPACE: 265 ml.

At the time of his admission to the hospital, no abnormal findings were noted on physical examination.

A roentgenogram of the heart and lungs and an electrocardiogram were normal. The red blood count, level of hemoglobin, total and differential white blood counts, and urine were normal.

When seen again in January, 1945, approximately 6 months after the initial observation, the patient was still working in the phosgene plant. There had been no progression of symptoms. There were no new complaints or physical findings.

PULMONARY FUNCTION STUDIES: The vital capacity is reduced below the lower limit of normal variation due primarily to a low complementary air. The residual air and the mid-capacity are large and comprise abnormally high portions of the total lung volume. The ratio of complementary air to total capacity is far below the limit of normal variation (Figure 1A).

The resting respiratory rate, tidal air, and minute volume are normal. On exercise there is a marked increase in tidal air; respiratory rate does not change and the minute volume remains within the normal range. The oxygen extraction and carbon dioxide output per volume of air breathed at rest is normal, rises close to the upper limit of normal variation during exercise, and remains there during the 2 minutes immediately following exercise (Table IA).

The lung nitrogen dilution rate is slow primarily because of a large mid-capacity. Intrapulmonary mixing of gases is abnormal. Pulmonary emptying rate is normal (Figures 1B, 1C).

The arterial blood and alveolar air oxygen tension studies indicate that there is no disturbance in gaseous exchange in the lungs at rest and during exercise. There is no anoxemia (Table IB).

1/16	After exercise 1 min.	114	110(108–113)	45	40	43	46.5	7.28

The voluntary breathing capacity in the erect posture is 127.6 liters. This is 102.6 per cent of the predicted value. The duration of breath-holding is normal.

The results of the tilt table studies are normal, except for a sustained tachycardia (100) in the erect posture. In the supine posture the pulse rate is 64 per minute. The cardiac output is 1.73 liters per minute per square meter body surface area. This is a normal value.

SUMMARY: There is impaired ventilatory function of the lungs as indicated by an absolute decrease in vital capacity, abnormally high relative volumes of mid-capacity and residual air, slow dilution rate, and impaired intrapulmonary mixing of gases. The respiratory function of the lungs is not impaired.

These findings are consistent with pulmonary emphysema.

Case 2 (C. E., Male, Age 50, Record No. 326252). Height 165 cm., Weight 77 kgm., Surface Area 1.83 M².

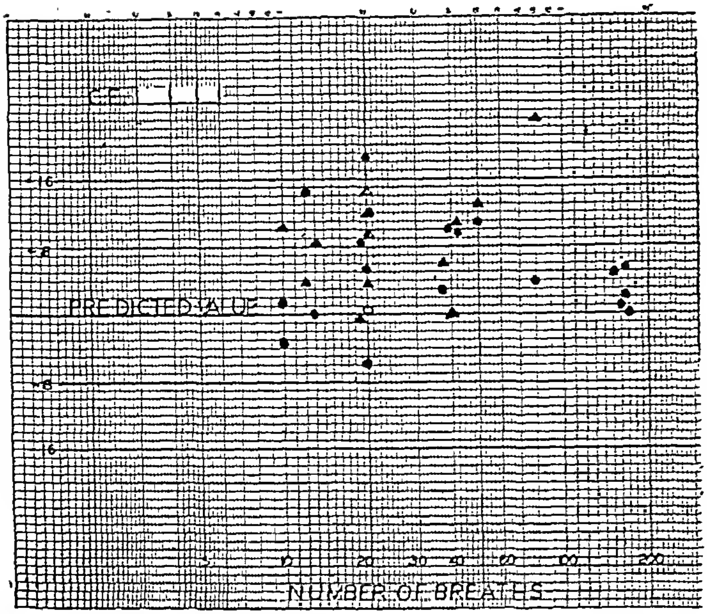
The patient voluntarily entered the Johns Hopkins Hospital on July 9, 1944, for pulmonary function studies.

His past history is non-contributory.

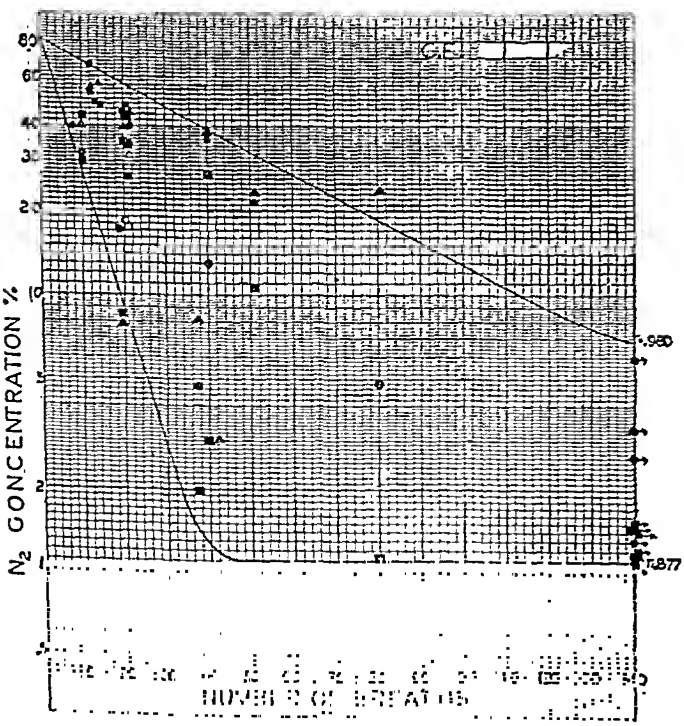
The patient has worked as a machinist in the phosgene plant, Edgewood Arsenal, since May, 1941. He has had numerous minor exposures to phosgene. These are generally followed by a sense of contriction in the throat, breathlessness, cough, nausea and vomiting of several minutes to hours duration.

He has experienced increasing shortness of breath on moderate exertion for about 3½ years, since the middle of 1941. For about one year there has been frequent cough productive of yellowish, thick sputum, which occasionally tastes of phosgene and has an offensive odor.

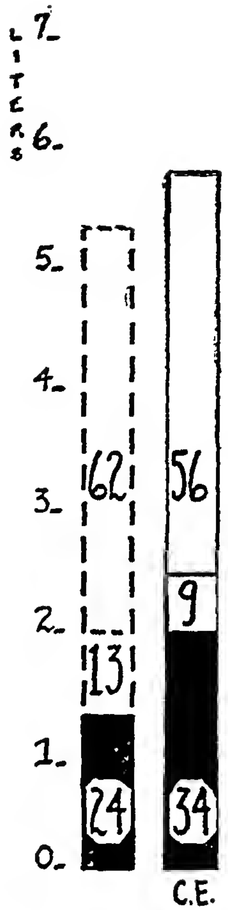
At the time of his admission to the hospital, no abnormalities were noted on physical examination.



2B



2C



2A

FIG. 2A. SUBDIVISIONS OF LUNG VOLUME. 2B AND 2C. INTRAPULMONARY MIXING OF GASES—TIDAL AIR: 213–537 ml. (generally 350 ml.), voluntarily deepened 410 ml. DEAD SPACE: 153 ml. (Tidal Air below 350 ml.), 205 ml. (Tidal Air above 350 ml.).

The patient was without complaint except for an occasional cough and expectoration of small amounts of tenacious, yellow, non-foul sputum.

Pulmonary emphysema was suggested by the appearance of roentgenograms. The blood counts, urine, chemical studies, and level of venous pressure were normal.

When last seen in January, 1945, approximately 6 months after the initial examination, there were no new complaints or progression of the symptoms previously noted; physical and laboratory findings were unchanged.

PSYCHIATRIC SUMMARY: C. E. seems to be a fairly sensible, stable fellow, who returns to the hospital at this time (January 16, 1945) for follow-up study. He has no particular complaint. From the psychiatric standpoint he presents no remarkable findings. His exposures, while repeated, seem to have not been very disabling from the physical or emotional standpoint. His attitude toward these experiments is quite reasonable, he seems to have been not unduly distressed by the incidents, his emotional reaction is quite appropriate, and his personal adjustment to these events, in general, is quite good. He has been able to work regularly, has been able to adjust his life very well, and he seems happy. There seems to have been no serious personality deviation.

PULMONARY FUNCTION STUDIES: The vital capacity is normal. The volume of residual air comprises a relatively high per cent of the total lung volume (Figure 2A).

The respiratory rate during rest is rapid, tidal air is usually lower than normal, and minute volume is high. Breathing oxygen does not alter the pattern of respiration. During exercise the minute volume increases within the normal range primarily by a rise in tidal air.

The carbon dioxide tension of alveolar air exceeds by far the normal range of variation and cannot be accounted for by breath-holding prior to collection of the alveolar sample. It would appear to be a reflection of impaired intrapulmonary mixing.

The oxygen extraction and carbon dioxide output are normal at rest, during exercise, and during recovery from exercise (Table IIA). The oxygen tension of arterial blood is significantly lower than that of the alveolar air at rest but not after strenuous exercise. There is no anoxemia (Table IIB).

Voluntary breathing capacity in the erect posture is diminished. It is 80.6 liters or 73 per cent of the predicted value. Breath-holding time is 24 seconds in room air and 36 seconds when breathing oxygen.

The cardiac output is 0.81 liter per minute per square meter body surface area. This is an abnormally low value according to the standards used.

SUMMARY: The volume of residual air relative to the total lung volume is high. Intrapulmonary mixing of gases is impaired. Respirations are rapid and shallow. Maximum breathing capacity and breath-holding time are low. The oxygen extraction per volume of air breathed is normal. The oxygen tension studies indicate an impairment in respiratory function of the lungs at rest. These results are consistent with pulmonary emphysema.

** Some expired air lost.

Case 3 (T., C., Male, Age 24, Record No. 326880). Height 180 cm., Weight 61.1 kgm., Surface Area 1.77 M².

The patient voluntarily entered the Johns Hopkins Hospital on July 16, 1944, for pulmonary function studies.

He has suffered from asthma during June and October since childhood. Subcutaneous injections of adrenalin afford prompt relief.

The patient worked in the chlorine plant during the winter of 1941 and had several minor exposures to chlorine.

He has worked in the phosgene plant since early 1942 and has at least on 6 occasions inhaled sufficient phosgene to cause him to experience immediate coughing, choking sensation, sweating, nausea and vomiting, and headache. He usually is fully recovered by the following day. He last inhaled phosgene in June, 1944, approximately 1 month prior to admission to the hospital.

Since 1942, the patient has experienced shortness of breath and dizziness on moderate exertion.

At the time of his admission to the hospital, the only positive findings noted on physical examination were kyphosis of the thoracic vertebrae and a few sonorous rales over the base of each lung.

A teleoroentgenogram showed voluminous, clear lungs, an emphysematous chest and a normal-sized heart. The red blood cell and total and differential white blood cell counts, level of hemoglobin, volume of packed red blood cells, and urine were normal.

When last examined, in January, 1945, approximately 6 months after the initial examination, the patient was still working in the phosgene plant. There were no new complaints or physical findings and the symptoms presented on the first admission were still present.

PSYCHIATRIC SUMMARY: T. C. seems to be a stable, hard working, conscientious individual of average intelligence, who is in no acute distress at the present time, January 19, 1945. He returns to the hospital for follow-up study and more careful evaluation. His exposures, though repeated, were not very serious and he was able to take them in his stride without their being particularly distressing or seriously altering his personal functioning. He is a quite mature man with a very sensible attitude toward his life's problems in general. His emotional reaction and present personal adjustment fall well within the normal range, and there seems to be little evidence that his personality structure or personal adjustment has been substantially influenced by his exposures at work.

PULMONARY FUNCTION STUDIES: The vital capacity is at the lower limit of normal predicted values. The residual air and mid-capacity volumes are abnormally high. Vital capacity and complementary air comprise an abnormally low percentage of the total lung volume and residual air and mid-capacity an abnormally high percentage (Figure 3A).

Respiration at rest when room air or oxygen is breathed is rapid and shallow. The minute volume is high. During exercise the rate of respiration increases moderately, the depth more than doubles, and the minute volume falls within the normal range (Table IIIA).

Intrapulmonary mixing of gases is impaired during quiet breathing when the dilution rate is slow and during voluntarily deepened breathing when the dilution rate is rapid. Pulmonary emptying rate is slow (Figures 3B, 3C).

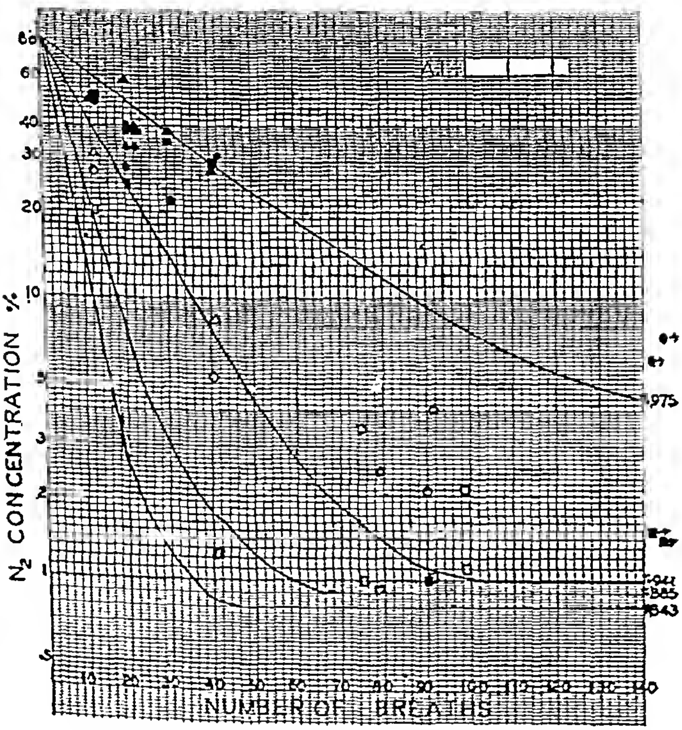
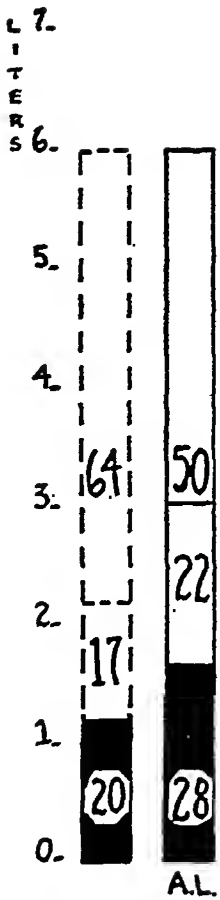
4B



4C



4A

FIG. 4A. SUBDIVISIONS OF LUNG VOLUME. 4B AND 4C. INTRAPULMONARY MIXING OF GASES—TIDAL AIR: 340–460 ml. (generally 380 ml.), voluntarily deepened 669–889 ml. (generally 750 ml.). DEAD SPACE: 262 ml.

The oxygen extraction and the carbon dioxide output at rest per volume of air breathed are at the lower range of normal. During exercise, the oxygen extraction per volume of air breathed is subnormal, but carbon dioxide concentration is normal. During the first 3 minutes of recovery from exercise, the oxygen extraction rises to the normal range and during the fourth minute falls to its resting level. The carbon dioxide concentration is normal during the recovery period (Table IIIA).

These findings are consistent with the results of the arterial blood and alveolar air oxygen and carbon dioxide tension studies (Table IIIB). At rest there is no disturbance in oxygen transfer in the lungs. During strenuous exercise the alveolar air oxygen tension is approximately 20 mm. Hg greater than that of the arterial blood. This suggests the presence of a large number of inadequately circulated alveoli. There is no anoxemia.

The voluntary breathing capacity is only 63 per cent of the predicted value when measured in the erect posture. It measures 82.6 liters. The cardiac output is 1.62 liters per minute per square meter body surface area. This is a normal value.

SUMMARY: Pulmonary ventilation is definitely impaired, as indicated by a low vital capacity and a high mid-capacity and residual air, abnormally low voluntary breathing capacity, impaired intrapulmonary mixing of gases, and slow pulmonary emptying rate. Respiratory function is adequate at rest and impaired during exercise. These findings are consistent with pulmonary emphysema.

Case 4 (A. L., Male, Age 31, Record No. 309556). Height 173 cm., Weight 62.5 kgm., Surface Area 1.74 M².

The patient voluntarily entered the Johns Hopkins Hospital on August 9, 1944, for pulmonary function studies.

The patient has worked in the Production Division, Edgewood Arsenal, since 1940. In July and November, 1942, he accidentally inhaled chlorine and experienced tightness of the chest for a few days.

In the spring of 1943 there was a recurrence of pain and tightness in the chest and an episode of bronchitis, laryngitis, and aphonia following inhalation of mustard vapor.

He began to work in the phosgene plant in the fall of 1943. In March and April, 1944, and during the summer of 1944, he had some minor exposures to phosgene which caused shortness of breath on moderate exertion and sticking pain in the chest. These symptoms along with ease of fatigue, anorexia, and occasional nausea were still present when the patient entered the hospital.

In December, 1943, he was found by the Diagnostic Clinic of the Johns Hopkins Hospital to be suffering from chronic otitis media of the right ear, chronic tonsillitis and adenoiditis, and a somewhat inadequate personality makeup.

The only positive findings noted on physical examination when he entered the hospital for pulmonary function studies were perforation of the right ear drum and a few sonorous rales at the base of each lung. He expectorated one to two ounces of glairy, white, non-foul smelling sputum a day.

Roentgenograms of the lungs taken in March and April, 1944, and during observation in the hospital exhibited only an old obliteration of the left costophrenic angle.

When last seen in January, 1945, there were no new complaints or physical findings. The symptoms previously noted were still present.

PSYCHIATRIC SUMMARY: A. L. is a man who was seen in 1943. At this time (October 20, 1944) he has no new complaints. As far as could be determined there had been no definite exposure and certainly no recent one. His desire for medical examination is, it would seem, largely related to his underlying uneasiness and general apprehension. For the most part he more or less continuously experiences symptoms of nervousness and shakiness, along with numbness, coldness, and pain over the left side of his face; these symptoms appear to be episodically exaggerated when he is under additional emotional stress. In a setting of difficult working conditions, an unresolved love affair with concern about marriage, the burden of taking care of an invalid father, and many other family responsibilities, he has grown increasingly tense, anxious, and restless. He dislikes his working conditions, is frankly frightened a great deal of the time, and experiences considerable turmoil resulting from conflict about not being in the army. It is interesting to note, though, that he apparently got some benefit from his previous interview and examination, following which he seems to have settled down some and to have been able to continue with his work Clinically, his present condition might be characterized as an anxiety state occurring in a somewhat ineffectual and inadequate personality, in a setting of emotional turmoil coincidental with his personal problems and situational stresses. While, at present, he seems to be making a neurotic adjustment, it is easily conceivable that his personality disorganization could progress to the point where it might well be thought of as a more frankly schizophrenic disorder.

PULMONARY FUNCTION STUDIES: Vital capacity is normal. The ratio of residual air and of mid-capacity to total capacity is in the upper range of normal (Figure 4A).

The respiratory rate at rest is rapid, the tidal air is at the lower limit of normal, and the minute volume is high. The alveolar air oxygen and carbon dioxide tensions are normal. During the exercise step test the minute volume of respiration increases within normal limits primarily due to a rise in tidal air (Table IVA).

The oxygen extraction per volume of ventilation at rest and during exercise is abnormally low. The carbon dioxide output at rest is low and during exercise and recovery is at the lower limits of normal. There is no deficiency in the oxygen uptake and the carbon dioxide output per minute because of the large minute volume of respiration (Table IVA).

The dilution rate is slow and mixing is abnormal. Impaired mixing persists even when the dilution rate is increased by voluntary deep breathing. The pulmonary emptying rate is abnormally slow (Figures 4B, 4C).

* Step test.

The oxygen tensions of alveolar and of arterial blood are low during rest but not sufficient to cause anoxemia. During strenuous exercise, the tension studies suggest the presence of many poorly circulated alveoli since the oxygen tension of the alveolar air (5 minutes after exercise) is 13 mm. Hg greater than that of the arterial blood (Table IVB).

The voluntary breathing capacity is 110.0 liters or 89.9 per cent of the predicted volume in the erect posture. Breath-holding time is normal. The cardiac output is 1.62 liters per square meter body surface area. This is a normal value.

* Held breath before delivered alveolar air sample. Note high alveolar air pCO_2.

SUMMARY: The residual air and mid-capacity are large in relation to the total capacity. Intrapulmonary mixing of gases is impaired and pulmonary emptying rate is slow. Voluntary breathing capacity is not reduced. Respiratory function is adequate at rest and impaired during exercise. These findings are consistent with pulmonary emphysema.

Case 5 (I. H., Male, Age 26, Record No. 330150). Height 170 cm., Weight 79.2 kgm., Surface Area 1.90 M².

The patient voluntarily entered the Johns Hopkins Hospital on August 20, 1944, for pulmonary function tests.

He worked in the phosgene plant from January, 1942 to February, 1943, in the chlorine plant from February, 1943 to November, 1943, and again in the phosgene plant from November, 1943, until admission to the hospital.

He has had a few minor exposures to phosgene which caused burning and watering of the eyes, cough, tightness in the chest, and headache. These symptoms have not at any time been disabling.

The patient has noticed moderate shortness of breath on exertion, tightness in the chest, and occasional attacks of coughing since the fall of 1943.

At the time of his admission to the hospital no abnormalities were noted on physical examination.

A roentgenogram of the lungs and heart appeared normal. There was no anemia. The total and differential white blood counts and urine were normal.

Shortly after discharge from the hospital the patient joined the Navy.

PULMONARY FUNCTION STUDIES: The relationship among the components of the total lung volume is normal (Figure 5A). The rate of breathing, tidal air, and minute

volume are within the normal range. Alveolar and expired air are normal in composition. With exercise there is an increase in the percentage carbon dioxide output and the oxygen extraction, as well as a normal rise in minute volume of respiration (Table VA). The nitrogen dilution rate is normal and there is no disturbance of intrapulmonary mixing of gases (Figures 5B, 5C).

Voluntary breathing capacity in the erect posture is abnormally low. It is 104.2 liters or 75.2 per cent of the predicted volume. Breath-holding time is normal.

SUMMARY: Pulmonary function is normal except for a reduction in voluntary breathing capacity.

FACTORS INFLUENCING THE URINARY EXCRETION OF CALCIUM.[1] I. IN NORMAL PERSONS

By ELIZABETH L. KNAPP

(*From the Department of Pediatrics, College of Medicine, State University of Iowa, Iowa City*)

(Received for publication March 8, 1946)

INTRODUCTION

It is common knowledge that the urinary calcium may be markedly altered from normal in many diseases affecting calcium metabolism. The normal range of urinary calcium is very wide, and its limits have never been determined; hence, use of the amount of urinary calcium for diagnostic purposes is limited to those patients whose urinary calcium is extravagantly far from values commonly observed. It is difficult to compare the studies of one investigator made under a given set of dietary conditions with those of another investigator, using a somewhat different regimen. Some attempts to circumvent this difficulty have been made, particularly through drastic limitation of the calcium intake. The effect of the sex and size of the subject on the urinary calcium still remains in doubt.

When the person studied is still in the period of growth, the decision as to whether a given urinary calcium value is normal or abnormal becomes even more difficult. Definite demarcation of the normal range for urine calcium at all ages and intake levels should serve as a useful aid both in diagnosis and in the study of the intermediary metabolism of calcium.

THE EFFECT OF AGE, SEX, AND CALCIUM INTAKE ON URINARY CALCIUM EXCRETION BY NORMAL PERSONS

Sources of data

Even a cursory examination of data on urinary excretion of calcium discloses the wide variability of this component among normal individuals under the same conditions of study. To cite but one example, eight normal girls, 11 to 14 years old, ingested identical diets containing 1.27 grams of calcium daily; the output of calcium in the urine varied from 25 to 217 mgm. a day. With such a wide range of excretion among individuals of the same sex and of limited age range, under identical dietary conditions, it is obviously necessary to use large numbers of data in order to obtain valid conclusions as to possible relationships between the level of excretion of calcium in urine and other factors, such as calcium intake and age, sex, and skeletal size of the subject.

During the course of several years of study of calcium metabolism during growth, a considerable mass of data on urinary excretion of normal infants, children, and adults has been accumulated in this laboratory, much of which as yet is unpublished. Many of these subjects were studied at more than one level of calcium intake. To the findings from this laboratory were added data from studies of normal children and adults reported in the literature (1–44). The recently reported studies of college women (19, 26) afforded the largest contribution of data from this latter source. All studies of patients ill or convalescing from any disease whatsoever were excluded. Excluded also were studies in which the dietary regimen differed in any notable degree from the customary, also those in which the diets were markedly acid in ash. However, it was not possible, for obvious reasons, to exclude all factors known or supposed to influence urinary calcium. Milk was the major source of calcium in all diets except those containing less than 0.3 gram of calcium daily. The total calcium intake was accurately known for all subjects; all figures for calcium intake were obtained by chemical analysis of the diet. Likewise the fecal excretion and retention of calcium were known for 95 per cent of all subjects. Since the emphasis of the present study is on the excretion of calcium in the urine, and because of limitations of space, com-

[1] This paper is condensed from a part of the dissertation submitted by Elizabeth L. Knapp in partial fulfillment of the requirements for the degree of Doctor of Philosophy, in the Department of Chemistry in the Graduate College of the State University of Iowa. The research was carried out in the Department of Pediatrics under the supervision of Dr. Genevieve Stearns.

plete data are not included, although they are available.[2] A study of the total excretion of calcium of a large number of the subjects included in this analysis has been reported in connection with other studies (19). The relative numbers and age distribution of the subjects studied are summarized in Table I.

McCrudden's method (45), or slight modifications thereof, has been used for the determination of urinary calcium in most of the studies used as source of material; therefore no serious error is introduced by combining the results from the separate studies.

[2] It is obviously impossible to include tabulations of the entire mass of data used for this study. These data are available to the investigator in the form of the thesis "Studies on Urinary Excretion of Calcium," by Elizabeth Knapp (1943), which is on file in the library of the State University of Iowa.

Urinary calcium excretion of individuals from 1 to 80 years of age

The crude relationships between the urinary calcium excretion, age, and calcium intake of the subject are shown in Table II and Figure 1. Table II gives a summary of the number of subjects, the mean values, and the standard deviations for urinary calcium excretion for each 5 years of age for all data from normal individuals from 1 to 80 years of age. In Figure 1 the mean values for four daily intake levels have been plotted and smoothed curves drawn through these points. It is evident that, although the standard deviation is always high, the mean urinary calcium excretion tends to increase both with age and with intake. At any given age the mean urinary calcium increases with the intake of calcium. In adults the amount of increase in urinary calcium with increase in intake appears to be greater than in children; hence, the spread of values becomes greater with increasing age.

The statistical validity of these assumptions was checked by analysis of several groups of data. For a study of the relationship of urinary calcium to calcium intake, it was necessary to limit the data to those studies wherein a given subject was observed with two or more levels of intake; each subject thus served as his own control. The data from 62 subjects studied in this laboratory were chosen for analysis and are summarized in Table III. Three groups, consisting of 42 boys under 12 years of age, 13 women, and 7 men, respectively, were studied at two widely differing levels

TABLE II

Summary of urinary calcium data according to calcium intake and age of subjects

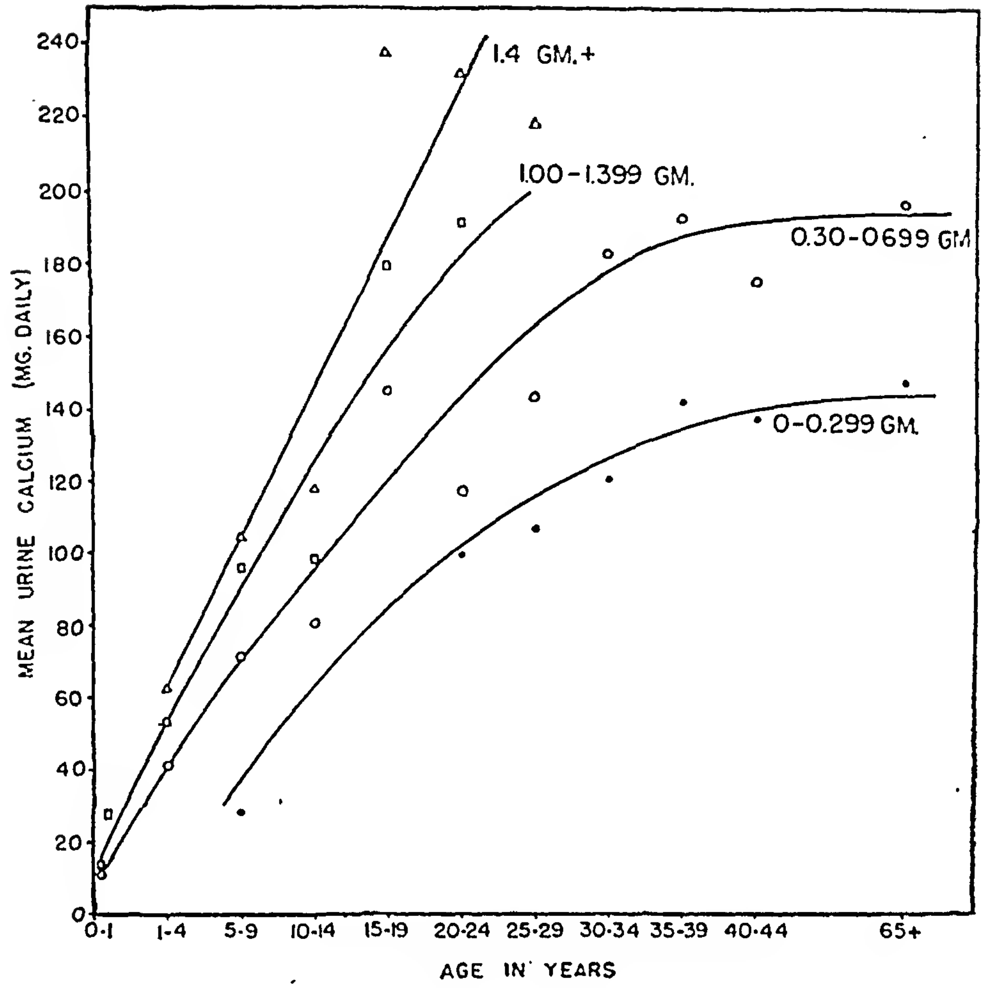

FIG. 1. THE RELATIONSHIP BETWEEN URINARY CALCIUM AND AGE OF THE SUBJECT, AT DIFFERENT LEVELS OF CALCIUM INTAKE

of intake each. Analysis showed "t" [3] to be 4.01, 5.9, and 4.6 respectively, highly significant increases in urine calcium with large increases in calcium intake.

Figure 1 also indicates that, with the daily calcium intake constant, the mean urinary calcium excretion increases with age throughout the period of growth. To determine if these differences in urinary calcium excretion at different ages were significant, the data from a group of 64 boys studied in this laboratory and ranging in age from 1 to 12 years were analyzed (Table IV). The age

TABLE III

Statistical summary of data showing range and mean urinary calcium excretion with changes in age or in calcium intake

Subjects	Number	Age range	Intake mean	Urine mean	Calcium range	Significance of differences*
		years	*grams per day*	*mgm. per day*		
Boys	42	1–12	0.554 1.446	56 81	7–224 10–260	+
Women	13	14–35	0.387 1.983	96 158	55–188 80–239	+
Men	7	20–25	0.226 2.339	131 229	81–188 130–287	+

* + = Significant at 1 per cent level.

[3] If the calculated value of "t" could occur by chance only once in 100 times, the difference is said to be "significant at the 1 per cent level," or highly significant; and if such a value could occur by chance only once in 20 times, the difference is said to be "significant at the 5 per cent level." In other words, when the values for significance are between 1 per cent and 5 per cent, there is a high probability that the differences in the means cannot be accounted for by variations due to sampling; or, as commonly expressed, the means are significantly different. Calculations of "t" were made when only 2 means were being compared, and calculations "F" when more than 2 means were compared. The standards for significance are the same for both values (75).

TABLE IV

Mean urinary calcium values of 64 boys from 1 to 12 years of age and of 23 college women. All received one quart of milk daily

	Age	Number of subjects	Calcium intake Mean	Urinary calcium Mean
	years		*grams per day*	*mgm. per day*
Boys	1	10	1.272	28
	2	7	1.267	62
	3	7	1.300	53
	4	6	1.382	79
	5	7	1.413	85
	6	5	1.397	93
	7–8	6	1.559	115
	9	5	1.574	135
	10–11	11	1.451	111
Women	17–25	23	1.378	210

range chosen covers the interval of most rapid increase of urinary calcium with age as shown in Figure 1. All boys were receiving 1 quart of milk daily in addition to the basal diet; therefore, the daily calcium intake was very nearly constant for all subjects. The number of subjects, the mean daily calcium intake, and urinary calcium for each year of age are shown in Table IV. It is obvious that although the mean calcium intake varies only about 20 to 25 per cent from 1 year to adulthood, the mean urinary calcium increases almost 10-fold during the same period. A value for "F" of 4.31 was obtained, which exceeds the value required for 1 per cent significance.

The mean urinary calcium for the 10- to 11-year old boys (Table IV) was compared with that of 23 college women receiving a similar intake (19, 26). The value of "t" was 3.94, showing that these differences also are highly significant.

It appears probable that the important factor during growth is the increase in skeletal weight of the child. In this country, skeletal weight remains approximately constant at 20 per cent of the total weight throughout life (Scammon) though the relative calcium content of the skeleton increases during growth. To test whether body weight, as a measure of skeletal weight, is the factor responsible for the change in urine calcium with age, calcium intake and urinary calcium per kgm. of body weight were calculated for all subjects for whom weights were available (606 studies). The available data were classified into 6 intake ranges and the mean, maximum, and minimum urinary calcium determined for each range (Table V). The range and mean urinary calcium values for groups 0 to 5 mgm. per kgm. and 5 to 10 mgm. per kgm. intake were so similar (Table V) that these two groups were combined, permitting a study of 148 values, representing an age range of 4 to 80 years. The mean values for urinary calcium for each 5 years of age within these groups are shown in Figure 2, compared with the mean excretion for all groups. Notwithstanding the wide range of values, the means for each age were not significantly different from the mean for the group ("F" = 1.53). A similar analysis of the possible effect of sex on excretion of urinary calcium by 67 men and 128 women showed that the differences, although significant, again were due to differences in weight of the subjects.

TABLE V

Urinary calcium per kgm. in relation to calcium intake per kgm.

Intake range	Age range	Urinary Ca Minimum	Urinary Ca Maximum	Urinary Ca Mean
mgm. per kgm. per day	*years*	*mgm. per kgm. per day*		
0–5	8–80	0.4	4.7	1.94
5–10	4–80	0.2	4.6	2.03
10–25	1–75	0.6	8.3	3.30
25–50	1–35	0.5	9.3	3.37
50–75	1–15	0.9	10.0	
75+	1–11	0.9	11.4	

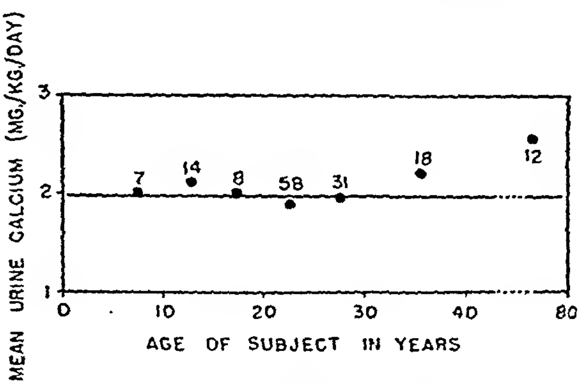

FIG. 2. THE LACK OF RELATIONSHIP BETWEEN URINARY CALCIUM, EXPRESSED IN MGM. PER KGM. DAILY, AND AGE OF SUBJECT

For this figure all data were used wherein the calcium intake was under 10 mgm. per kgm. as the range and mean urinary calcium values for groups with intakes 0–5 mgm. per kgm. and 5–10 mgm. per kgm. were almost identical (Table V). The line represents mean urinary calcium for all ages. Numbers above the dots show the number of subjects in each age group.

* 350 I.U. of vitamin D given daily.

Skeletal weight or quantity of bone, as represented by total body weight, is thus the factor responsible for differences in urinary calcium excretion with increasing age and with sex. The relative importance of weight among the various factors affecting urinary calcium was studied by determination of the correlation coefficient, "r," between weight and urine calcium. For 45 boys 10 to 14 years old whose calcium intake was 1.0 to 1.399 grams daily, the value of "r" was 0.149; for 41 boys 10 to 14 years old with calcium intakes between 1.4 and 2.0 grams daily, "r" was 0.302. The figures required for 5 per cent significance are 0.288 and 0.304 respectively. These data tend to confirm the findings of Wang, *et al.* (43) who found no significant correlation between weight and urinary output of calcium for 23 girls, 11 to 15 years old. Thus, while urinary calcium increases significantly with increase in weight of the individual, no direct correlation can be observed between the two. Such a conclusion is to be expected if the skeletal weight is the true factor concerned. Differences in total weight due to differences in fat content of the body would not influence urinary calcium.

In studies of normal adults, McCance (23) found that the amounts of calcium in the urine varied directly with the amount of calcium absorbed and considered that "changes in the urinary excretion of calcium may be used as an index of changes in the amount of calcium absorbed." Examination of the entire group of data from this laboratory shows that in children, at least, urinary calcium level bears no relationship whatever either to calcium absorption or retention. A few illustrative examples of this lack of relationship are shown in Table VI. Apparently during the period of calcium storage, urinary calcium does not reflect the amount of calcium absorption. When storage is complete, increased urinary excretion of calcium would be expected with increased absorption of this element.

Of the factors thus far considered to affect urinary calcium, two only have been shown to be significant, calcium intake and the weight of the individual. The wide range of values obtained for individuals of the same weight and calcium intake shows that some other factor or factors peculiar to the individual are of major importance in determining the amount of calcium excreted in the urine. In an attempt to find a measure for these unknown factors, presumably endocrine, the urine calcium values were calculated as per cent of intake. The proportion of calcium intake excreted in the urine of a given person is not constant at all intake levels but is highest when the intake is low, rapidly decreasing as the intake is increased. The percentage of any given intake excreted in the urine varied widely among individuals, but all showed a decreasing percentage excreted as the intake increased. The urine calcium values calculated as per cent of calcium intake were then plotted against the calcium intake per kgm. of body weight. By using the per kgm. intake, the weight factor was eliminated and the intake factor retained. The data so compared showed a definite pattern of excretion, the percentage of intake excreted in the urine decreasing at a decreasing rate as the intake rose.

Figure 3 shows the data from 606 studies of persons 1 to 80 years old (2–44, 46, 47). The urine calcium as per cent of intake is plotted against the intake per kgm. body weight, using

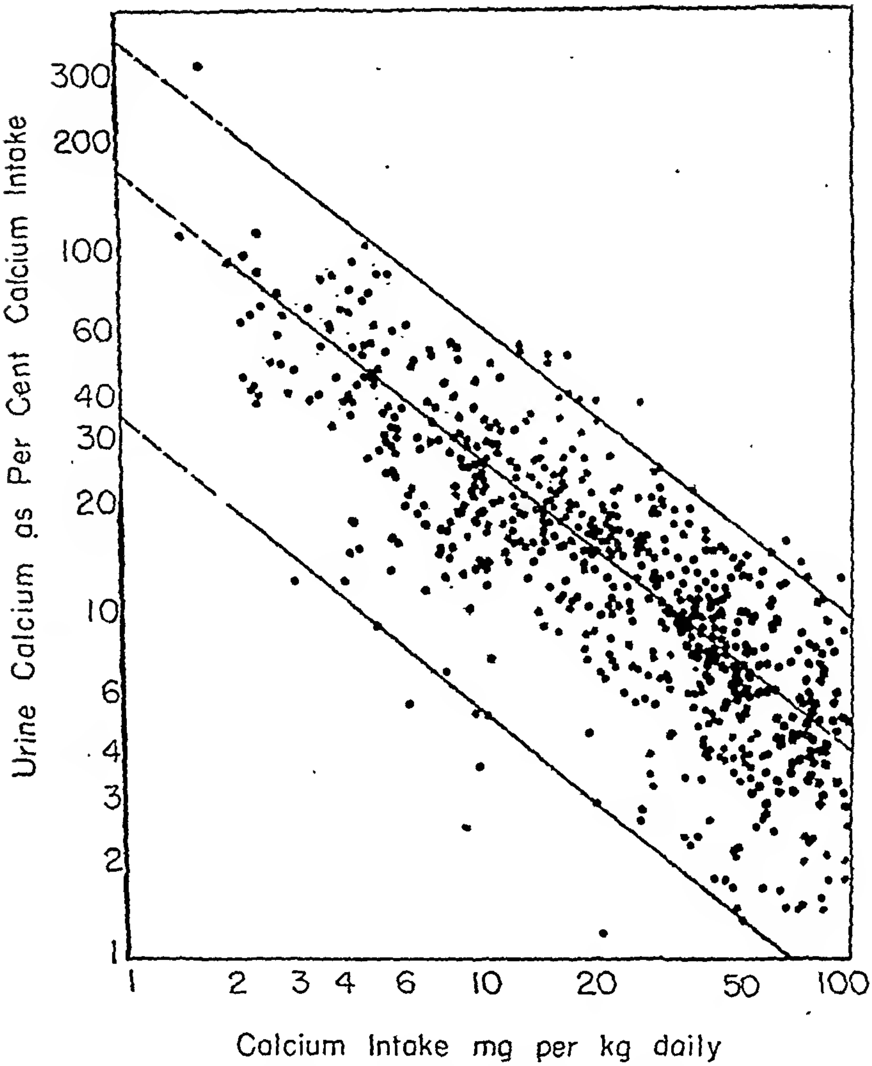

FIG. 3. THE RELATIONSHIP BETWEEN URINARY CALCIUM EXPRESSED AS PER CENT OF INTAKE, AND THE CALCIUM INTAKE IN MGM. PER KGM. DAILY

Logarithmic scales are used for both ordinate and abscissa. Mean, maximum, and minimum normal values are plotted in preference to mean and standard deviation curves. The data include 606 studies from subjects from 1 to 80 years of age (2–44, 46, 47).

a log-log scale. So plotted, it is obvious that $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ is an exponential function of the per kgm. intake. The formulas for maximum, mean, and minimum values are

$$\begin{aligned} &\text{maximum } M = 365\ I^{-.801} \\ &\text{mean } \quad y = 158.9\ I^{-.802} \\ &\text{minimum } m = 34.1\ I^{-.835} \end{aligned}$$

I being the intake per kgm. of body weight. The pertinent data for maximum, minimum, and mean lines of Figure 3 are given in Table VII. In preference to standard deviation, maximum and minimum normal values were chosen as being more useful in diagnosis of disease.

Examination of Figure 3 shows that the urinary calcium may normally be greater than the intake when the intake is less than 5 mgm. per kgm. With an intake of only 2 mgm. calcium per kgm., a urine calcium greater than 100 per cent of the intake may not be abnormal, whereas with an intake of 50 mgm. per kgm., the maximum normal excretion is 16 per cent of the intake.

TABLE VII

Urinary calcium as per cent of intake in relation to calcium intake per kilogram of body weight

Calcium intake	Urine Ca as per cent intake		
	Minimum	Mean	Maximum
mgm. per kgm. per day	*per cent*	*per cent*	*per cent*
2	19.1	91.1	210
5	8.9	43.7	101
10	5.0	25.1	58
15	3.6	18.1	42
20	2.8	14.4	33
30	2.0	10.4	24
50	1.3	6.9	16
75	0.9	5.0	12
(100)*	(0.7)	(4.0)	(9)

* Extrapolated value.

It seems probable that the position of urine calcium values of any individual person relative to the mean, as shown on Figure 3, will depend on the endocrine balance of the person. If this is true, the values for any one individual should maintain the same position relative to the mean at all levels of intake. Also, if age *per se* is not a factor, it is expected that the normal range and the mean values should be the same for all ages studied. The validity of these assumptions is shown by Figures 4 to 6. In these figures, individual data are plotted as in Figure 3. When several intake levels of calcium have been studied in one individual these values are connected by dotted lines. $\frac{\text{Urine Ca} \times 100}{\text{Intake Ca}}$ of each individual tends to maintain a constant position relative to the mean at all levels of intake. For each group, the values tend to be distributed about the mean in a manner similar to that of the entire group. The only exceptions to this rule are the values for children 1 to 2 years of age, which tend to lie almost wholly below the normal mean, though

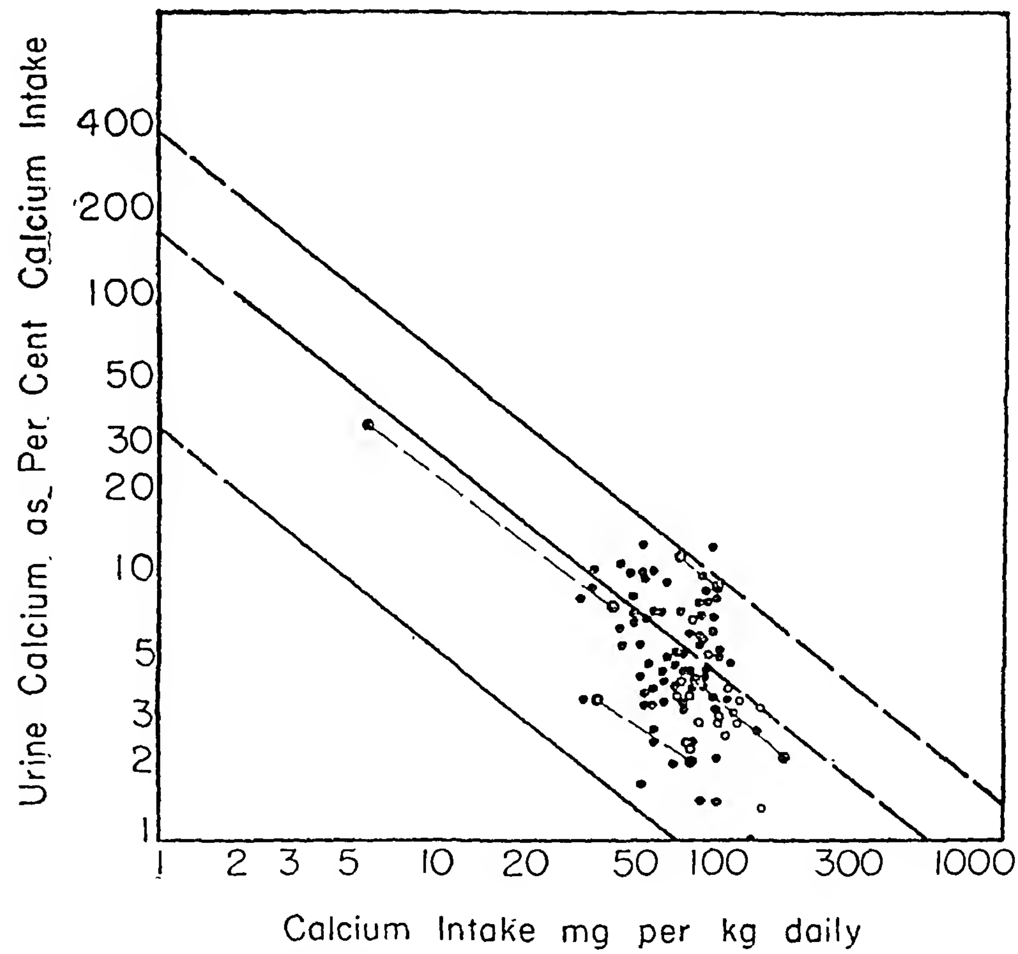

FIG. 4. URINARY CALCIUM VALUES FOR CHILDREN 1 TO 5 YEARS OLD

Solid lines represent mean, maximum, and minimum curves as in Figure 3. The dotted lines connect values obtained from one child at two or more levels of calcium intake. The hollow symbols show urinary calcium values of children 1 to 2 years old.

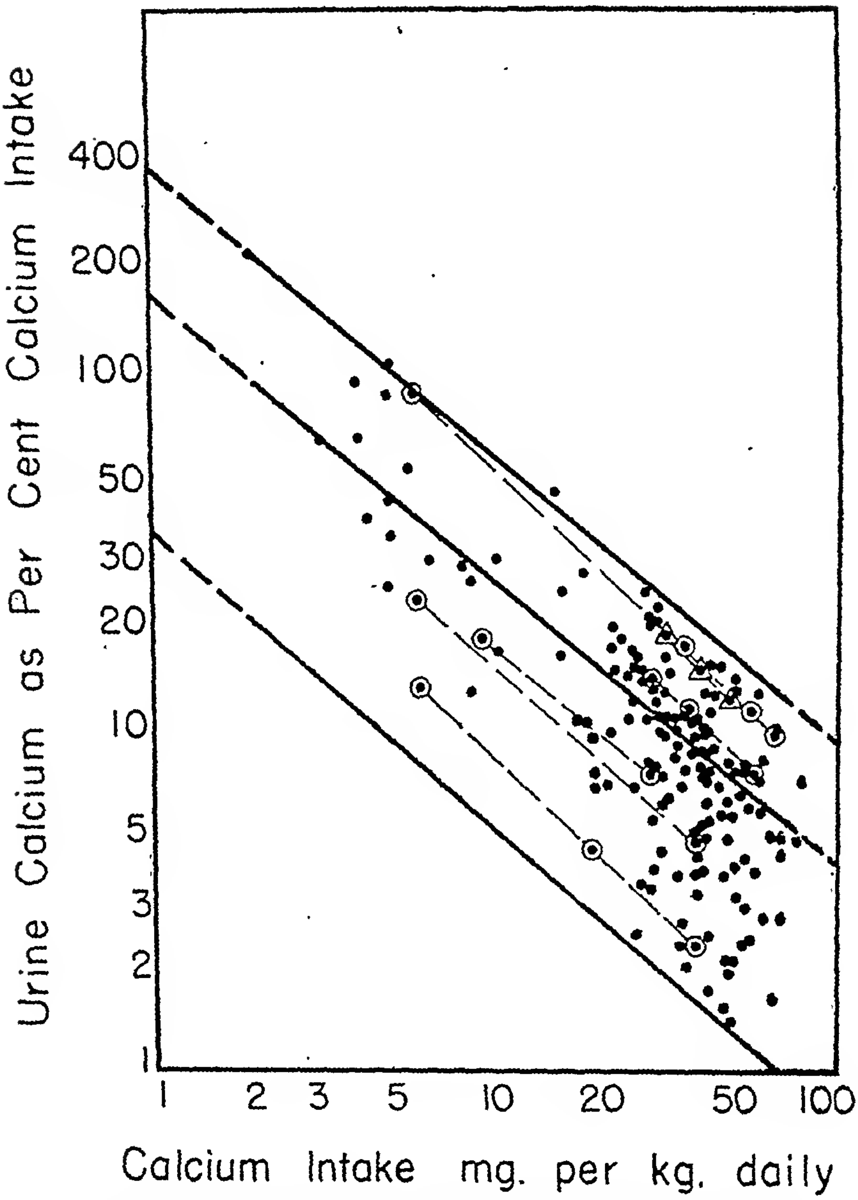

FIG. 5. URINARY CALCIUM VALUES FOR CHILDREN 10 TO 15 YEARS OLD
Solid and dotted lines as in Figure 4.

well within the normal range. The significance of this finding will be discussed later.

The relationships between calcium intake and urinary excretion set forth in Figures 3 to 6 were derived from data on all subjects, irrespective of calcium retention. In order to determine whether a total calcium excretion greater than the calcium intake would modify this relationship, the data for all subjects with negative calcium retentions were plotted as shown in Figure 7. It is obvious that the relationship expressed by the equations for mean, maximum, and minimum excretion and denoted by the lines in Figure 7 is equally valid for subjects in positive and negative calcium balance. In passing, one may note that a calcium intake of 20 mgm. per kgm. seems to be the critical level for negative calcium retentions. Irrespective of age, very few subjects lost calcium from the body when the calcium intake was greater than 20 mgm. per kgm.

A log-log chart of the maximum, mean, and minimum values for urinary calcium has proved

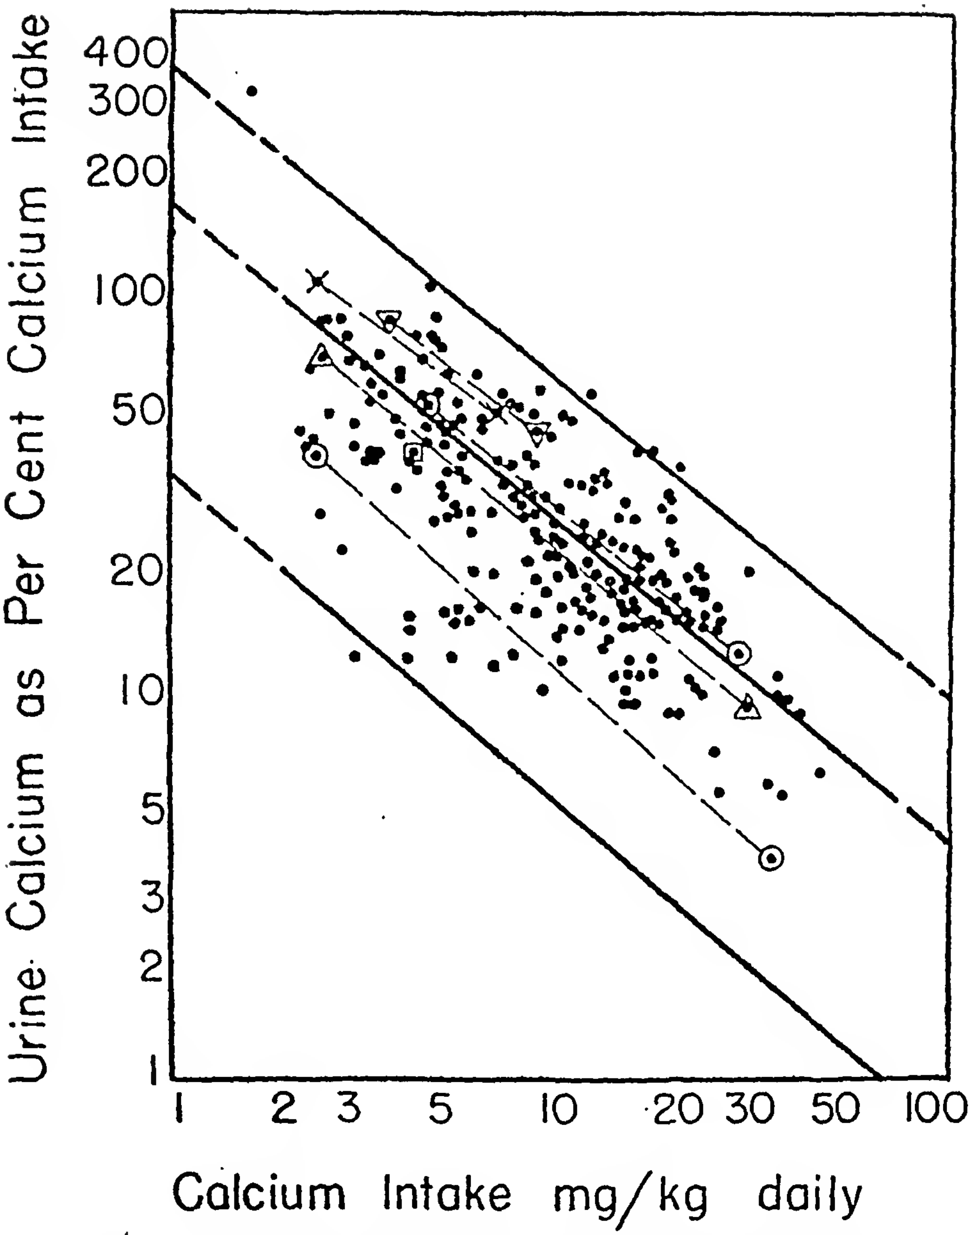

FIG. 6. URINARY CALCIUM VALUES FOR ADULTS 20 TO 80 YEARS OLD
Solid and dotted lines as in Figure 4.

useful in checking the normality of urinary calcium excretion in hospital patients. Three values only are needed for the determination: the daily calcium intake, 24-hour urinary calcium, and the weight of the person. If the milk intake is known, the dietary calcium may be estimated with sufficient accuracy for the large percentage of cases wherein the true values will lie close to the mean. For example, a 20-kgm. child drinks a pint of milk daily and excretes 100 mgm. of calcium in the urine. The true calcium intake would probably lie between 700 and 900 mgm. daily, or 35 to 45 mgm. per kgm. The urine calcium is between 14 and 11 per cent of these intakes. The ranges of these two values outline a square lying above the mean but well within the normal range. Had the urinary calcium been 200 mgm. daily, the values of 22 to 28 per cent of intake would indicate a urine calcium above the normal range, and an accurate study would be indicated.

Urinary calcium in infancy

The urinary excretion of calcium during the first year of life has been considered separately from that of the older subjects. Data were available from 980 3-day studies of 95 normal male infants fed cow's milk and ranging in age from 3 to 52 weeks (46, 48) and for 31 studies of in-

fants under 26 weeks of age given human milk exclusively (49–52).

Each infant given cow's milk received 350 I.U. of vitamin D daily and retained ample amounts of calcium. The daily urine calcium excretion was relatively small, from 1 to 82 mgm. for the infants under 6 months of age and from 3 to 86 mgm. for those over 6 months. The variability of urinary calcium was much greater among the group of infants and for the same infant during the first year of life than was observed with the older children.

The $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ of infants fed cow's milk was compared with the intake per kgm. The mean values obtained for each week of age are plotted in Figure 8. The mean values are consistently below the mean noted for the older subjects, but well within the normal range. The values for the youngest infants are lowest and the mean $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ tends to approach the mean curve with increasing age and decreasing per kilogram intake of the infants.

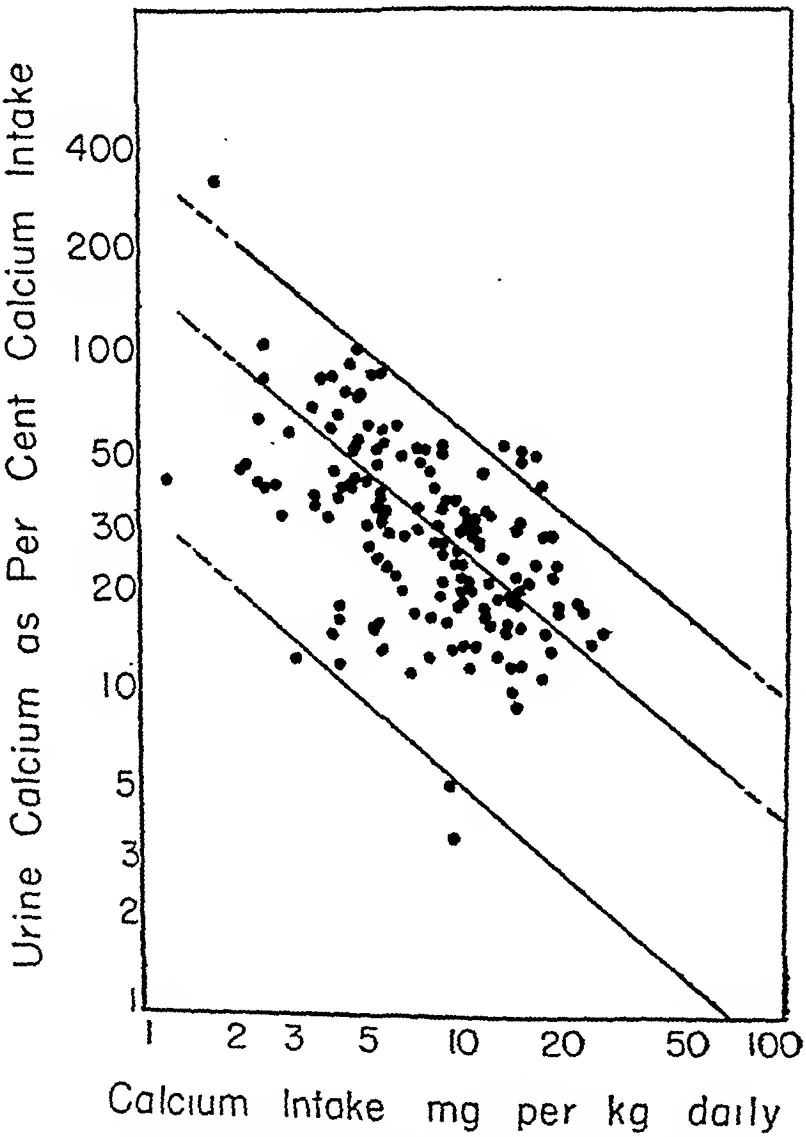

FIG. 7. URINARY CALCIUM VALUES FOR SUBJECTS IN NEGATIVE CALCIUM BALANCE

Solid lines represent mean, maximum, and minimum curves as in Figure 3. The data include 164 studies from subjects 4–76 years old.

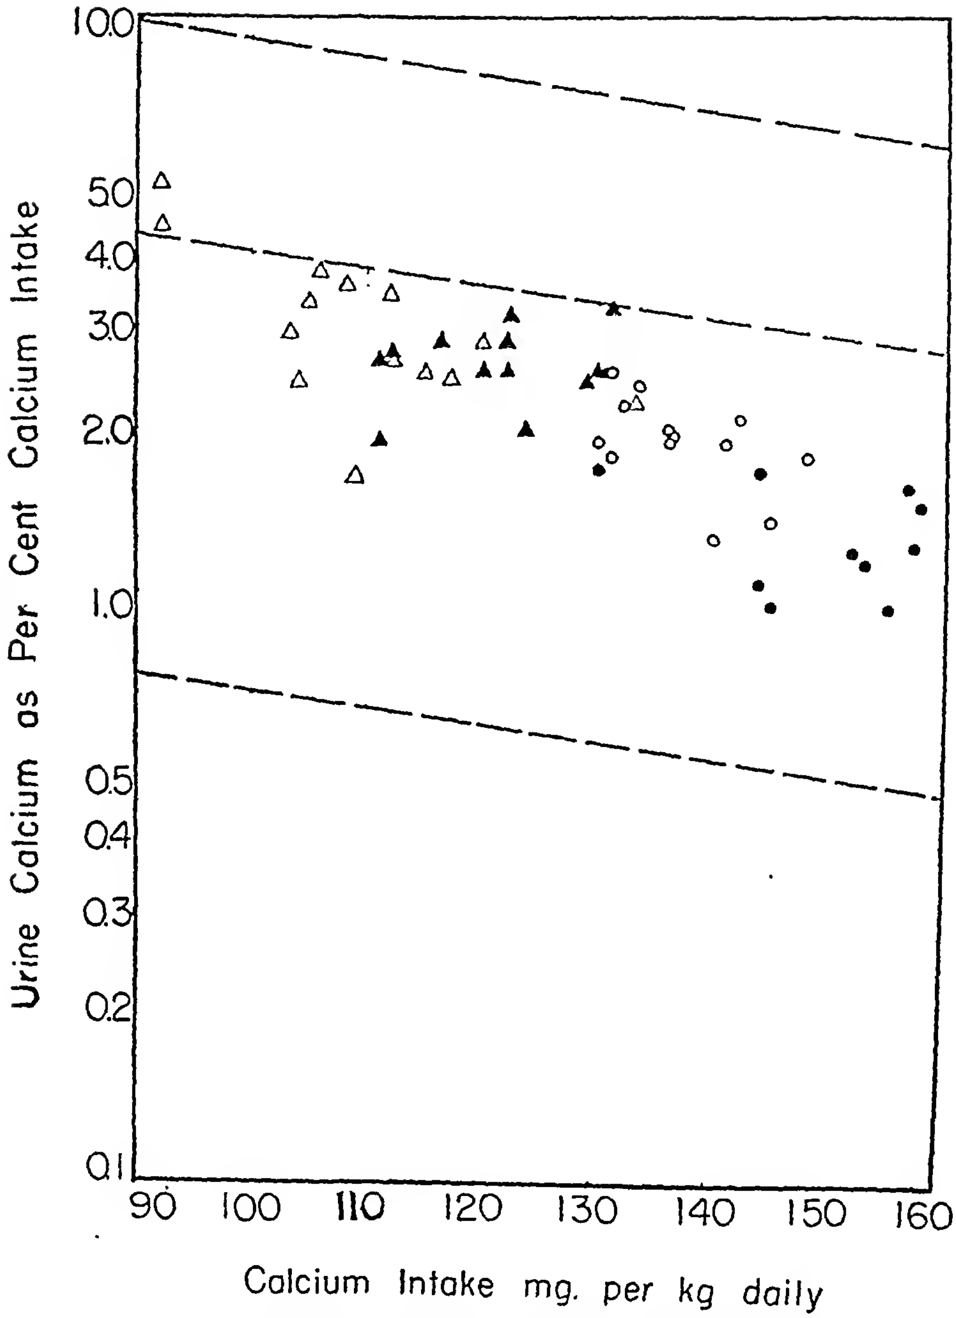

FIG. 8. URINARY CALCIUM VALUES FOR INFANTS FED COW'S MILK (47, 48)

Note that in this figure only the ordinate is on a logarithmic scale. Mean, maximum and minimum curves are extrapolated from those of Figure 3. Values are averaged for each week of age. Solid circles show average values for infants under 3 months old; open circles, those 3 to 6 months old; solid triangles, infants 6 to 9 months old; and open triangles, infants 9 to 12 months of age.

A similar study of the urinary calcium excretion of breast-fed infants whose daily calcium intakes varied from 44 to 125 mgm. per kgm., shows values comparable to those of the infants fed cow's milk. No consistent differences were observed between the values for babies under 3 months and those 3 to 6 months of age (Figure 9).

It thus appears that all normal infants, whether the per kgm. calcium intake be high or low, will excrete an amount of calcium in the urine that is within the range of normal values for older subjects, but below the mean for the latter group. It appears that the decrease in mean excretion is greatest during the first 6 months of life and tends to approach the normal during later infancy.

From the findings in Figure 4, in which the values for $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ for children 1 to 2 years of age are still below the mean, it seems probable that the mean level of excretion characteristic for older subjects is not achieved until the child is about 2 years old.

The decrease in urinary calcium observed during infancy has two possible causes. Although individual babies, over a period of several months, tend to maintain a fairly constant level of excretion in relation to the mean, it may be that the endocrine glands, the secretions of which we believe make up the "endogenous factor," function less efficiently in the young infant than in the older child. As an example, hypoparathyroid tetany of the new-born is occasionally observed and appears to be always a transitory disturbance.

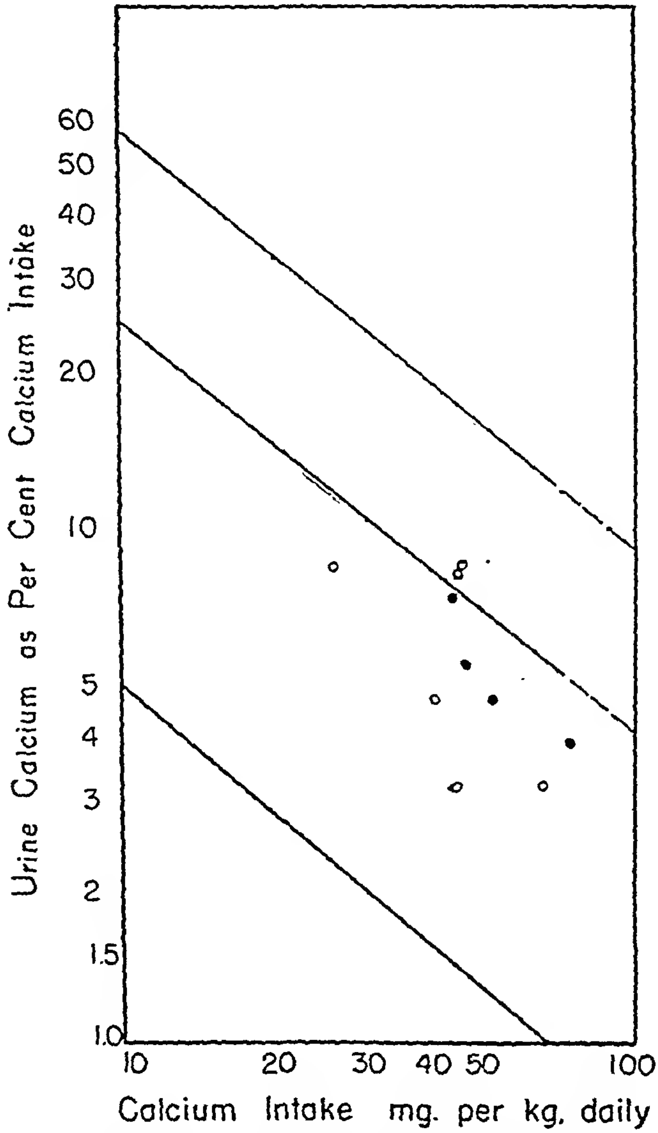

FIG. 9. URINARY CALCIUM VALUES FOR INFANTS FED HUMAN MILK (47, 49–52)

Lines as in Figure 8. The data have been averaged for each week of age. Hollow symbols represent values for infants under 3 months of age; solid symbols, infants 3 to 6 months old.

Also, the relatively marked calcium undersaturation of the skeleton in early infancy may have the same effect on decreasing urinary calcium as does severe calcium undernutrition in older subjects. It appears highly probable that both factors are active in determining the quantity of calcium excreted in the urine of infants.

Undernutrition and overnutrition

During recovery from severe undernutrition, especially calcium undernutrition, the relative unsaturation of bone may be sufficient to cause an unusually large deposition of calcium in bone and result in lowered urinary excretion of calcium. The fact that urine calcium values of infants are below the mean value for older children and adults lends support to this possibility.

Several studies of undernourished children (41, 53) and infants (54) are available for analysis. Figure 10 shows changes in $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ occurring as the children gained weight. For the children most seriously undernourished (30 to 45 per cent underweight), urine calcium values were

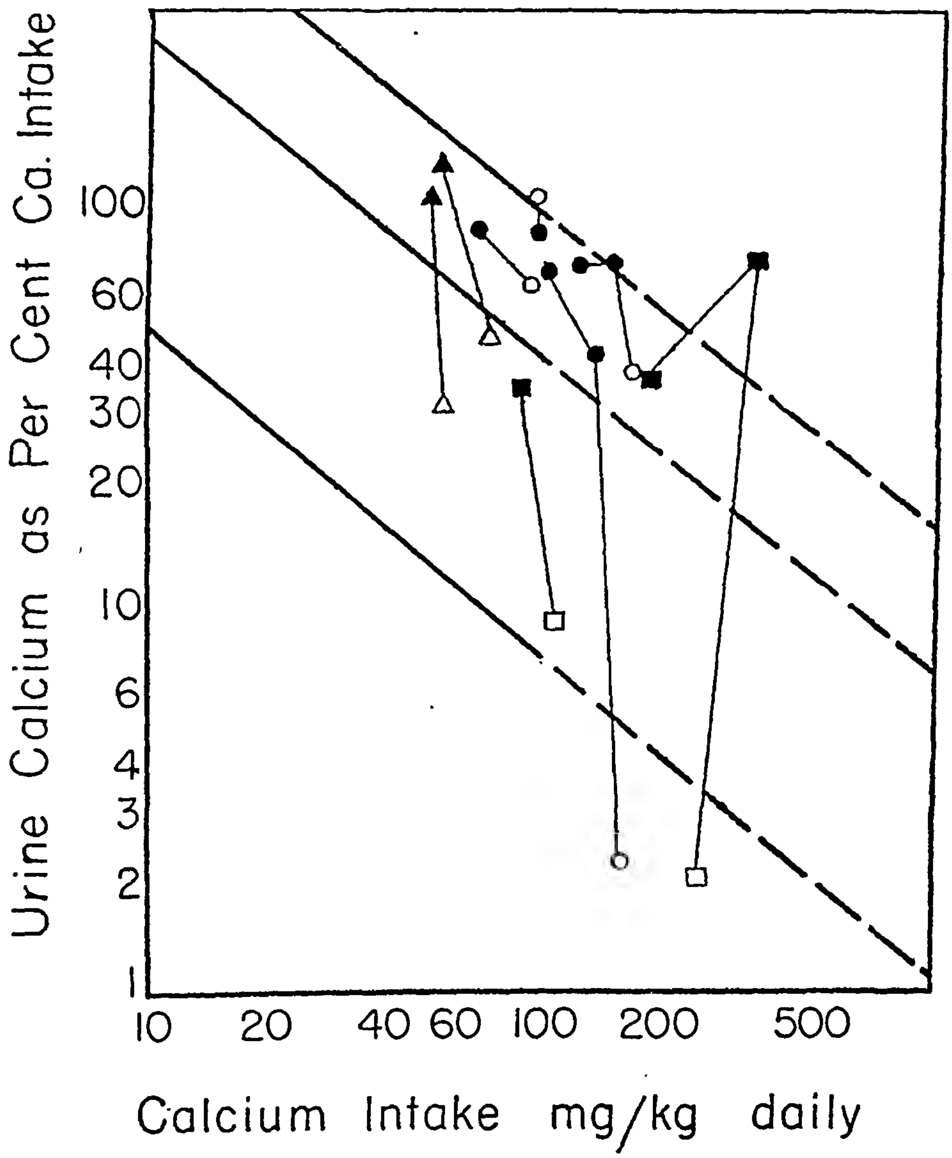

FIG. 10. URINARY CALCIUM VALUES FOR CHILDREN DURING RECOVERY FROM SEVERE MALNUTRITION

The hollow symbols represent the first observation, when the child was most underweight. In most of the cases of severe undernutrition the urinary calcium increased with the gain in weight.

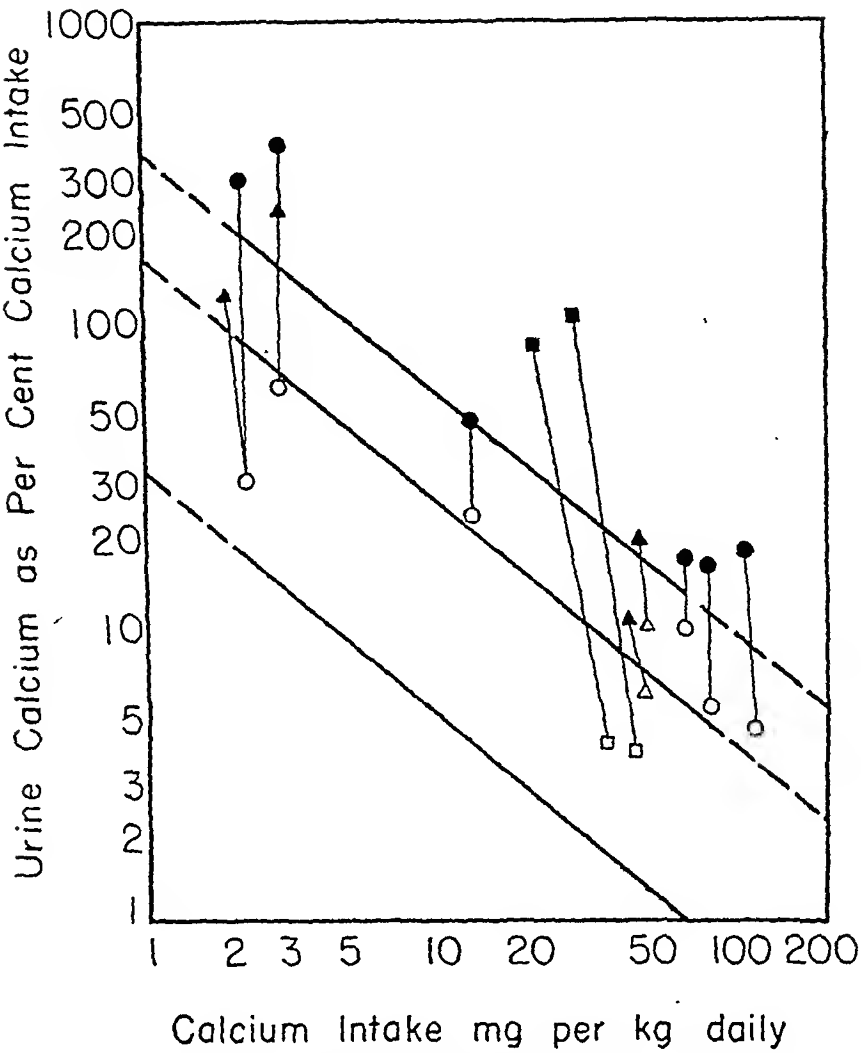

FIG. 11. THE EFFECT OF INCREASING METABOLIC ACIDITY ON EXCRETION OF URINARY CALCIUM

The background lines represent the normal maximum, mean, and minimum $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ in relation to calcium intake in mgm. per kgm. Hollow symbols represent control studies with a neutral ash diet; solid symbols, findings after increasing the metabolic acidity by ketogenic diet (■), NH_4Cl by mouth (●), or by ingestion of an acid-ash diet (▲). It is obvious that the first two methods of increasing metabolic acidity can result in increasing urinary excretion of calcium to above normal limits.

uniformly low and increased sharply as the child's weight approached normal. Some children less severely undernourished showed lowered urinary calcium values during the period of undernutrition, but several of this group excreted as much calcium in the urine during the period of undernutrition as when normal weight was attained.

The effect of calcium undernutrition *per se* can be illustrated by a study of a woman of 34 with severe osteoporosis (55). In this subject the presence of a low-grade steatorrhea for over 10 years, although symptomless, had led to a severe osteomalacia even though the milk intake had been adequate. The urinary calcium excretion before treatment was 16 mgm. daily or 1.2 per cent of the calcium intake of 40 mgm. per kgm. This value is minimum normal. She was not retaining calcium. Treatment consisted of cod

liver oil, bile salts, and pancreatin in conjunction with a diet high in calcium and phosphorus and low in fat content. After 4 months on this regimen, the patient showed dramatic improvement; she gained weight and the osteoporosis was very nearly healed. The calcium retention at this time approximated 0.5 gram daily. However, the urinary calcium excretion was only 9 to 11 mgm. daily, or 0.5 to 0.7 of the intake of 36 mgm. per kgm., values well below the normal minimum. Practically all the absorbed calcium was being retained in the bones, and very little remained to be excreted in the urine. Similar low values for urine calcium may be observed during recovery from hyperparathyroidism.

In obesity, there seems no reason to assume abnormality of calcium excretion, unless the obesity is accompanied by endocrine disturbance. As it seems probable that the relationship observed between weight of the subject and urinary calcium is due primarily to a relationship between skeletal weight and urinary calcium, the urinary calcium may be expected to be low. Therefore, the use of theoretical rather than actual weight of the obese individual seems preferable in calculating normality of urinary calcium. For example, a boy of 11 during reduction of weight from 124.5 to 99 kgm. excreted 8.5 to 9.3 per cent of his calcium intake of 9 to 14 mgm. per kgm. actual weight, or 26 to 33 mgm. per kgm. theoretical weight. These values are within normal limits for both intake levels, approach the mean value for theoretical per kgm. intake, and are well below the mean value for actual per kgm. intake.

THE INFLUENCE OF DIETARY FACTORS OTHER THAN CALCIUM INTAKE

In addition to the major factors affecting urinary calcium, namely, calcium intake, amount of bone measured by body weight, and endogenous factor, other factors exert lesser effects, which though not great in themselves, must be considered in planning dietary regimens whenever urinary calcium is to be studied. Of these other factors, the increase of acid metabolites in the body, the quantity of protein ingested, the calcium-phosphorus intake ratio, dietary roughage, vitamin D, and the possible effects of intake of other salts have all been discussed as factors affecting urinary calcium (56–73). The relative importance of these factors can now be evaluated.

The increase of acid ions in the body may be accomplished by feeding of mineral acids or acid salts such as ammonium chloride, by producing ketosis through the use of a high fat diet, or by the use of a diet giving an acid ash. Figure 11 shows the effect of these factors on urinary calcium. All data were taken from the literature (27, 56–58), and in every study each subject served as his own control. The calcium intake was nearly constant in all studies except one (27) in which the experimental diet contained less calcium than the control. Ingestion of ketogenic diet (fatty acid: glucose = 2.6) by children resulted in the most marked increase in urinary calcium. Values for $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ were increased far above the normal maximum. Ammonium chloride increased the urine calcium excretion of children (27) and adults (56) above the normal maximum. Ingestion of an acid-ash diet by adults (56), although less effective than NH_4Cl, did increase the urine calcium from values near the mean to values near the normal maximum level of excretion. The importance of ingestion of a neutral-ash diet when urinary calcium excretion is studied is thus emphasized.

An additional factor known to influence the quantity of urinary calcium is the ratio of calcium to phosphorus in the diet. The data shown in Figure 12 taken from studies made in this laboratory (46, 61) illustrate the effect of changing the calcium to phosphorus ratio without altering the total calcium content of the diet. The high calcium to phosphorus intake ratios were attained by giving young adults a constant basal diet and providing the dietary calcium as calcium phosphate for the control period and as calcium gluconate or lactate for the experimental periods. The data for the lower calcium intake levels were obtained by giving children a low calcium diet and decreasing the calcium to phosphorus ratio by the addition of sodium glycerophosphate to the diet. The results show consistent increase in $\frac{\text{urine Ca} \times 100}{\text{intake Ca}}$ with increasing calcium to phosphorus intake ratio and constant calcium intake. In some cases, the increases in urinary calcium

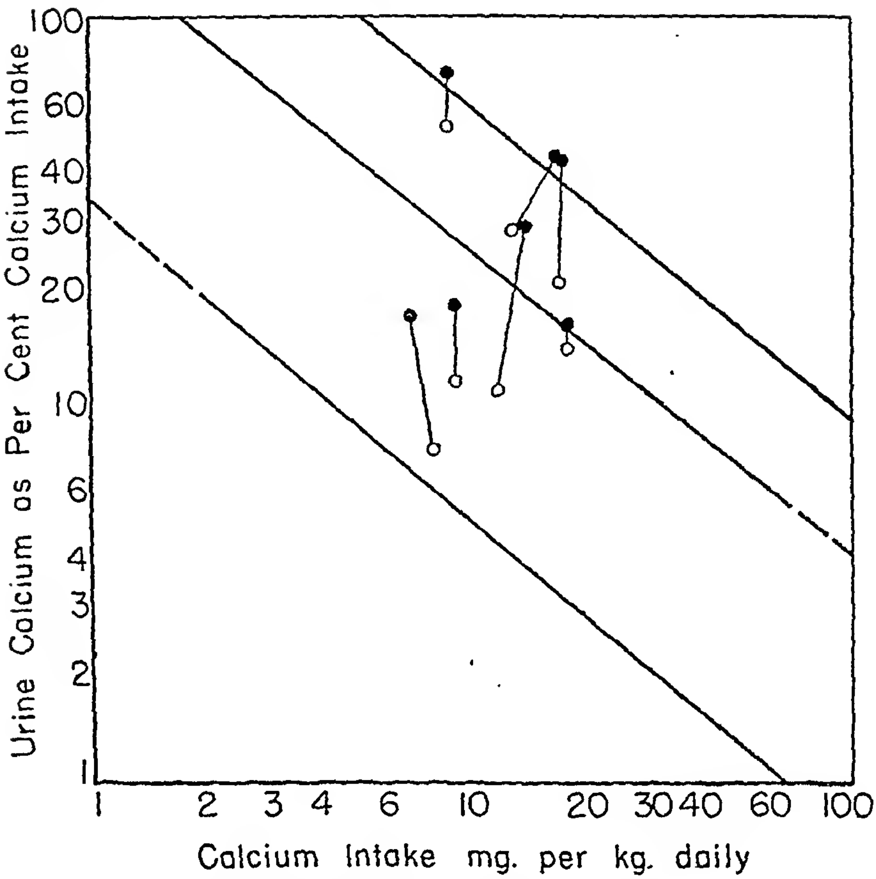

FIG. 12. THE EFFECT OF INCREASING THE CALCIUM TO PHOSPHORUS INTAKE RATIO ON THE EXCRETION OF URINARY CALCIUM

The hollow symbols represent the control studies and always indicate the lower calcium to phosphorus ratio of each pair. Increasing the calcium to phosphorus intake ratio results in variable increases in the per cent of intake excreted in the urine.

were sufficient to bring the values above the normal range.

In a similar study of an infant (62), the dietary calcium to phosphorus ratio was changed from 1.3 to 2.8 and finally to 5.1 by changing the diet from a milk formula to a soybean mixture containing $CaCO_3$. The daily urinary calcium values with the 3 diets were 23, 86, and 286 mgm. respectively.

Another factor affecting urinary calcium is the quantity of dietary protein. The significance of several studies on this subject is obscured by the fact that concurrent changes occurred in acid-base and calcium-phosphorus ratios of the diet. A few studies are available, however, in which these factors were controlled [Pittman and Kunerth (18, 30), McCance *et al.* (59), and Hawkes *et al.* (60)], and wherein each subject served as his control. In these studies and in a study from our own laboratory (46), the diets were controlled by the addition of minerals where necessary, so that the calcium and phosphorus intakes and calcium to phosphorus ratios were held very nearly constant. Also acid-base ratios varied only slightly between the low and high protein diets in all the studies except that of McCance (59), in which no mention is made of possible changes in acidity of the diet on addition of protein. The changes in urinary calcium values obtained in these studies are shown in Figure 13. The figures for high calcium intakes were obtained in pre-school children (60) with relatively minor changes (from 3 to 4 mgm. per kgm. per day) in dietary protein. It appears that increase in dietary protein without

notable concurrent increase in acidity of ash of the diet or change in dietary calcium to phosphorus ratio causes a small but consistent increase in urinary calcium. However, the amount of increase was not sufficient to bring the urine calcium outside the normal limits in any of the studies reported.

The question of the mechanical effect of the extra bulk of the cellulose from vegetables on the absorption and excretion of calcium has been studied by several investigators. Particular interest is centered on such vegetables as also contain oxalate. The results of vegetable feeding are somewhat conflicting and the changes in urine calcium are rarely marked. Spinach given to adults (63) decreased both absorption and urinary excretion of calcium. With children, spinach feeding was without significant effect on urine calcium (5), while studies of 4 infants fed small amounts of spinach gave variable results (64). Figure 14 records mean values for urine calcium of infants, children, and adults given diets of low and high vegetable content. In general, the feeding of increased amounts of vegetables appeared to decrease the urinary calcium, particularly when the chief source of intake calcium was vegetables (22, 31, 32, 38, 63), but the effect of the roughage was minor and inconsistent.

The well-known effect of vitamin D in increasing the retention of calcium in the body is usually considered to be the result of increased absorption of calcium from the intestine. Vitamin D given to rachitic infants increases both the absorption and urinary excretion of calcium. However, in amounts of about 400 I.U. daily, vitamin D has small and inconsistent effects on urinary calcium

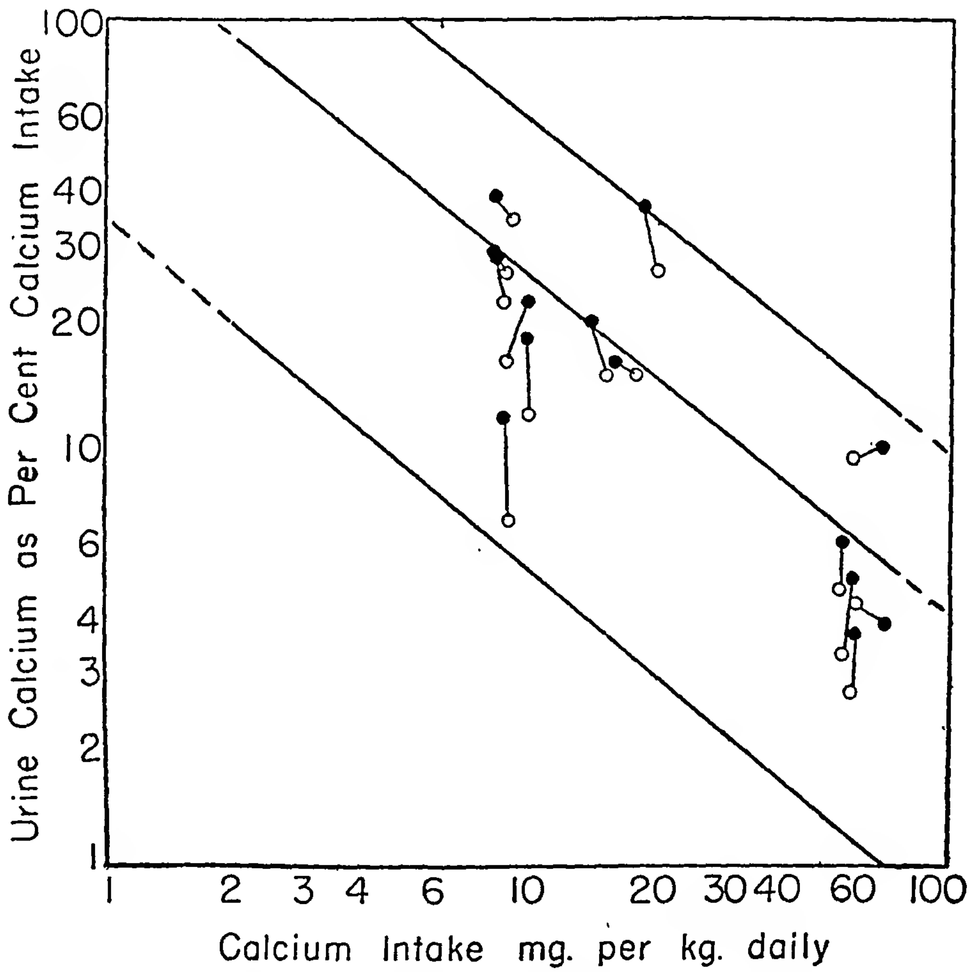

Fig. 13. The Effect of Increasing Protein Intake Without Increasing the Acidity of Ash of the Diet or the Calcium to Phosphorus Intake Ratio

Background lines and symbols are the same as in Figure 11. Increasing the protein intake results in small increases in urinary calcium excretion which do not exceed the normal limits.

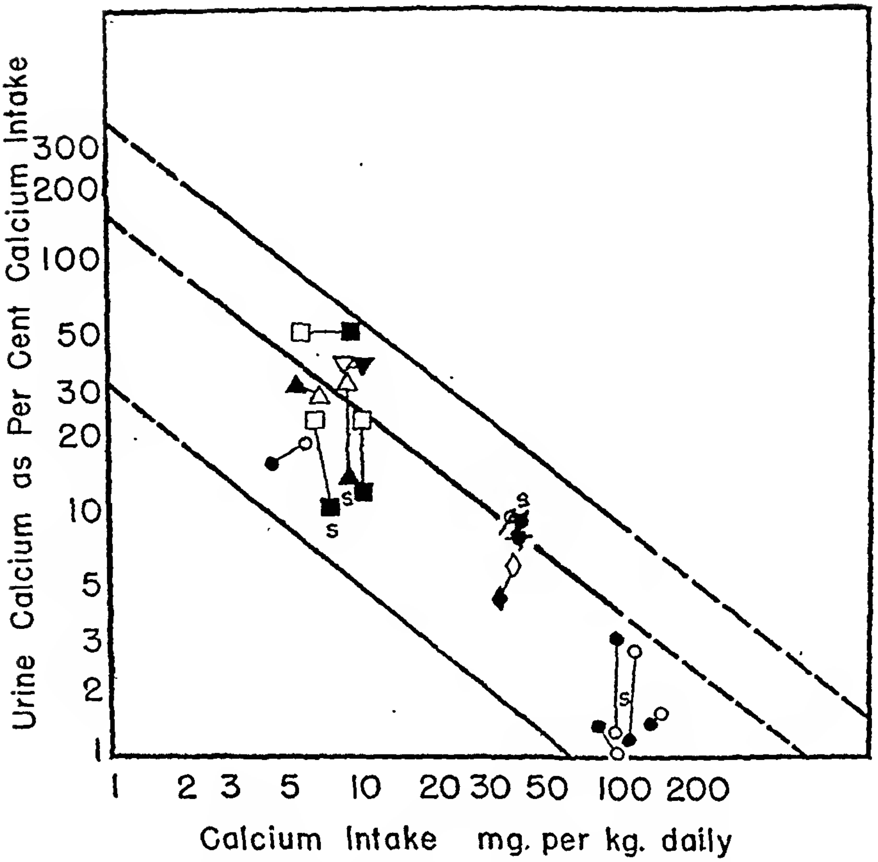

FIG. 14. THE EFFECT OF INCREASED INTAKE OF VEGETABLES ON EXCRETION OF URINARY CALCIUM

Solid symbols represent the higher roughage intake, hollow symbols represent control studies. S indicates that the vegetable studied was spinach.

of healthy children. In one study of 8 children, a consistent slight increase in average urinary calcium was noted (9); in another, no change was observed (66). Data from studies made in this laboratory on boys given 340 I.U. vitamin D as cod liver oil daily at two levels of calcium intake are presented in Table VIII. The administration of vitamin D appeared to increase urinary calcium slightly in 11 of 15 subjects when the calcium intake was moderate. With more ample calcium intake, the changes in urinary calcium were very small and not consistent. Similarly for 8 adolescent girls receiving ample calcium intake (Table VIII), 300 to 400 I.U. of vitamin D daily increased calcium absorption but caused no change in the urinary excretion of calcium. In adults the effect of moderate doses of vitamin D on urinary calcium is negligible (13, 16, 23, 67).

In hypervitaminosis D, the urinary calcium is usually greatly increased above the normal (68).

TABLE VIII

Influence of vitamin D intake on urinary excretion of calcium by children 1–15 years old

Age	No. subj.	Approx. intake	Vitamin D per day: 0 — Urine Mean	Vitamin D per day: 0 — Urine Range	Vitamin D per day: 300–400 I.U. — Urine Mean	Vitamin D per day: 300–400 I.U. — Urine Range
years		*grams per day*	*mgm. per day*		*mgm. per day*	
Boys						
1–3	2	0.750	29	13–45	43	36–50
1–3	4	1.350	36	27–55	38	25–52
4–7	7	0.750	65	33–128	80	24–142
4–7	6	1.450	94	76–165	79	46–181
8–12	6	0.850	82	40–122	174	114–240
8–12	5	1.650	186	83–279	112	60–159
Girls						
11–15	8	1.270	118	26–224	110	25–210

Doses of vitamin D much larger than are physiological, although not necessarily large enough to produce hypervitaminosis, are also reported to increase urinary calcium (67, 69).

Increases in urinary calcium have been noted after ingestion of large amounts of urea (70), magnesium citrate (3), and magnesium lactate (72) by adults. Lactose caused a consistent decrease in urinary calcium of 5 little boys (71). Small increases in urinary calcium were noted after addition of sodium or potassium chloride to the diet of infants studied in this laboratory (61) and in adults (73). Potassium citrate consistently lowered urinary calcium excretion of 8 preschool children (74).

Because dietary factors such as acid-base balance, calcium to phosphorus ratio, and other factors discussed above modify somewhat the level of urinary calcium excretion characteristic for the individual, it is important that they be controlled in any study of the effect of other factors, particularly when small groups of subjects are used.

SUMMARY AND CONCLUSIONS

Through the study of the urinary calcium excretion of 606 normal persons, from 1 to 80 years of age, under standard dietary regulation, the normal range of urinary excretion of calcium has been established and a new tool provided for the study of calcium metabolism.

1. The quantity of urine calcium is dependent on an endogenous factor or factors, presumably endocrine, and on calcium intake per unit of weight. Age and sex are not factors except as they affect skeletal weight. It is thus possible to compare data from subjects of all ages and with varying dietary intakes.

2. Urinary calcium expressed as per cent of calcium intake varies inversely with the intake per kgm. and is an exponential function of the latter. Values for mean, minimum, and maximum normal urinary calcium may be expressed by specific equations.

3. The urinary calcium excretion of subjects below 2 years of age is within the normal range but below the mean value for older children and adults.

4. Dietary factors other than calcium intake have relatively minor effects on urine calcium, with the exception of ingested acids, ketogenic diets, or diets with a high calcium to phosphorus ratio, all of which increase urinary calcium, often above maximum normal limits.

5. The ability to demarcate the normal range of urinary calcium with a considerable degree of accuracy should prove a useful aid in further studies of calcium metabolism, as well as an aid in diagnosis of disease entities associated with alteration of urinary excretion of calcium.

The author wishes to acknowledge receipt of additional data from Drs. Julia Outhouse Holmes, Gladys Kinsman Lewis, Icie Macy Hoobler, Helen Hunscher, Martha Pittman, Margaret Ohlson, and Miss Hughina McKay. Mrs. Helen Kelly and Dr. William Berg carried out the statistical analyses (75).

DIFFERENTIAL SPINAL BLOCK. II. THE REACTION OF SUDOMOTOR AND VASOMOTOR FIBERS [1]

By STANLEY J. SARNOFF AND JULIA G. ARROWOOD

(From the Department of Surgery and the Anesthesia Laboratory of the Harvard Medical School and the Surgical Services at the Massachusetts General Hospital, Boston, Massachusetts)

(Received for publication August 7, 1946)

In a previous communication (1), a technic was described for differentially blocking axones as they traverse the subarachnoid space. This was based upon the assumption that the smaller, unmyelinated fibers would be more susceptible to an anesthetic agent in the spinal fluid than the larger, myelinated fibers. At that time, we tested motor power and the patient's appreciation of pin-prick, touch, deep pressure, position sense, and vibratory sense. Skin temperature measurements were used as the index of vasomotor fiber block. It was found that when a 0.2 per cent solution of procaine hydrochloride was used, vasomotor fibers and pin-prick fibers were blocked while motor power and the modalities of touch, deep pressure, position sense, and vibratory sense remained unaffected.

Emmett (2) presented a series of cases in which it was rarely possible to produce a sensory and sympathetic block without a motor block by giving a small volume of procaine solution in the usual high concentrations. Unfortunately, however, the various sensory modalities were not individually examined and the observations on the results of the block were confined to the feet.

Gasser and Erlanger (3), working with cocaine, and Heinbecker, Bishop, and O'Leary (4), working with procaine, have demonstrated that the class C fibers, the least myelinated of a mixed nerve, are the first to be blocked when subjected to local infiltration with the anesthetic agent. It does not necessarily follow that these fibers (in which class autonomic fibers generally fall) are blocked by a lower concentration, but it does suggest that this is so and that, therefore, these fibers could be preferentially blocked.

In this laboratory, preliminary experiments performed on the cat indicated that this was true. A powerful sympathogenic reflex, the carotid sinus reflex, could be abolished in the vagotomized cat by a 0.15 per cent procaine perfusion of the spinal canal [after the method of CoTui (5)], at a time when the animal maintained spontaneous respiratory activity and gave a contralateral muscular response to the electrical excitation of one femoral nerve.

The experiments of Judovich and Bates (6) are interesting in this connection. They demonstrated that varying the concentrations of ammonium chloride surrounding the saphenous nerve of the cat exerted a partially selective effect in obliterating the action potentials of the A and C type fibers. They did not clearly demonstrate that this was not a time gradient as in the work mentioned above. The selective effect of the pitcher plant distillate and ammonium salts, peripherally and intraspinally, in relieving neuralgic pain while leaving the usually tested sensations unimpaired is most stimulating; but the mechanism and fiber types involved are not clear.

This report is concerned mainly with the selective effect, on the basis of a graded concentration, on sudomotor, vasomotor and pin-prick fibers in the subarachnoid space.

MATERIAL AND METHOD

Nine sets of observations were made on seven patients of the Massachusetts General Hospital. Two of these patients were suffering from amputation stump pain, two patients were in the hospital for repair of an inguinal hernia, two for the treatment of herpes zoster, and one for diagnostic procedures relating to sciatic nerve pain. All were otherwise in a good state of health.

Six of the nine sets of observations were concerned with the reactions of the individual to a differential spinal block. The technique used was essentially that as previously described (1). It was somewhat modified in that a larger initial dose (15 ml. rather than 10 ml. of a 0.2 per cent solution) and a higher rate of subsequently administered procaine were used. This was done because it was found that by so doing it was possible to hasten the onset of the differential block without affecting the nature of the response.

[1] Presented at the Ether Day Centenary at the Massachusetts General Hospital on October 15, 1946.

Three sets of observations on the reaction of the patient to the usual or full spinal block were obtained. The manner in which these blocks were performed is specified in the individual protocol. These observations were used as control studies. In two instances both the differential and undifferentiated block were performed in the same patient (R. B. and D. M.).

Iron-constantan thermocouples were placed on the plantar surface of the distal phalanx of the great toe (labelled A in the figures), on the medial aspect of the dorsum of the foot (B), and four inches above the internal malleolus (C). This was done on both lower extremities. A seventh thermocouple (RF) was placed on the palmar surface of the distal phalanx of the right third digit. The eighth thermocouple was placed just under the operating table so that it would register room temperature. The eight thermocouples were connected to a temperature recording device which printed in rotation every 30 seconds. By this means the temperature at each of the designated points was recorded every 4 minutes.[2]

The degree of skin resistance was used to record the order of magnitude of sweating and the changes that occurred. The instrument used was that advocated by Richter (7). The sensitivity of the indicating microammeter, or dermometer, was set at an appropriate level for each individual. This made it impossible to compare the skin resistance and the degree of sweating of one patient with that of another. However the sensitivity setting remained the same for the entire duration of the experiment in any given patient, and, therefore, qualitative changes were accurately reflected. In Figures 2 to 8, the dermometer readings are inversely proportional to the skin resistance.

The patient was brought into a constant temperature room in which the temperature was between 17° and 25° C. In any given experiment the room temperature did not vary more than 1.6° C. The patient's trunk was covered with a cotton sheet; the remainder of the body was bare. The patient was placed supine on the operating table which was maintained in the horizontal position at all times. Blood pressure determinations were done with the mercury manometer, adhering to the criteria of Ragan and Bordley (8). A needle was placed in the subarachnoid space in the third lumbar interspace and connected with tubing which allowed the administration of the 0.2 per cent solution of procaine. This tubing was connected to a leveling bottle which contained the anesthetic solution. A spinal fluid manometer was interpolated by means of a three-way stopcock and held by a clamp so that the zero point was on a level with the skin of the back (Figure 1). The neurologic examination used was that previously described (1). Thermal appreciation was not accurately tested and therefore the results stated do not include this modality. At the suggestion of Dr. J. C. White, tickle was tested in those two patients who were ticklish (E. H. and D. M.), by scratching the soles of their feet.

[2] Brown Instrument Co., Boston, Mass.

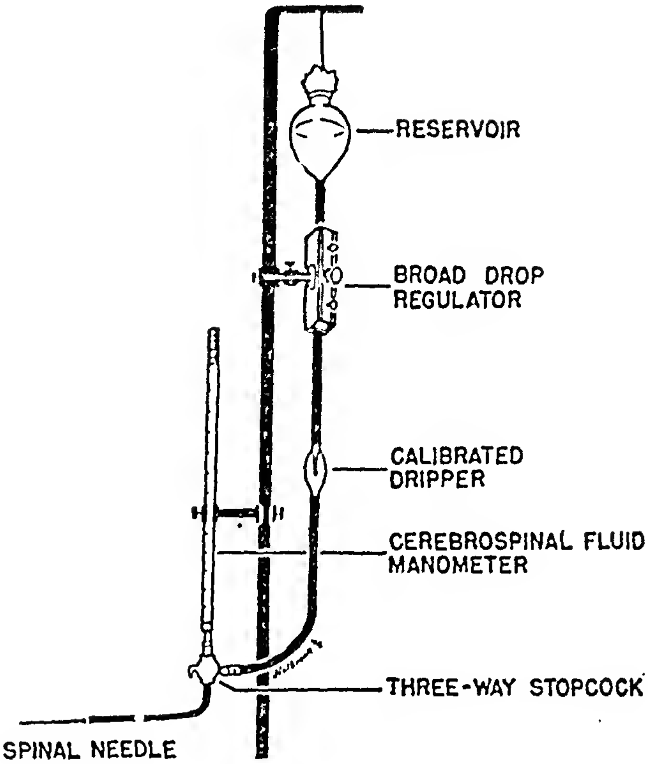

FIG. 1

The results indicate that there is a paralysis of the preganglionic sudomotor fibers which sets in at the same time as the block of the vasomotor fibers. This was true of the differential spinal block as well as of the full spinal block. The difference between the two types of block was mainly in the promptness with which the vasomotor-sudomotor block occurred. It was to be expected in addition that the full spinal block caused the loss of motor power and the other sensory modalities.

Case No. 1 (R. B.): Age 55, male, right inguinal hernia.

(Figure 2A) Satisfactory control skin resistance and skin temperature levels having been obtained, 15 ml. of a 0.2 per cent solution of procaine were administered from 11:37 to 11:42 A.M. 0.6 ml., or 1.2 mgm., per minute were then run in until 12:26 P.M. At 12:00 noon there was evidence of a beginning rise of skin temperature and skin resistance in both lower extremities. The change in the resistance and temperature of the right foot preceded that in the left foot by a few minutes, indicating the similar susceptibility of the two sets of fibers. The skin temperature of both lower extremities soon reached levels indicative of maximal vasodilatation. At 11:54 A.M., there was a spotty loss of the appreciation of pin-prick on the right. This eventually rose to the fifth thoracic segment bilaterally at 12:50 P.M. The remainder of the neurologic examination was negative. The blood pressure

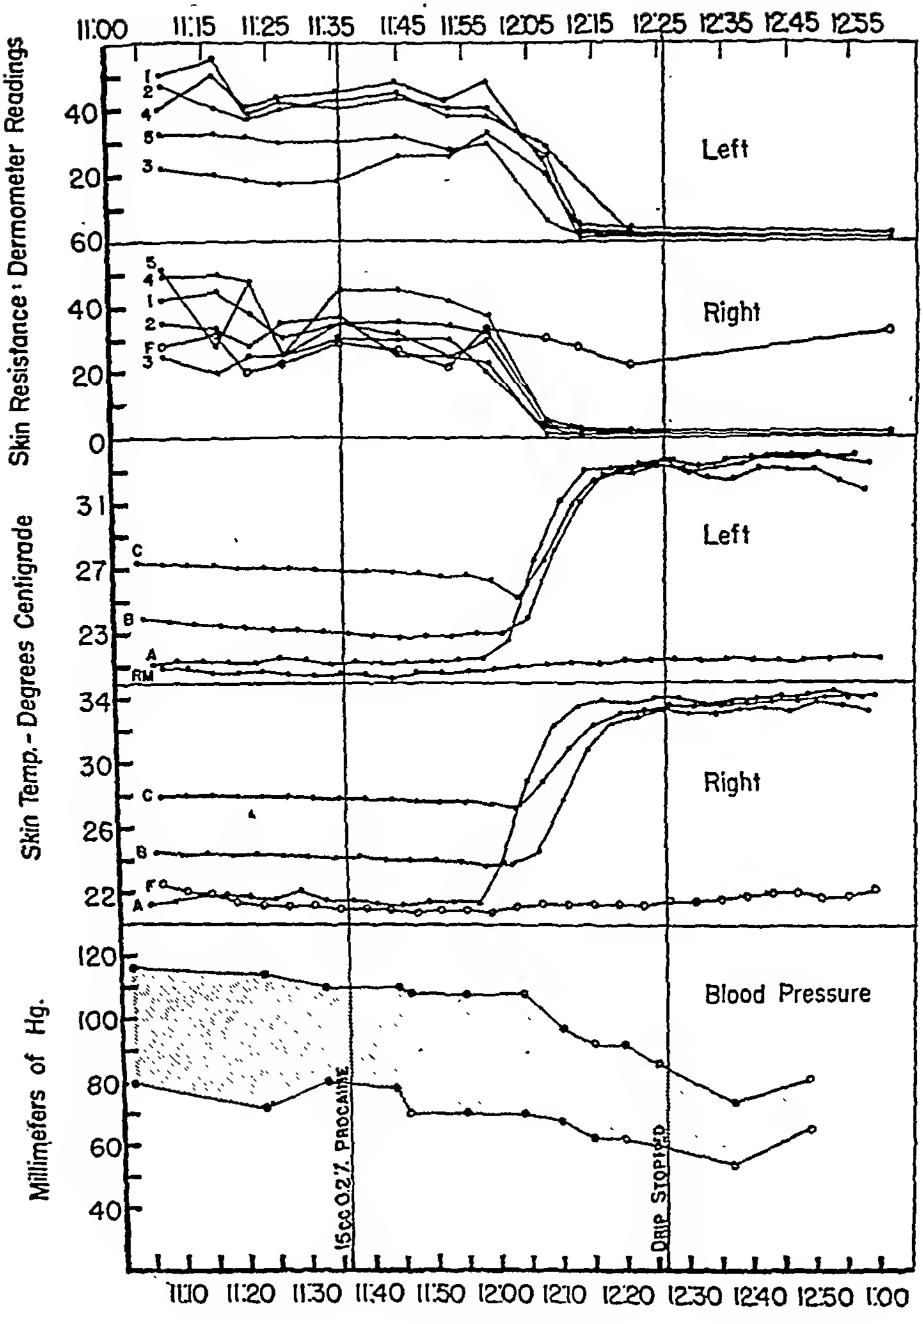

FIG. 2A

Under skin resistance, the number indicates the toe examined. The plantar surface of the distal phalanx was used in each case. F indicates the readings obtained from the palmar surface of the distal phalanx of the fourth right finger. The dermometer readings are inversely proportional to the skin resistance. Under skin temperature, A represents the readings obtained from the plantar surface of the distal phalanx of the great toe, B from the medial aspect of the dorsum of the foot, and C from the inner aspect of the leg four inches above the internal malleolus. F represents readings from the palmar surface of the distal phalanx of the third right finger.

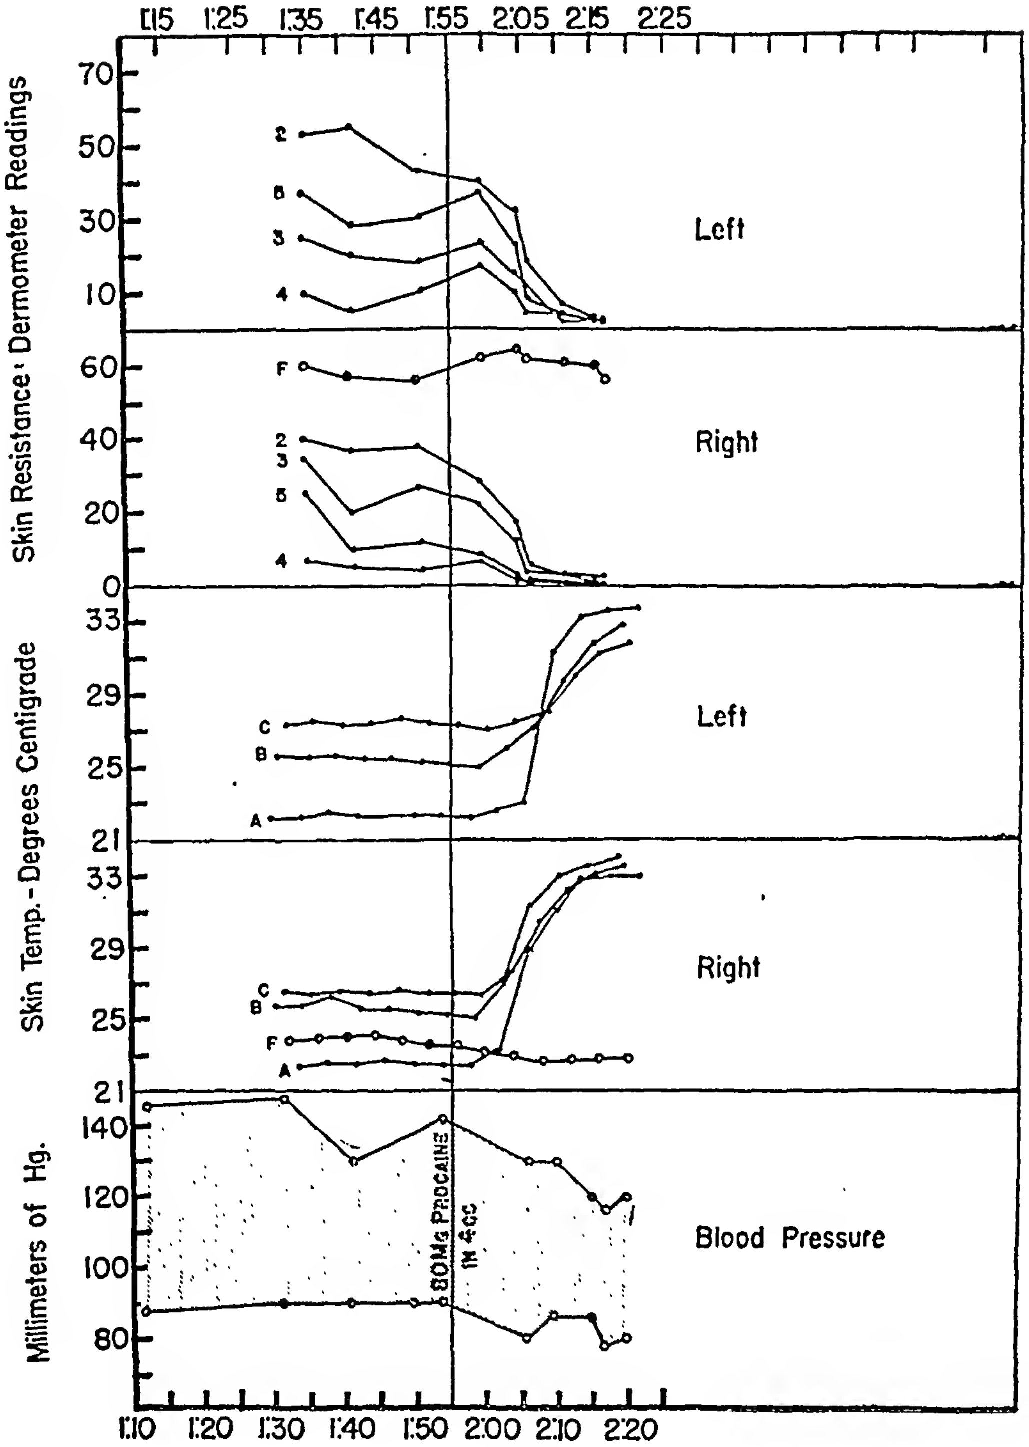

Fig. 2B

Under skin resistance, the number indicates the toe examined. The plantar surface of the distal phalanx was used in each case. F indicates the readings obtained from the palmar surface of the distal phalanx of the fourth right finger. The dermometer readings are inversely proportional to the skin resistance. Under skin temperature, A represents the readings obtained from the plantar surface of the distal phalanx of the great toe, B from the medial aspect of the dorsum of the foot, and C from the inner aspect of the leg four inches above the internal malleolus. F represents readings from the palmar surface of the distal phalanx of the third right finger.

fell from the control level of 110/80 to a low of 74/54 at 12:37 P.M. A total of 90 mgm. of procaine was administered over a period of 50 minutes. At 12:58, 32 minutes after stopping the drip, a full sudomotor and vasomotor block was still present.

Ten days later, a full spinal block was administered to the same patient (Figure 2B). After control levels were established, 80 mgm. of procaine hydrochloride in 4 ml. of cerebrospinal fluid were injected into the subarachnoid space in the third lumbar interspace. This was followed by the administration of 0.3 ml. per minute of a 0.5 per cent solution of the same agent. A rise in skin temperature and skin resistance in the feet was in evidence within 5 minutes of the injection. The slope of the curve was slightly steeper than when the differential block was administered, but in other respects they were similar. The loss of motor power and sensation was that usually seen with full spinal blocks. The fall in systolic arterial pressure was not so great after the full spinal block as after the differential block (in terms either of absolute or percentile change) despite the fact that muscular paralysis accompanied the former and not the latter.

Case No. 2 (D. M.): Age 38, male. Left mid-thigh amputation stump pain.

(Figure 3A) Control levels having been obtained, 15 ml. of a 0.2 per cent solution of procaine hydrochloride were run in between 3:52 and 3:55 P.M. From then until 4:50 P.M., 1.6 mgm. per minute of the same solution were administered. The skin temperature and skin resistance of the right foot began to rise simultaneously between 4:10 and 4:15 P.M. The skin temperature reached levels indicative of maximal vasodilatation. At 4:10 P.M., there was a just discernible, spotty loss of appreciation of pin-prick on the right anterior thigh. Complete loss of pin-prick sensation eventually rose to the first thoracic segment at 4:51 P.M. At 4:43 P.M., the appreciation of tickle was unchanged. The remainder of the neurologic examination was negative. The blood pressure remained

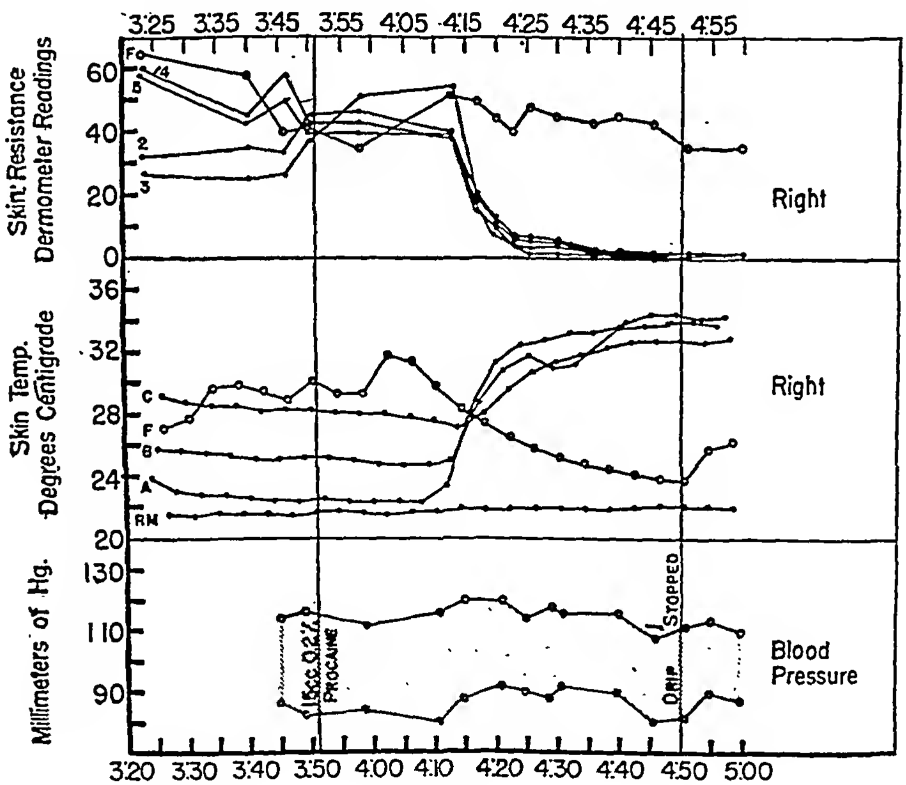

FIG. 3A

Under skin resistance, the number indicates the toe examined. The plantar surface of the distal phalanx was used in each case. F indicates the readings obtained from the palmar surface of the distal phalanx of the fourth right finger. The dermometer readings are inversely proportional to the skin resistance. Under skin temperature, A represents the readings obtained from the plantar surface of the distal phalanx of the great toe, B from the medial aspect of the dorsum of the foot, and C from the inner aspect of the leg four inches above the internal malleolus. F represents readings from the palmar surface of the distal phalanx of the third right finger.

essentially unchanged. A total of 116 mgm. of procaine was administered over a period of 60 minutes.

Two days later, a full spinal block was administered to the same patient (Figure 3B). After obtaining control levels, 150 mgm. of procaine in 5 ml. of normal saline were injected into the subarachnoid space at the third lumbar interspace. No additional injections were made. This was followed almost immediately by a rise in skin temperature and skin resistance. The curves obtained closely resembled the curves obtained with the differential spinal block in the same patient, with the exception that, with the full block, the skin temperatures did not rise so high during the period of observation. The blood pressure did not change appreciably; but, if anything, the average post-injection level was slightly higher than the average control level.

Case No. 3 (A. D.): Age 68, female. Post-herpetic neuralgia.

(Figure 4) Satisfactory control levels of skin temperature and skin resistance having been obtained, 15 ml. of a 0.2 per cent solution of procaine hydrochloride were run in between 4:35 and 4:39 P.M. From then until 4:58, 1.2 mgm. per minute were administered and from 4:58 to 5:22 P.M., 2.0 mgm. per minute of the same solution were given. The changes in skin temperature and skin resistance in the feet were manifest in the right foot slightly before the left, indicating, as in Case R. B., the similar susceptibility of the two types of fibers to the given concentration of procaine. It is likely that the presence of hypertensive and arteriosclerotic disease limited the height to which the skin temperature rose in this individual. The contour of the curve, however, indicates that the

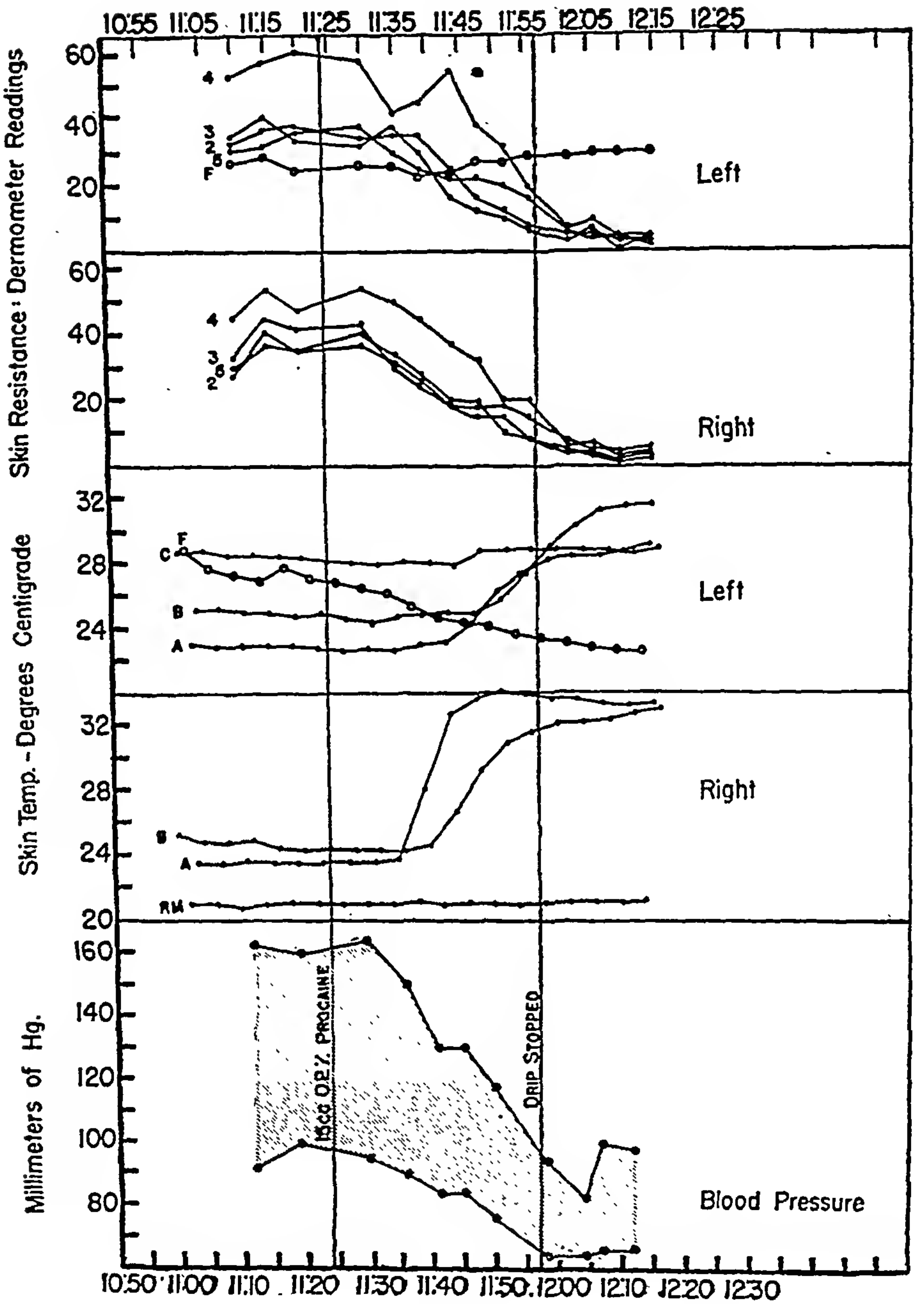

FIG. 6

Under skin resistance, the number indicates the toe examined. The plantar surface of the distal phalanx was used in each case. F indicates the readings obtained from the palmar surface of the distal phalanx of the fourth right finger. The dermometer readings are inversely proportional to the skin resistance. Under skin temperature, A represents the readings obtained from the plantar surface of the distal phalanx of the great toe, B from the medial aspect of the dorsum of the foot, and C from the inner aspect of the leg four inches above the internal malleolus. F represents readings from the palmar surface of the distal phalanx of the third right finger.

greatest vasodilatation possible in this individual with the use of a chemical block was achieved. At 4:40, there was a patchy loss of the appreciation of pin-prick on the dorsum of both feet. Complete loss of pin-prick sensation eventually rose to the fourth thoracic segment at 5:01 P.M. The remainder of the neurologic examination was negative. The systolic arterial pressure fell from the control level of 178 to 115 mm. Hg. A total of 101 mgm. of procaine was administered over a period of 47 minutes.

Case No. 4 (E. H.): Age 72, female. Amputation stump and phantom pain.

(Figure 5) Previous local nerve section in an attempt to ameliorate the pain in the absent right fifth toe, resulted in high levels of skin resistance in that foot in the control period. The vibratory sense was severely impaired during the control period. After obtaining satisfactory control levels, 15 ml. of a 0.2 per cent solution of procaine were administered between 11:17 and 11:20 A.M. From then until 11:50 A.M., 1.2 mgm. per minute of the 0.2 per cent solution was administered. Between 11:25 and 11:30 A.M. there was evidence of an increase in the skin temperature and skin resistance of the feet. The skin temperature rose to levels indicative of maximal vasodilatation. At 11:27 A.M. there was a beginning loss of appreciation of pin-prick. This eventually rose to the eighth thoracic segment. The remainder of the neurologic examination, including tickle, remained unchanged. The systolic arterial pressure fell from a control level of 185 mm. to 150 mm. Hg. A total of 66 mgm. of procaine was administered over a period of 33 minutes.

Case No. 5 (C. P.): Age 42, male. Differential diagnosis between right sciatic nerve pain and psychoneurosis.

(Figure 6) Satisfactory control levels having been obtained, 15 ml. of a 0.2 per cent solution of procaine were administered from 11:24 to 11:27 A.M. From then until 11:57 A.M., 1.6 mgm. per minute of the same solution were given. At 11:35 A.M. there was evidence of vasomotor and sudomotor block in both lower extremities. The rise in skin temperature of the right foot indicated maximal vasodilatation while that on the left resembled the curve seen with moderate peripheral vascular disease of the occlusive type. There was no dorsalis pedis pulsation to be felt on that side. The slope of the increase in skin resistance was gentler than that seen in the preceding patients. At 11:43 A.M., there was a loss of appreciation to pin-prick at the level of the third lumbar segment and this rose to the second lumbar segment at 11:46. The systolic arterial pressure fell from the control level of 161 to 82 mm. Hg. The remainder of the neurological examination remained unchanged. A total of 75 mgm. of procaine was administered over a period of 33 minutes.

Case No. 6 (J. B.): Age 42, male. Question of post-herpetic neuralgia.

(Figure 7) At the onset of this period of observation, the patient's lower extremities were quite dry and the skin resistance correspondingly high, despite the slightly higher room temperature than that generally used. A higher room temperature could not be used because the skin temperature was already at a level where further elevation would compromise the end-point for vasomotor block. Thus the sensitivity setting of the dermometer had to be set quite high. After obtaining control levels, 15 ml. of a 0.2 per cent solution of procaine were administered between 2:56 and 3:01 P.M. From then until 3:48, 1.6 mgm. per minute of the same solution were given. At 3:04 P.M., there was evidence of a rise in skin temperature and skin resistance in both lower extremities. The skin temperature rose to levels indicative of maximal vasodilatation. The rise in skin resistance was less striking and less regular than in any of the previous patients. It was thought that further drying off of a foot that is already quite dry might yield such a curve. In any case the evidence for a sudomotor block is not so clear as in the other cases observed. At 3:13 P.M., there was a loss of the appreciation of pin-prick to the level of the tenth thoracic segment. This eventually rose to the second thoracic segment at 3:38 P.M. The rest of the neurological examination remained unchanged. A total of 105 mgm. of procaine was administered over a period of 52 minutes.

Case No. 7 (J. M.): Age 21, male. Right inguinal hernia.

(Figure 8) A full spinal block was performed in this patient. He was quite apprehensive, since this procedure was performed immediately prior to operation. All premedication had been omitted for the purposes of this experiment. The room temperature was the highest used for any experiment in this series, and the patient's extremities were all obviously moist. The sensitivity setting of the dermometer thus had to be made quite low in order to bring the needle deflections within the readable scale. At 11:11 A.M., during the control period, the particular surgeon whom the patient knew was to perform the operation, came into the room and announced that they were ready to start. At 11:13 there was a sharp fall in the skin resistance. At 11:17, 100 mgm. of procaine in 4 ml. of cerebrospinal fluid were injected into the subarachnoid space at the third lumbar interspace. This was followed by the administration of 0.4 ml. per minute of a 0.5 per cent solution of the same agent. At 11:21 there was evidence of vasomotor and sudomotor block. The skin temperature of the feet rose to levels indicative of maximal vasodilatation, and the skin resistance rose sharply. The patient was not followed closely thereafter, but inasmuch as the operative procedure was completed without discomfort to the patient and with adequate muscular relaxation, it is likely that the full block was that as usually seen. At the end of the period of observation (11:32) the patient's blood pressure had risen about 5 mm. Hg.

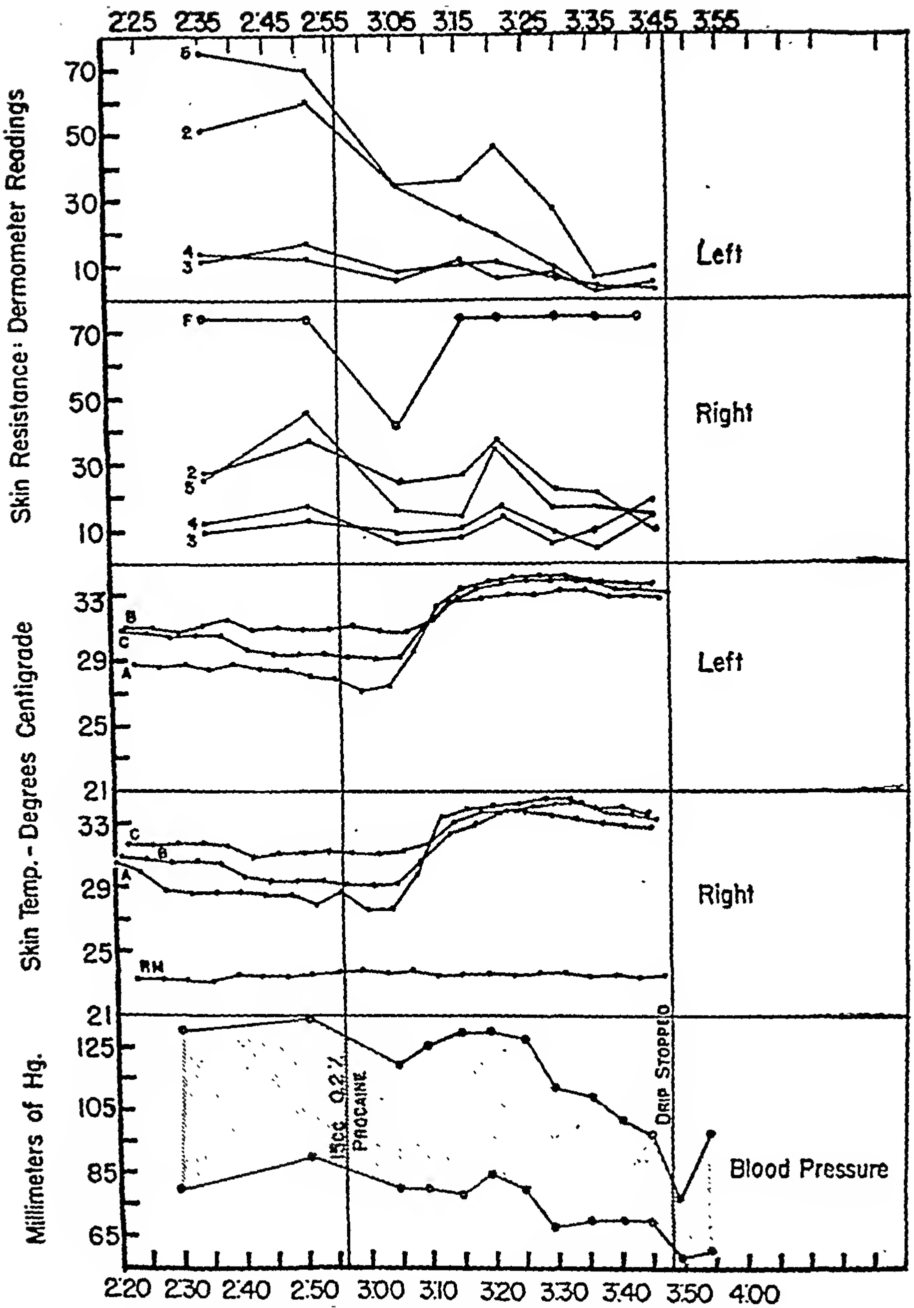

FIG. 7

Under skin resistance, the number indicates the toe examined. The plantar surface of the distal phalanx was used in each case. F indicates the readings obtained from the palmar surface of the distal phalanx of the fourth right finger. The dermometer readings are inversely proportional to the skin resistance. Under skin temperature, A represents the readings obtained from the plantar surface of the distal phalanx of the great toe, B from the medial aspect of the dorsum of the foot, and C from the inner aspect of the leg four inches above the internal malleolus. F represents readings from the palmar surface of the distal phalanx of the third right finger.

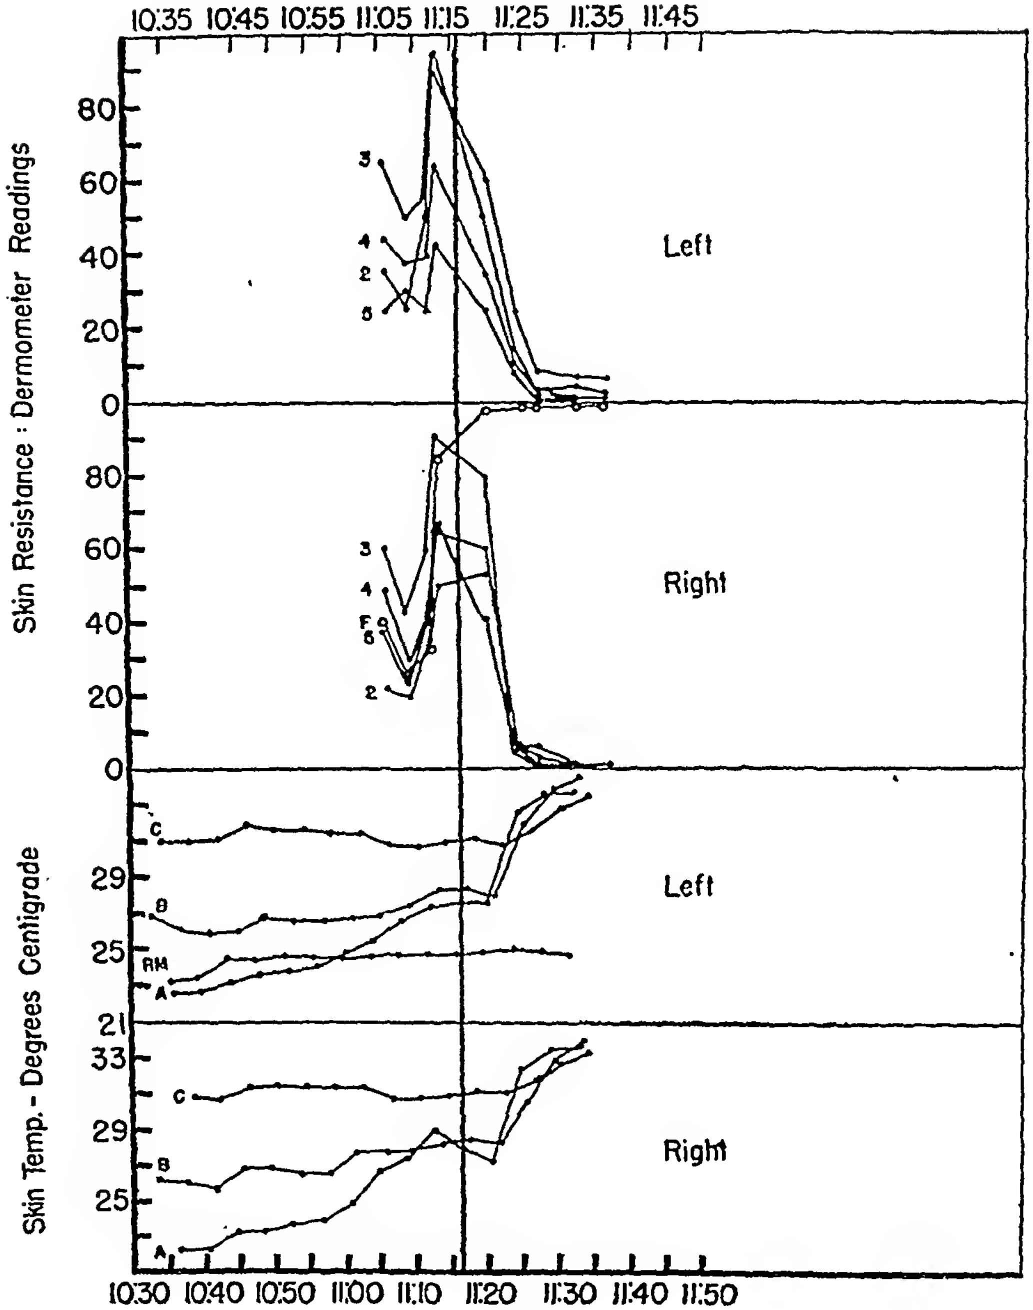

FIG. 8

Under skin resistance, the number indicates the toe examined. The plantar surface of the distal phalanx was used in each case. F indicates the readings obtained from the palmar surface of the distal phalanx of the fourth right finger. The dermometer readings are inversely proportional to the skin resistance. Under skin temperature, A represents the readings obtained from the plantar surface of the distal phalanx of the great toe, B from the medial aspect of the dorsum of the foot, and C from the inner aspect of the leg four inches above the internal malleolus. F represents readings from the palmar surface of the distal phalanx of the third right finger.

DISCUSSION

The data just presented indicate that preganglionic sudomotor fibers are blocked by the concentration of procaine which results from the dilution of the 0.2 per cent solution introduced in the amounts stated above. They are apparently blocked simultaneously with the preganglionic vasomotor fibers and either preceded or followed by a block of fibers concerned with the appreciation of pin-prick. This concentration of the

agent leaves unaffected the fibers, mediating position sense, vibratory sense, touch, deep pressure, and motor power, insofar as this is reflected by the neurological examination used. The data presented here may be considered confirmatory of the preliminary report recently published (1).

In the two patients of this series in whom tickle was tested, the sensation was unimpaired at a time when there was a complete loss of the appreciation of pin-prick. Three subsequent patients have been studied in regard to this modality. In one of these there was no impairment, in one there was partial impairment, and in one there was complete loss. It would seem therefore, that although this modality is distinct from that of appreciation of pin-prick, the fiber that subserves it is more nearly like that of the pain fiber in size and myelination than are the fibers subserving motor power, position sense, touch, and vibratory sense.

The degree of myelination and fiber size of the various components of spinal nerves have been reviewed by Ransom (13). He states that efferents to skeletal muscles are myelinated fibers, which are, for the most part, of large caliber. Touch is mediated by larger myelinated fibers, while pain is mediated by the fine myelinated or unmyelinated fibers. It is also stated that proprioceptive fibers are myelinated. Sympathetic fibers (efferent) are all finely myelinated (14).

If the assumption is made that the centrally directed axones from the spinal ganglia are similar to those of the peripheral axones, the data herewith presented would seem to be in accord with accepted morphologic data. One important exception has been noted (11) in that it has been found that the knee kicks and ankle jerks disappear at a time when position sense is unimpaired. This would make it seem that the stretch afferents differ from other proprioceptive fibers in that they are relatively small unmyelinated fibers. It should be emphasized that these data are significant only for the subarachnoid portion of the spinal nerves.

It was previously stated that a differential block, without motor loss, induced a degree of hypotension similar to that seen in full or undifferentiated spinal block (1). This was interpreted as meaning that muscular paralysis and the venular stasis that supposedly follows it contribute little to the hypotension of spinal anesthesia in the horizontal position. With one exception, the falls in arterial pressure seen in the patients of this series subjected to a differential block were of the same order of magnitude as those seen after full spinal block. This one exception (Case D. M.) failed to have a fall with a full spinal block as well, and indeed, had a slight rise. The nature of this patient's response is not clearly understood.

The technic of differential spinal block is not to be construed as an anesthetic procedure. Rather, it has proved useful in the investigation of problems concerned with the peripheral nervous system such as amputation stump and phantom limb pain (9). The technic has yielded interesting information in patients with intestinal dyskinesia and colonic atony. Since somatic motor paralysis is not present, one may introduce amounts of procaine solution high enough in the spinal canal to be sure of blocking all visceral efferents to the intestinal tract (10).

In a recently concluded study, the knee kick, ankle jerk and abdominal reflexes were examined in twelve patients under the influence of a differential spinal block as described above. It had previously been thought that position sense and the stretch afferents were, by and large, subserved by the same group of proprioceptive afferent fibers. That this is not the case is indicated by the fact that these reflexes were abolished in every case while position sense remained unchanged (11).

It had previously been demonstrated that the undifferentiated type of spinal block confers benefit upon the patient suffering from pulmonary edema due to cardiac decompensation (12). It was thought that the arteriolar dilatation would diminish the resistance against which the left ventricle would have to work, and also that the pooling of blood in the periphery would significantly diminish the return flow to the right heart. The drawback to the procedure as it was practised at that time is that a partial intercostal paralysis accompanied the peripheral pooling effect. This was felt to be hazardous in the dyspneic patient in need of full respiratory excursions. The technic of differential spinal block, however, allows one to induce the peripheral vasodilatation without the intercostal paralysis. Two patients have been so

treated and responded with a convincing clinical improvement. This was temporary in one. In one of these patients arterial and venous oxygen determinations were performed and clearly confirmed the clinical impression.

Previous data (1) demonstrated that it was possible to produce a chemical sympathectomy of the upper as well as the lower extremity by means of a differential spinal block. From the above data it can be seen that the degree of vasodilatation induced with the differential spinal block is equivalent to that induced with a full spinal block. It should therefore be useful as a prognostic technic in patients with peripheral vascular disease.

At the present time a differential spinal block is performed almost routinely preoperatively in hypertensive patients. Since the technic is essentially a reversible sympathectomy, an attempt will be made to ascertain whether or not the fall in blood pressure induced by the block will correspond to that accomplished by sympathectomy.

An interesting but as yet unexplained side effect noticed in about one-third of patients is the observation that they become distinctly somnolent at a time when procaine is high in the spinal canal.

If the basic assumption is correct, and we believe it to be so, that relative susceptibility to graded concentrations of the anesthetic agent depends upon fiber size and degree of myelination, then the above data are indicative of the nature of the preganglionic sudomotor fibers. Such a conclusion, based upon this type of clinical evidence, is in agreement with the early observations of Gaskell (14) who demonstrated that preganglionic sympathetic efferents were morphologically indistinguishable from one another.

SUMMARY

1. Preganglionic sudomotor fibers in the subarachnoid space are blocked by the introduction of appropriate amounts of 0.2 per cent procaine hydrochloride.

2. The onset of the sudomotor block is simultaneous with the paralysis of the preganglionic peripheral vasoconstrictor fibers. This is either preceded or followed by a block of fibers concerned with the appreciation of pin-prick.

3. The preganglionic sudomotor fibers are susceptible to a concentration of anesthetic agent which leaves motor, touch, deep pressure, vibratory sense, and position sense fibers intact.

4. Fibers subserving the tickle sensation are generally unaffected and are distinct from those mediating pain.

5. The rôle of muscular paralysis in the genesis of the hypotension seen with spinal anesthesia must be very limited.

would throw light on some of the ... symptoms and signs which occur during and following therapy for diabetic acidosis.

MATERIAL

Fourteen patients, ranging from ages 12–69, who entered the hospital in severe diabetic acidosis (carbon-dioxide combining power expressed as milliequivalents of bicarbonate, under 9 milliequivalents) were studied. All of these patients survived with the exception of a 56-year-old woman who died within 30 hours, with unexplained hyperpyrexia and morbilliform rash. Post-mortem examination did not contribute to the solution of the problem, although virus studies are not yet completed. Serial determinations of serum potassium, sodium, calcium, magnesium, and total protein were made on all patients, in addition to the usual determinations of blood sugar, carbon-dioxide combining power, and non-protein nitrogen. In seven of the patients pH, and albumin and globulin fractions were also determined. Phosphorus levels determined as inorganic phosphate were run on two patients.

METHODS

The pH was determined on venous blood by the use of the Beckman pH meter, serum sodium by a modification of the zinc uranyl acetate method of Barber and Kolthoff

...mer and Tisdall (7) cobalti-

...y the Clark and Collip (8)

...method, and magnesium and

...ethods from this laboratory (9,

...in fractions and total protein

...nethod of Kingsley (11), the

...the method of Benedict (14).

...calculated from the mass action

$$\frac{(\ldots\text{ate}^{=})}{(\text{Calcium Proteinate})} = 10^{-2.22}$$

(pK Calcium Proteinate = 2.2) (15).

Total protein was converted to grams per 1000 grams H_2O by the formula:

grams water per 100 ml. = 99–0.75 × protein (grams per 100 ml.) (16)

and albumin and globulin fractions corrected accordingly.

The base combining capacity of the albumin and globulin were calculated at each pH, using the values of Van Slyke, *et al.* (17).

M.eq. Base per grams albumin = 0.125 (pH − 5.16).

M.eq. Base per grams globulin = 0.077 (pH − 4.89).

RESULTS

Table I shows the changes in electrolytes, blood sugar, carbon-dioxide combining power, and non-protein nitrogen, correlated with treatment (amount of insulin, fluids, sodium, and glucose), and with the clinical state.

Certain general features appear from inspection of this table:

1. The marked acidosis, and hemoconcentration on entry. The total protein concentration was used as a gauge of hemoconcentration.
2. The fall in serum potassium concentration during therapy. In some patients the values reached critically low levels—1.9 and 2.18 M.eq.

[1] Since the preparation of this manuscript a report of 1 patient in diabetic acidosis who developed low potassium levels (2.5 milliequivalents) during therapy, which were associated with respiratory paralysis, and which responded to potassium intravenously, has appeared. Holler, Jacob W., Potassium deficiency occurring during the treatment of diabetic acidosis. J. A. M. A., 1946, 13, 1186.

* Numbers of patients correspond to numbers in Table I.

* Phosphorus calculated as $HPO_4^{=}$.

patients had levels under 4 M.eq. Small drops in concentration also occurred with therapy.

6. The wide range of blood sugar level on entry—285 to 1,092 mgm. per cent (5 patients had levels over 800 mgm. per cent), with carbon-dioxide combining power below 9 M.eq. (7 patients had values below 4.5 M.eq.).
7. The wide range of insulin requirement in the first 24 hours—110 to 1,000 units.
8. The large amount of parenteral fluid—4 to 12 liters—given in the first 24 hours, with variation in amount of sodium from 10.5 grams to 27.5 grams, and glucose from 39 to 350 grams.
9. The clinical state varied from coma to consciousness, and 5 of the 14 patients were in shock.

The same general type of electrolyte changes occurred regardless of the amount of insulin, fluids, sodium, or glucose given in the first 24 hours, the rapidity of fall of the blood sugar, or the presence or absence of coma or shock.

More detailed analyses of the changes in the potassium levels are given in Figure 1. This figure demonstrates that the lowest point in potassium concentration usually occurred within the first 24 hours. Not enough serial determinations were made to determine the exact time of the lowest level, and this may vary from patient to patient, but it was usually between 12 and 24 hours. Within 2 to 3 days, the potassium concentrations had returned to normal levels, although in several patients this was delayed for several more days. Potassium concentrations as seen in Figure 1 were usually slightly elevated on entry in the majority of instances. There was no definite correlation

between the rate of fall of the blood sugar, or the total amount of insulin and fluids given in the first 24 hours and the degree of lowering of the serum potassium. However, Figure 2 shows the close correlation in two patients (T. B., No. 1, Table I, and A. B. No. 2, Table I) between fall in blood sugar, inorganic phosphate and potassium levels.

Table II summarizes the range of potassium values found. It is seen that 6 patients (46 per cent) had low potassium values (under 4 M.eq.) and 8 patients had elevated levels (over 6 M.eq.). As it was not always possible to follow some of these patients during the first 24 hours, due to entry on holidays or at night, some abnormalities of potassium levels were doubtless missed.

TABLE II

Range of serum potassium levels in 13 patients

Potassium level	Number of patients*	Per cent of patients
meq.		*per cent*
1–3	2	15
3–4	4	31
Summary of low values	6	46
6–9	7	55
9+	1	8
Summary of high values	8	63

* The same patient may be represented under both low and high levels.

Two of the patients complained spontaneously of marked muscle weakness after therapy. Both showed low serum potassium concentrations at the time.

While the majority of the calcium concentrations fell within the normal range, it was felt that with the fluctuations in pH and albumin and globulin levels the ionized calcium values might show more variation. The relationship between the calculated ionized calcium values and the total calcium concentrations is given in Table III. While the calculated ionized calcium levels tend to follow the fall and rise in total calcium concentrations this is not a constant relationship. This is illustrated by patient B. M. No. 2, Table III. With a total calcium concentration of 5.7 M.eq. the calculated ionized calcium was 2.25 M.eq. or 39 per cent of the total calcium. With a total calcium of 4.4 M.eq. the ionized value was 2.05 M.eq. or 47 per cent of the total.

* Table I.

Magnesium concentrations fell markedly during therapy, particularly during the first 24 hours, although in some instances the maximum fall occurred later. Even after several days, the magnesium concentrations had not returned to the normal level in the majority of the patients. The range of serum magnesium levels is given in Table IV. Forty-one of the 67 determinations (61 per cent) in the 14 patients were below normal, while 11 (16 per cent) were elevated. Five patients showed very low levels—under 1 M.eq.

Correlation between the state of consciousness and the level of magnesium at entrance was found,

TABLE IV

Range of serum magnesium levels in 14 patients

	Magnesium levels	Number of determinations at level indicated	Number of patients(1)
	meq.		
Very low	0.56–1.00	5	5
Low	1.00–1.50	36	13
Normal(2)	1.50–1.92	15	11
Slightly elevated	1.92–2.30	4	3
High	2.30–3.30	7	5

(1) The same patient may be represented under each level due to changes in concentration with therapy.
(2) The normal range for the method used—1.50 to 1.92 milliequivalents.

although none of the values obtained was abnormally high. Three of the patients with magnesium levels over 2.5 M.eq. were in deep coma; one was stuporous. All eight patients with magnesium levels under 2.5 M.eq. on entry were conscious. There was no correlation between the level of magnesium at entrance and the presence or absence of hemoconcentration.

DISCUSSION

Some of the changes in the potassium, calcium, and magnesium levels are undoubtedly due to hemoconcentration or dilution, although study of Table I will show that many of the changes bear no direct relationship to this factor. The concentration of electrolytes at any one moment, regardless of total circulating amount, conditions many of their physiologic functions. This is well attested by the striking changes in the T waves in the electrocardiogram with changing levels of serum potassium (18). It has also been demonstrated that the total circulating amount of any electrolyte, particularly sodium, may be important, as seen in the clinical improvement in patients with Addison's disease after salt therapy, even before the serum sodium concentrations return to normal (19). In general the importance of potassium, calcium, and magnesium in many biologic functions has been adequately reviewed (20, 21, 22).

The marked drop in serum potassium is the most striking of the electrolyte changes noted and has not been stressed previously. The level of 1.9 M.eq. found in one of our patients is, to our knowledge, the lowest level mentioned in a diabetic. Very low levels of serum potassium have been reported in several conditions: sprue—1.1. M.eq. (23); familial periodic paralysis—1.3 M.eq. (24); Addison's disease with therapy—2.9 M.eq. (25).

In diabetes there are several factors relevant to the problem which are known to effect the serum potassium levels. Potassium moves in or out of the cell fairly closely with phosphorus and nitrogen during periods of either tissue catabolism or anabolism (26, 27). With periods of excess tissue breakdown, there is increased urinary excretion of potassium; and, conversely, during protein storage there is decreased urinary excretion of potassium. Administration of certain hormones, or their lack due to disease, can cause such shifts in potassium and nitrogen. Testosterone (28) causes protein anabolism and decreased potassium excretion in the urine, while desoxycorticosterone acetate (19) causes increased urinary excretion of potassium, and decreased extra- and intra-cellular potassium concentrations. Lack of insulin is known to lead to tissue breakdown and a negative nitrogen balance with loss of large amounts of potassium in the urine (5). Administration of insulin leads to a positive nitrogen balance and decreased urinary potassium excretion (5). As the blood levels of potassium and urinary excretion of potassium (and phosphorus) decrease after insulin, it has been suggested (28) that there is an increased intracellular level of potassium and phosphorus, possibly without increase in muscle mass. This possibility must remain a suggestion, however, until determinations of intracellular levels of potassium are made in man following insulin therapy and until the amount which may shift into the liver can be determined. In the normal individual, as well as the diabetic, insulin is known to decrease the serum potassium levels (4, 29, 30). The exact mechanism of this action of insulin on serum potassium is not known, but it has been suggested that it is correlated with shifts of glucose and phosphate into the cell, for formation of a potassium hexosephosphate (see Figure 2), or into the liver in glycogenesis (4, 29, 31, 32).

Another condition that may possibly decrease serum potassium levels in severe diabetic acidosis is the use of large amounts of intravenous saline. Administration of large volumes of fluid parenterally (isotonic) (33) causes loss of some potassium in the urine with the loss of large amounts of sodium. Whether this factor is counterbalanced in diabetics by the effect of insulin in decreasing urinary potassium excretion has not been studied.

Clinically the feature that impressed us as related to the low levels of serum potassium was the marked muscle weakness exhibited by several patients. One of these patients, following a minor insulin reaction, which was treated promptly, showed striking generalized muscle weakness and lethargy. In many respects she resembled the picture seen in familial periodic paralysis. All pa-

tients showed clinical improvement in muscle strength with rise in serum potassium levels. The relationship between muscle weakness, intracellular and extracellular potassium levels is still not settled. Following the use of testosterone, the serum potassium may drop to very low levels, with increased or normal intracellular potassium, and no associated muscle weakness (28). Desoxycorticosterone acetate therapy, if excessive, causes marked loss of potassium, and decreased intracellular potassium concentrations, and is associated with marked muscle weakness (25). In familial periodic paralysis (24) and diabetes with low serum potassium levels there is also marked muscle weakness. The drop in serum potassium concentrations, with decreased urinary excretion during insulin therapy, may be theoretically associated with either increased or decreased intracellular levels, depending on whether the shift is predominantly into the cells, or into the liver in intermediary carbohydrate metabolism and glycogen formation. That there are other factors involved in muscle strength beside intracellular potassium levels has been demonstrated experimentally in rats, who despite very low levels of muscle potassium, were still able to swim (34).

On entry, many of the patients showed elevated levels of potassium. Most of this rise in concentration can be explained on the basis of hemoconcentration. Another factor is decreased renal function secondary to shock which may occur in diabetic acidosis.

The calcium concentrations were maintained at normal or slightly low normal levels in most instances, despite the fact that in diabetic acidosis there is increased urinary excretion of calcium (5). Total circulating calcium is presumably depleted. As many diabetics show marked osteoporosis, periods of negative nitrogen balance and acidosis may be pathogenic factors. The lack of constant correlation between total calcium concentration and percentage ionized fraction is important, as the ionized fraction determines many of the physiologic effects of calcium, such as the length of the electrical systole of the heart. This suggests that both values should be determined.

The mechanism of the marked drop in magnesium concentrations during insulin therapy has not been studied. Possibilities include changes in urinary excretion or use in carbohydrate metabolism with insulin therapy. It should be noted, however, that the amount of magnesium necessary for coenzyme action in the phosphorylation of glucose would appear to be too small to account for the marked changes observed. It is interesting, but not conclusive, that there was some correlation in our series between levels of consciousness and the magnesium concentrations at entry. However, at levels similar to those found in our comatose patients, many individuals appear to have no effects or clinical symptoms. Also, many factors presumably contribute to the state of coma, and no one chemical factor is entirely responsible.

The therapeutic implications of these findings are important. The occurrence of low potassium levels after therapy in 46 per cent of the patients, and very low magnesium levels in 36 per cent of the patients, suggests that these patients should receive potassium and magnesium salts as an adjunct to other therapy. The warning should be given, however, that a diabetic patient in shock, with decreased renal function, should not receive potassium therapy because of the danger of producing dangerously high blood levels (35). This is true also for magnesium. The presumed decrease in total circulating calcium and occasional decreases in the percentage ionized fraction suggest that these salts should be beneficial, too.

SUMMARY

The results of determinations of potassium, magnesium, and calcium levels in 14 patients in severe diabetic acidosis are given.

Forty-six per cent of the patients showed a marked fall in serum potassium levels during therapy. In several patients this was associated with marked muscle weakness. It is suggested that this fall may be related to the effect of insulin on nitrogen storage and urinary excretion of potassium, and the carbohydrate cycle with passage of glucose, phosphorus, and potassium into the muscle cell, or into the liver in glycogen formation.

There was no constant correlation between total calcium concentrations and the ionized fraction. While the concentrations of calcium on entry were usually within the normal range, total circulating amount was presumably decreased, in view of the

hemoconcentration present. This may be a factor in osteoporosis.

There was a marked fall in serum magnesium concentrations in 36 per cent of the patients during therapy, and the levels returned very slowly to the normal range. No explanation can be given for this change. Elevated magnesium levels may play a rôle in the production of coma.

The therapeutic implications of these findings are discussed.

ACKNOWLEDGMENTS

Appreciation is expressed to Dr. D. G. Simonsen and Dr. John W. Mehl for help on all aspects of the chemical problems involved in this study.

STUDIES ON GANGRENE FOLLOWING COLD INJURY. I. A METHOD FOR PRODUCING GANGRENE BY MEANS OF CONTROLLED INJURY BY COLD[1]

By FREDERICK A. FUHRMAN and J. M. CRISMON

(From the Department of Physiology, Stanford University School of Medicine, Stanford University, California)

(Received for publication September 1, 1946)

INTRODUCTION

The incidence of gangrene associated with a wide variety of injuries, in which infection is not a primary factor, continues to present problems of treatment at all levels of handling military casualties from the front line dressing stations to the large general hospitals. Gangrene results from injury due to freezing, prolonged exposure to wet and cold without freezing (immersion or trench foot), burns and vascular occlusion. It seems probable that the fundamental factors responsible for the appearance of gangrene are similar in all of these cases. A more detailed examination than has previously been made of the primary mechanisms by which gangrene is produced, and the steps which may be taken to prevent its occurrence, may have wide application to the general problem of the prevention and treatment of gangrene, irrespective of the primary injury.

Local injury resulting from exposure to cold may take one of several different forms depending chiefly upon the temperature to which the part is exposed. Injury occurring after relatively brief exposure to severe cold, in which the skin and sometimes deeper tissues are actually frozen, will be referred to as "frostbite" (1). It is this type of injury with which this series of papers is primarily concerned. Exposure to milder degrees of cold, especially for long periods of time and under conditions favoring rapid transfer of heat from the body, results in a type of cold injury in which no actual freezing of tissue occurs. This "trench foot" or "immersion foot" type of injury is not specifically considered in this study, although it is recognized that the fundamental features of both may be similar.

The present investigation is an attempt to analyze the factors responsible for the production of gangrene following freezing (frostbite) and to examine methods of treatment of frostbite which are designed to prevent the appearance of gangrene or to reduce its extent. We have not been directly concerned with the surgical management of gangrene following cold injury or with nerve and vascular abnormalities which persist after the acute stages following injury by cold.

SUMMARY OF AVAILABLE PROCEDURES FOR PRODUCING EXPERIMENTAL FROSTBITE

Before it is possible to conduct an adequate study of methods for the treatment of gangrene following experimental frostbite, it is necessary first to obtain reproducible degrees of injury in experimental animals. A variety of methods have been used by previous workers for producing frostbite injury. Since in many cases the results are, to a large degree, dependent upon the method used for producing the frostbite, the available methods will be reviewed briefly.

1. *Liquid immersion.* Some of the first observations on the pathology of frostbite injury, made by Cohnheim (2), were carried out on rabbits' ears frozen by immersion in cold liquids. Lake (3) used liquid immersion in a study of experimental frostbite. Fell and Hanselman (4) produced shock in dogs by freezing the legs in CO_2 and alcohol. Recently Lange and Boyd (5) produced frostbite by liquid immersion, but the limb was first inserted into a boot of thin rubber to protect it from wetting. These authors refer to this procedure as "contact cooling."

2. *Sprays.* In early work Rischpler (6) and others (7) utilized ether spray for producing cold injury. Sprays of ethyl chloride have been used extensively by the Russian investigators Ariev (8, 9, 10) and Orlov (11).

3. *Cold air.* Exposure of a limb to moving cold air most nearly approximates the conditions under which frostbite of face, ears, and hands occurs. Ariev (12) and Ariev and Esberg (9) have reported results obtained by the use of this method. Greene (13) obtained a "stand-

[1] The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Stanford University.

ard frostbite" of mouse tails by the use of a small chamber containing the tail, surrounded by a larger chamber filled with solid carbon dioxide.

4. *Direct contact with cold solids.* Precooled metal bars were applied to the skin by Lewis and Love (14) for the production of cold injury. The direct application of solid carbon dioxide to the skin was used by Harkins and Harmon (15) and Tittel (16) and beakers containing solid carbon dioxide were used by Lange and Boyd (5).

The method selected for the production of quantitative frostbite should be one which is applicable to fingers and toes, since injuries in man most often involve these parts (12, 7). Uniform cooling of all surfaces of these parts is difficult by means of the direct application of cold solids. The spraying of volatile liquids upon the skin of appendages is also difficult to control in extent and might be expected to be much more variable in effect than cold air or liquid applied directly. While it is true, as Ariev points out, that cold air is most nearly comparable to the conditions under which frostbite sometimes occurs in man, it does not seem so suitable as liquid immersion for the purposes of producing a quantitative frostbite in experimental animals. The cooling effect of the air is dependent not only upon the temperature, but also upon the air velocity, thus introducing an additional variable. Very long exposures to cold air are necessary to produce frostbite if the velocity is low. Ariev (12) found that after exposing rabbits' ears to still air at a temperature of − 40° C., the ears were still at a temperature of + 11° C. after 4 hours.

The method which we have selected for the production of experimental frostbite involves the immersion of an extremity in a liquid mixture cooled to the desired temperature. Frostbite of rabbits' feet and ears has been compared using varied temperatures from − 10° C. to − 55° C. for a constant time, and using varied times of exposure at − 55° C. Frostbitten extremities in which the injury was produced by exposure to cold air have been compared to those in which the injury was produced by immersion.

Conditions for the production of quantitative frostbite

Rabbits' feet and ears were frozen by immersion in a liquid mixture consisting of 50 per cent by volume ethylene glycol in water, to which were added 150 ml. per liter of 95 per cent ethyl alcohol. This mixture was cooled as needed by the addition of solid carbon dioxide. A mixture of this composition is suitable for cooling to about − 55° C., at which temperature it is still fluid. Lower temperatures may be achieved by the addition of larger amounts of alcohol and CO_2. The relatively high specific heat of this liquid makes it preferable to ether or acetone which have been used by other workers.

Rabbits were anesthetized by the administration intraperitoneally of dial, 90 mgm. per kgm. Occasional experiments were done using pentobarbital (37.5 mgm. per kgm.) anesthesia. The hair was removed from the area to be frostbitten by close clipping (Oster small animal clipper, size 40 blades). Immediately before frostbite the barbiturate anesthesia was supplemented with ether to the point of disappearance of the corneal reflex. This level of anesthesia was found to be necessary to prevent struggling during the period when freezing of the tissue occurred. Hind feet of rabbits were immersed in the freezing mixture as far as the tuberosity at the base of the fifth metatarsal. The distal 4 to 5 cm. of rabbits' ears were frozen in a similar manner. During the period of immersion the ear or foot was kept in motion in order to equalize the temperature of the liquid immediately surrounding it.

Frostbite was produced in a few animals under barbiturate anesthesia only, and in one with local anesthesia (procaine infiltration). The course following injury was not different from that occurring after barbiturate-ether anesthesia.

The ethylene glycol-alcohol mixture was tested for possible irritant properties by immersing rabbits' feet and ears in it at room temperature for periods as long as 30 minutes. These immersions were not followed by hyperemia or by visible alterations of any kind from the time of removal of the part from the mixture to the end of the observation period 3 weeks later.

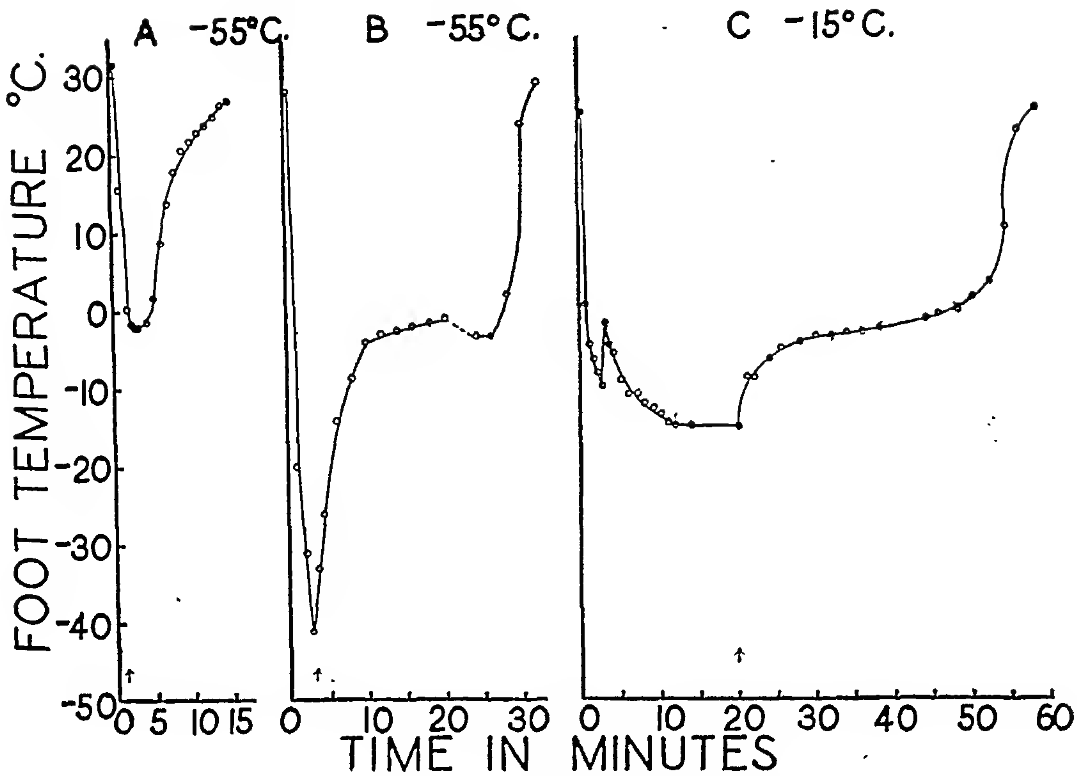
For comparison with the results obtained by immersion in cold liquids, a few rabbits' feet and ears were frostbitten by exposure to a blast of cold air at approximately − 68° C. Compressed air at approximately 18 pounds per square inch pressure was dried, cooled by passing through a chamber filled with solid carbon dioxide, and then directed into a second chamber of about 1 liter capacity which contained the foot or ear to be frozen.

The temperatures of the liquid mixtures and cooled air were measured with Weston bi-metallic thermometers which were checked at intervals by comparison with mercury thermometers.

Deep tissue temperatures in rabbits' feet during immersion in freezing liquid

In order to determine the extent of temperature reduction during frostbite, thermocouples were implanted in the feet of anesthetized rabbits and the temperature determined during immersion in the freezing liquid and during the thawing period after removal from the cold liquid.

A thermocouple made of No. 26 gauge iron-constantan wire was inserted into the foot above the level of immersion and thrust distally deep into the foot at the base of the toes. Temperatures were determined by means of a Leeds and Northrup type K potentiometer. Temperature measurements were made during three different types of frostbite: (a) 1-minute immersion at − 55° C., (b) 3-minute immersion at − 55° C., and (c) 20-minute immersion at − 15° C. The results of representative experiments are given in Figure 1.



DEEP TISSUE TEMPERATURE CHANGES IN RABBITS' FEET DURING FREEZING AND THAWING

Temperature measurements made by means of thermocouples implanted deep in the foot near the base of the toes. See text for complete description. In each case the foot was immersed in the freezing liquid at 0 time and withdrawn at the time indicated by the arrow.

FIG. 1–A. 1-minute immersion at − 55° C.

FIG. 1–B. 3-minute immersion at − 55° C. Thermocouple moved slightly in foot at point indicated by dotted line.

FIG. 1–C. 20-minute immersion at − 15° C. The break in the curve at 3 minutes represents temperature changes resulting from supercooling (see text).

During 1-minute immersion at − 55° C. the deep tissue temperature falls to approximately zero (Figure 1–A). Removal from the liquid is followed by a slight additional fall in temperature to about − 2° C. Upon removal the foot is stiff and the superficial tissues are solidly frozen. The foot remains frozen (with deep temperature at 0° or below) for about 5 minutes, and then warms until it reaches 27° C. after about 15 minutes.

During 3-minute immersion at − 55° C. the lowest temperature reached by the deep tissues was − 40° C. (Figure 1–B). After removal from the freezing mixture the foot warmed slowly until blood flow was reestablished 27 minutes after immersion. Rapid warming of the foot by the blood then raised the temperature to about 30° C. within the next 5 minutes.

During immersion at − 15° C. the foot froze after about 3 minutes and reached temperature equilibrium with the bath in 12 minutes (Figure 1–C). The phenomenon of supercooling, which has been observed frequently in biological material (17), is well illustrated in Figure 1–C. The foot cooled to − 9.4° C. in 155 seconds without freezing. During the next 28 seconds the temperature increased to − 1.5° C. and freezing occurred. The frozen foot then cooled to the temperature of the liquid. After removal from the freezing mixture the foot temperature remained below zero for 28 minutes and then increased rapidly.

EXPERIMENTAL RESULTS

Incidence of gangrene and extent of tissue loss following untreated cold injury

The general course of events leading to gangrene in frostbitten ears and feet will be considered in a subsequent paper. The data given here illustrate the uniformity with which gangrene is produced by controlled cold injury and serve as the basis for evaluation of the methods of treatment to be discussed later.

1. *Frostbite of rabbit ears*

Following immersion of the ear for time periods ranging from 60 seconds to 10 minutes, at temperatures from − 32° C. to − 70° C., the entire frostbitten portion of the ear became gangrenous and was eventually lost. Shorter periods of immersion at − 55° C. led to loss of varying amounts of the distal part of the ear.

In two animals the ears were frostbitten by means of an air blast at a temperature of − 68° C. In one case, after a 2-minute exposure, the ear became edematous, but no loss of tissue occurred. In the other, after 4-minute exposure, complete loss of the injured region resulted.

The data showing the extent of tissue loss together with the time after exposure at which gangrene appeared are given in Table I. The injuries selected for the study of methods of treatment were (a) 1½-minute immersion at − 55° C., and (b) 1-minute immersion at − 55° C. The extent of tissue loss and the extent and rate of development of gangrene following these injuries were quite uniform, as may be seen from Table I. In every instance the whole of the distal portion of the ear to the point of immersion became gangrenous and separation occurred at the line to which the ear had been immersed. Following 1½-minute exposure at − 55° C., wet gangrene appeared in about 70 per cent of the animals on the third day after immersion and drying occurred on the fifth day. Following 1-minute exposure at − 55° C., 80 per cent of the animals developed wet gangrene on the third day and dry gangrene on the fifth day. The time of separation of the injured part of the ear varied somewhat depending upon the activity of the animal in the cage.

3	−35	2	50	50	0	50	0	50
60	−15	4	0	100	0	0	25	75

Series 1 consisted of animals in which one hind foot was immersed for 1, 2 or 3 minutes at a temperature of − 55° C. Following immersion for *1 minute* no loss of tissue occurred in 92 per cent of the animals, and gangrene did not develop in spite of massive edema. After 4 to 7 days the only consequences of the frostbite were thickening of the toe pads and slight to moderate induration of the foot. Following immersion for *2 minutes* gangrene appeared on the toes after the times given in Table III. Spontaneous amputation of the toes took place at varying times after the initial injury. The foot showed some scarring on the dorsum near the base of the toes and sometimes along the edges of the foot extending 0.5 to 1 cm. proximally. The stump was thickened, especially at the distal margin. Immersion at − 55° C. for *3 minutes* resulted in complete loss of the foot as far proximally as the line to which it was immersed in 69 per cent of the cases, and loss of the entire foot with the exception of a narrow tongue of tissue on the plantar surface in 25 per cent of the animals. The incidence of gangrene is given in Table III. Separation near the line of immersion occurred spontaneously; in some cases separation occurred 1 to 2 cm. distal to the line of immersion leaving a dry stump which was then worn away by the movements of the animal.

Series 2 consisted of animals in which one hind foot was immersed for a constant time (3 minutes) at − 45°, − 35°, − 25° and − 15° C. The extent of tissue loss is given in Table II and the incidence of gangrene in Table III. Freezing of the foot did not occur at − 15° C. in 3 minutes. At the other temperatures gangrene developed and varying amounts of tissue were lost, the injury being more severe at the lower temperature.

Series 3 consisted of animals in which one hind foot was immersed for longer periods of time, up to 1 hour, at − 15° C. Freezing of the foot usually occurred after 10 to 15 minutes at this temperature. In one animal, given a supplementary dose of pentobarbital immediately before frostbite and requiring artificial respiration, the foot did not freeze during 1 hour at − 15° C. When freezing did not occur edema was absent and gangrene did not develop. Following immersion of 60 minutes at − 15° C. the final tissue loss involved the entire foot in 2 cases and all except a narrow segment of the plantar surface in two others. The foot retained a flattened shape, with toes spread, for several weeks, and induration was severe. Gangrene developed somewhat later in these animals than in those injured at lower temperatures (Table III).

The animals comprising Series 1 and those in Series 3 injured by immersion for 60 minutes at − 15° C. serve as controls for evaluation of methods of treatment of experimental cold injury to be considered in a subsequent paper.

Effect of precooling on the extent of tissue loss following frostbite of rabbit feet

In three animals the foot was immersed in the liquid mixture at a temperature of 0° to + 2° C. for 30 minutes preceding a frostbite of 1-minute duration at − 55° C. In all instances the resulting injury was more severe than following a frostbite of only 1 minute at − 55° C. Parts of the toes of all three animals were lost; in one the loss involved one toe and the distal phalanx of another; in the second, only the distal phalanx of one toe; and in the third, the distal and middle phalanges of two toes. In contrast to these results, frostbite of 1 minute at − 55° C. without precooling usually resulted in no loss of tissues, but only thickening of the toe pads (Table II).

One animal was placed in a cold room at + 4° C. for 2 days preceding frostbite. The hair had been removed from both feet. Exposure of one foot for 1 minute at − 55° C. immediately upon removal from the cold room resulted only in the usual thickening of toe pads and no loss of tissue. The rectal temperature upon removal from the cold room was 38.7° C.

On one animal the hair was removed from both feet and the animal was placed in the cold room at + 4° C. for 24 hours. The animal was then anesthetized with dial and returned to the cold room for 2 hours, by which time the rectal temperature had fallen to 35° C. Following frostbite for 1 minute at − 55° C. the foot was slightly thickened, but no loss of tissue ensued.

SUMMARY

Controlled cold injury (frostbite) of rabbit ears and feet was produced by immersion of the depilated part in a water-ethylene glycol-alcohol mixture cooled to the desired temperature by means of the addition of solid carbon dioxide.

The immersion of ears of anesthetized rabbits in liquid at temperatures ranging from − 32° C. to − 70° C. for periods of 1 to 10 minutes resulted in freezing of the ear, edema, gangrene and spontaneous amputation of the entire injured part of the ear. Immersion for 15 or 30 seconds at − 55° C. resulted in loss of about 80 per cent of the injured part of the ear.

The effects of immersion of the hind feet of anesthetized rabbits in cold liquid varying from − 15° C. to − 55° C. for different lengths of time were determined. At − 55° C. the extent of tissue loss could be increased by increasing the duration of exposure from 1 to 4 minutes. At − 15° C. the deep tissue temperature of a foot became equal to that of the bath in 15 minutes. At this temperature the extent of tissue loss could also be increased by increasing the duration of exposure. When the time of exposure was maintained constant at 3 minutes and the bath temperature varied from − 15° C. to − 45° C., progressively greater loss of tissue was encountered with reduction of exposure temperature.

Precooling of feet for 30 minutes at about + 2° C. increased the severity of injury following a subsequent exposure for 1 minute at − 55° C. Gangrene did not result from exposure for 1 hour at − 15° C. if freezing of the tissue did not occur. Gangrene resulting from cold injury was qualitatively identical in each case regardless of the time or temperature of exposure.

Readily reproducible degrees of injury and amounts of tissue loss could be obtained by exposure at a given temperature for a given period of time.

ACKNOWLEDGMENT

The authors are grateful to Alexis I. Shelokov for his excellent translation from the Russian of the papers by Ariev, Orlov, Girgolav and Sheinis cited in the bibliographies of the papers in this series. The aid of Geraldine J. Fuhrman in carrying out many of the experiments in this study and the technical assistance of Ruth L. Dryer and Benjamin Bloom throughout the course of this work are greatly appreciated.

STUDIES ON GANGRENE FOLLOWING COLD INJURY. II. GENERAL COURSE OF EVENTS IN RABBIT FEET AND EARS FOLLOWING UNTREATED COLD INJURY[1]

By FREDERICK A. FUHRMAN and J. M. CRISMON

(From the Department of Physiology, Stanford University School of Medicine, Stanford University, California)

(Received for publication September 1, 1946)

In part I of this series (1) a method for the production of controlled cold injury (frostbite) of the ears and feet of rabbits was described, and data were given illustrating the incidence of gangrene and extent of tissue loss following injury. The general course of events, including gross changes, skin color, and temperature measurements of injured ears and feet will be given here.

EXPERIMENTAL RESULTS

A. Gross changes following injury

Following immersion of the ear of rabbits for periods ranging from 60 seconds to 10 minutes, at temperatures from − 32° C. to − 70° C., the entire frostbitten portion of the ear becomes gangrenous and is eventually lost (1). Loss of the entire injured part of hind feet occurs after exposure for 3 minutes at temperatures of − 45° C. or lower and after 60 minute exposure at − 15° C. The gross changes following injury of various degrees in which actual freezing of the tissues occurs are at first similar enough so that a general description will suffice.

Immediately upon removal from the freezing mixture the ear or foot is solidly frozen, stiff and pale greyish-pink in color (Figure 1–A). The ear and toes are not "brittle" in that they cannot be broken when bent between the fingers. This observation is in agreement with the work of Ariev (2) who found that brittleness of frozen fingers, ears, and whole frogs and mice did not occur until a tissue temperature of about − 80° C. was reached.

In ears, thawing is first evident in the region immediately surrounding the central artery and in the proximal frostbitten region immediately distal to the unfrozen part of the ear. After about 3 minutes, blood flow in the larger vessels becomes apparent. Within 5 minutes, the frozen region is thawed. The vessels are engorged with blood and the temperature of the frostbitten portion of the ear rises rapidly. Swelling of the ear is first evident in the region immediately surrounding the larger vessels, especially around the central artery. The edema first involves only the frostbitten region and then extends proximally until the entire ear is swollen to approximately 4 times the initial volume (3). During the first several hours after injury the advancing edge of the edematous area is clearly visible and may be seen to progress proximally toward the base of the ear. This edge is frequently pointed in the center, with the point lying in the region of the central artery. Blisters form on the inner surface of the frostbitten portion of the ear about 1 to 6 hours after frostbite. They are most commonly seen overlying the central artery, about 1 cm. from the tip. Profuse exudation of fluid from the injured portion of the ear is seen 1 to 2 days after frostbite. A crust of dried protein usually forms.

Three to 4 days after injury the frostbitten portion of the ear becomes cool and the cartilage of this region appears to be entirely lacking in elasticity. This change marks the beginning of the period of "wet gangrene" during which no blood flow is demonstrable. Drying becomes grossly evident by the fourth to the sixth day. Fluid loss from the gangrenous tissue occurs largely by surface evaporation, although in the earlier stages some may be taken up via the lymphatics and intact circulation of the neighboring normal tissue. The dried mummified part may remain attached for several weeks but is eventually lost. Loss of tissue has in all cases involved only the frostbitten area and does not extend into the proximal, un-

[1] The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Stanford University.

injured portion of the ear. The edge of the surviving stump is at first somewhat red and thickened by induration. The redness and induration disappear within a few weeks and are replaced by firm scar tissue well covered by hair-free epithelium at the edge where separation occurred.

In feet, thawing begins at the proximal part of the frostbitten region. It occurs first superficially, and the skin may become pliable while the deeper tissues are still hard. Once the foot is thawed it warms rapidly to temperatures about 5° C. below body temperature. Swelling begins when blood flow is reestablished. It occurs first only in the injured region, and then extends up the leg (Fig. 1–B). The color of the foot becomes darker within 2 hours; at this and somewhat later times the dorsal surface of the foot may be engorged with blood, extremely cyanotic, and moist. Exudation occurs through any skin abrasions. Swelling reaches a maximum in the frostbitten region within 6 hours after injury, although further fluid loss to the foot may occur after this time (3). Since the skin over the frostbitten part of the foot is maximally distended, the fluid is forced into the leg and may reach the thigh. After 1 to 4 hours, blisters appear on the hair-free toe pads and are always confined to that region. The edema begins to diminish after 1 to 3 days, depending upon the severity of the injury. Exudation and wet gangrene follow severe injuries (1). Fluid is lost both externally and internally as in the ears. The foot shrinks and areas of wet gangrene become dry within 2 to 3 days (Figure 1–C). The dried, mummified part remains attached for several weeks (Figure 1–D). In a few cases (about 2 per cent, all involving colored rabbits) the animals chewed the dead portions and rapidly removed the stump. More often it was worn away by the movement of the animals in the cage or separated spontaneously after about 3 weeks.

B. Skin color changes following injury

In spite of the ultimate development of gangrene in frostbitten ears and feet of rabbits there is abundant evidence that, for some period between the moment of injury by cold and the appearance of unmistakable signs of ischemia and death of tissue, blood flows through the injured region, often at faster rates than are encountered in uninjured tissues.

In the period immediately after the frozen part is removed from the freezing mixture and before the completion of thawing, the skin color changes from a faintly pink, opaque grey to bright pink. The bright pink color appears first over the large blood vessels and is most strikingly apparent in the ear. The color change in the ear is noticeable within the first 3 minutes after removal from the freezing mixture. Within 5 minutes, the pink color deepens to a bright red and spreads in all directions from the larger vessels. Edema formation begins early in this period of hyperemia, but, in spite of the accumulating fluid, the injured part does not begin to take on a cyanotic appearance until the edema is well advanced. In sharp contrast to the persistent bright red color of the injured regions when they are allowed to thaw at room temperature is the immediate deep cyanosis that is produced by rapid thawing of the tissues in water at 41° to 42° C. (a method of treatment to be described later). In the rapidly thawed ears and feet, good arterial pulses can be felt, but cyanosis is present and marked from the time of return of blood flow.

Examination of the central artery of the ear in the region proximal to the injured portion shows that the period of marked dilatation lasts for about 1 hour after frostbite. Between the first and second hour after frostbite, there is a progressive constriction of the central artery in the normal part of the ear while the portion of the artery within the injured area retains its wide diameter. Close observation with the aid of transillumination shows that the apparent gross diameter of this vessel does not correspond with the width of the column of blood contained but is, in part, due to perivascular edema.

In general, skin color of the normal part of the ear parallels accurately the changes in blood flow which are indicated by the skin temperature measurements described below. Between 4 and 24 hours after frostbite, the massive edema and hyperemia tend to obscure the early sharp differentiation between the appearance of the frostbitten and the normal part, but demarcation of the two regions again becomes clear with the development of deepening cyanosis of the injured area. The

association of the cyanosis with reduced flow of blood is indicated by the accompanying fall in skin temperature of the distal portion of the ear as compared with the uninjured portion and by the weakening and final disappearance of palpable pulsations in the distal segment of the central artery.

While the details of the circulation cannot be so clearly made out in the frostbitten feet of rabbits, the changes in skin color are very similar to those observed in the ears.

C. *Skin temperature changes following cold injury*

1. *Methods for measurement of skin temperature*

Measurements of skin temperature of rabbit feet and ears following frostbite were made continuously during the first day following injury and at intervals during the next 120 hours. Readings were taken routinely for 5 minutes with each of 5 iron-constantan thermocouples which were soldered to thin copper discs 7 mm. in diameter and secured to the skin by means of "Sealskin" (polyvinyl butyral in isopropyl alcohol and castor oil). Temperatures were recorded on a Leeds and Northrup Micromax recording potentiometer.

On frostbitten feet the thermocouples were placed between the third and fourth toes and on the dorsal and plantar surfaces of the foot in the midline, about 1.5 cm. proximal to the base of the toes. On the normal foot the thermocouples were placed in the same relative positions, although in many cases only the toe and dorsum temperatures of the normal foot were measured.

On frostbitten ears one thermocouple was placed about 1 cm. from the margin and far enough laterally from the midline to avoid the central artery, another about 2 to 3 cm. proximal to this in the injured region, and a third about 3 cm. proximal to the line to which the ear was immersed.

Although the measurements of skin temperature were not made in a constant temperature room, the air temperature of the laboratory was relatively constant (25° C.) and varied only about ± 1° C. from day to day and throughout a single day. Care was taken to shield the thermocouples from ambient air currents by use of a tubular gauze sock slipped over the ear or foot after the thermocouples were in place. Some experiments were carried out with the foot or ear encased in a cellophane jacket. It was found that the skin temperature changes were very similar whether or not the cellophane jackets were used, except that gangrenous toes and tips of ears tended to be warmed by the warm air inside the cellophane. The experiments reported are those in which cellophane was not used.

2. *Time course of temperature changes following injury*

Following 60- or 90-second exposure of an ear at − 55° C., the temperature of the frostbitten portion increases rapidly until the maximum is reached in 20 to 60 minutes. This temperature is usually 32° C. to 35.5° C. The proximal, uninjured part of the frostbitten ear is usually several degrees warmer than that of the contralateral ear. The temperature of the frostbitten part of the ear is maintained within a few degrees of the maximum temperature attained for the first 3 to 5 hours following injury; after this a progressive fall in skin temperature is observed. Figure 2 shows the mean skin temperature of the ears of 3 animals for 120 hours following 90-second immersion at − 55° C. It is clear from this figure that the mean temperature of the tip of the injured ears is lower than that of the normal ears 5 hours after injury and that it falls continuously during the first 50 hours after injury until it reaches a level 1° to 2° C. above room temperature. Wet gangrene appears about 48 hours after injury and drying occurs after 72 hours. Thus the reduction in blood flow to the ear is not immediately brought about by frostbite but is a continuous process occurring during the first 50 hours after exposure. The stabilization of skin temperature of the injured region at a low level marks the beginning of the stage of wet gangrene.

FIG. 1. GENERAL COURSE OF EVENTS FOLLOWING FROSTBITE OF RABBIT FEET PRODUCED BY LIQUID IMMERSION

A. Appearance of frozen foot, 20 minutes after removal from freezing mixture at − 52° C. (3 minute immersion). Thawing has not yet occurred.

B. Edematous foot 3 hours after immersion for 3 minutes at − 45° C. Foot volume 2.6 times initial volume.

C. Appearance of foot 4 days after injury produced by immersion for 3 minutes at − 55° C. showing wet gangrene on the dorsal surface.

D. Dry, mummified foot 7 days after frostbite produced by immersion for 3 minutes at − 55° C.

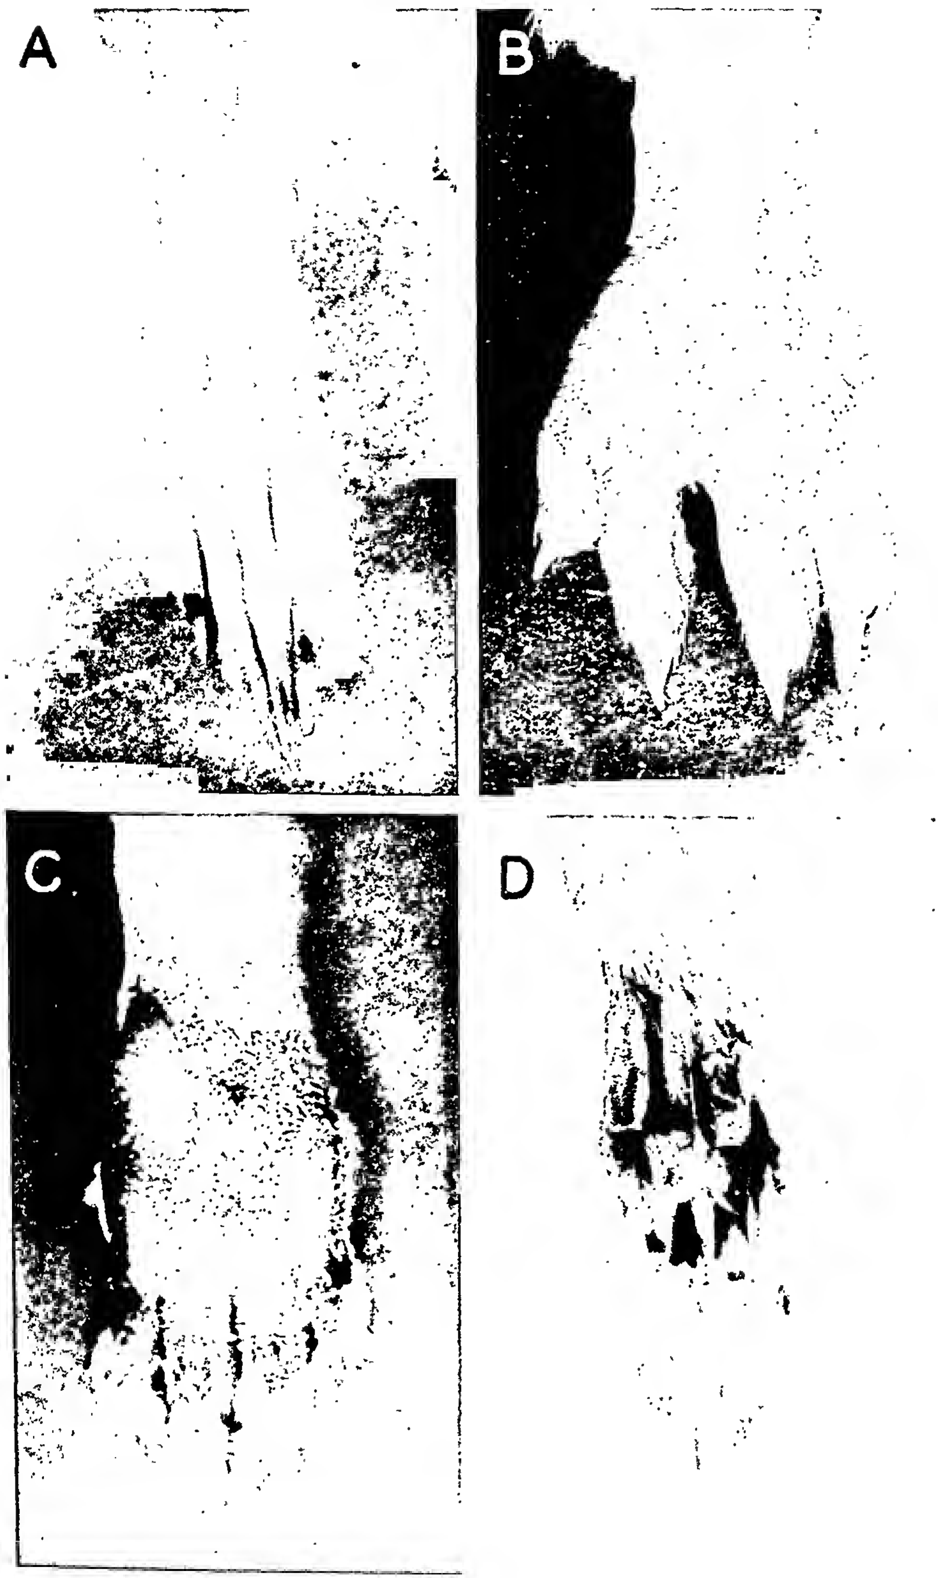

FIG. 1

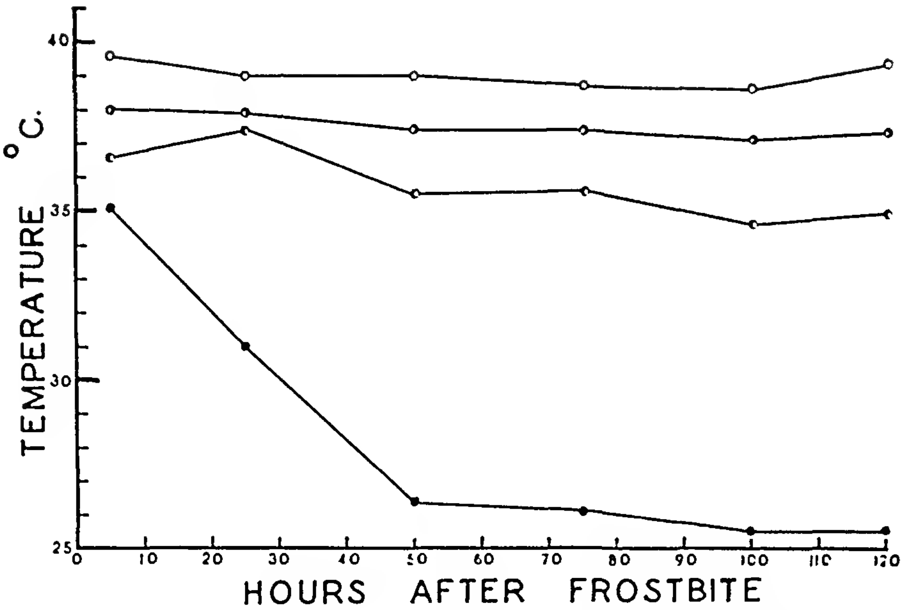

FIG. 2. TIME COURSE OF SKIN TEMPERATURE CHANGES IN RABBIT EARS AFTER EXPOSURE OF THE DISTAL PART OF THE EARS AT − 55° C. FOR 90 SECONDS. RECTAL TEMPERATURES ARE ALSO SHOWN

Mean data from three animals are plotted in the figure.

◐ ....Tip of normal ear
Solid circles........Tip of frostbitten ear

Rabbits' feet removed from the freezing liquid remain solidly frozen for about 20 minutes after 3-minute immersion at − 55° C. After thawing, the temperature rises rapidly as blood flow to the injured region is reestablished. Within 1 hour the temperature of the frostbitten toes reaches a maximum of 28° to 31° C. This temperature is maintained for a variable period, sometimes not more than 20 to 30 minutes; a progressive fall in temperature of the toes then occurs until it reaches 26° to 30° C. after 4 hours. The maximum temperature of the dorsum of the injured foot is attained 20 to 30 minutes earlier than that of the toes and remains 2° to 3° above that of the toes. After 4 hours it has fallen to 31° to 33° C. Figure 3 shows the mean temperatures of frostbitten feet (3 minutes exposure at − 55° C.) and the contralateral feet of three animals during a period of 120 hours after injury. It may be seen that the dorsum and toes of the frostbitten feet show consistently lower temperatures than does the dorsum of the normal foot for the first 50 hours after injury. After this time the skin temperatures of the dorsal surfaces of the injured and normal feet closely parallel each other. The temperature of the frostbitten toes remains lowest during the entire time and eventually falls even farther when the toes dry and become mummified. The tissue loss in these animals (Figure 3) involves the toes and most of the dorsal surface of the feet. The relatively high temperature of the dorsum of the injured feet may be attributed to persistence of blood flow in deeper vessels, arising from the plantar arch. A limited number of measurements of skin temperature of the plantar surface of the foot indicates that it may be several degrees higher than that of the dorsal surface.

When the foot is exposed at − 55° C. for only 1 minute, which usually produces only severe edema but no loss of tissue, the initial temperatures which are attained by the toes of the frostbitten foot are higher than after 3 minutes of exposure. Within 1 hour after injury the toes usually reach a temperature of about 35° C. (33° to 38° C.), and then fall several degrees during the first 4 hours. The temperature of the dorsum of the frostbitten foot is often 1° to 2° C. higher than that of the contralateral dorsum. In 2 animals, in which the toes were lost following a 1-minute exposure at − 55° C., the temperature of the toes

dropped sharply after 40 to 50 hours to a level only 2° to 3° C. above room temperature. This drop in temperature of the toes, which are eventually lost, is progressive and coincides in time with the other local signs of gangrene.

3. *Relationship of skin temperature changes to tissue loss*

The temperatures of normal and frostbitten feet have been further analyzed in consideration of the extent of subsequent tissue loss in the injured feet. The temperature of the toes of the frostbitten foot has been compared with the temperature of the dorsal surface of the normal foot of the same animal at various times during the first 6 hours after injury. The data for these comparisons are given in Table I.

The column in Table I headed "Temperature difference" gives for each animal the mean of a number of comparisons between the temperatures of the injured toes and the dorsum of the normal foot during the first 6 hours. The column headed "P" expresses the probability that such differences would occur through errors in random sampling. These probabilities were calculated by the "t" test of Fisher (4).

TABLE I

Comparison of skin temperatures during the first six hours after injury in normal and frostbitten rabbit feet
Feet frostbitten by immersion at −55° C. for the time indicated

Duration	Tissue loss	Skin temperature. Mean of determinations during first six hours		Temperature diff. ° C.	P[1]
		Frostbitten	Normal	FB–N

ture were found to be of decided value in predicting the ultimate loss of tissue. The data in the table illustrate the association of low skin temperature of the injured parts and eventual development of gangrene. Following 1-minute exposure at − 55° C., in the animals in which no tissue loss resulted, the mean temperature differences between the normal and injured feet ranged from + 4.0° to − 1.9° C. and the probability that such differences would occur through errors in random sampling ranged from 2 in 100 to 50 in 100 ($P = 0.02$ to 0.5). For comparison with these are 2 animals which lost parts of the toes following exposure for 1 minute at − 55° C. In both of these animals the temperature of the toes of the injured foot was consistently lower than that of the normal foot. The smaller values of P (< 0.01 and 0.001 respectively) indicate that the differences are statistically significant. Following 3-minute exposure at − 55° C., the temperature of the injured feet was always lower than that of the normal feet and these differences are also statistically significant ($P < 0.001$). From the data given in Table I it is apparent that as early as the first 6 hours after injury the temperature of the toes of the injured foot is significantly lower than that of the normal foot in those animals in which the toes are subsequently lost. As described previously this temperature difference becomes more marked with time, so that with the appearance of wet gangrene the temperature of the gangrenous part is only slightly above that of the environment.

4. *Vascular spasm in extremities during the first hours after injury*

Temperature changes in frostbitten and normal extremities of rabbits have been studied during

the application of heat and cold generally as well as locally to a part remote from that injured by frostbite. In all cases the experiments were carried out during the 7-hour period immediately following frostbite, at a time when the animals were still anesthetized with dial. The dial was given, in most cases, approximately 1 hour before frostbite.

Similar results have been obtained in a number of animals. A representative experiment is plotted in Figure 4. One hind foot was frostbitten for 3 minutes at − 55° C. Application of cold to the ears at "A" and to the body at "D" resulted in a temperature drop in the toes of the normal foot of 8.5° and 12° C. respectively, while the toes of the frostbitten foot showed much less change in temperature. Application of heat to the ears at "B" and general body warming at "C" and "E" resulted in marked rise in temperature of the normal toes. It is apparent (Figure 4) that after the first 1½ hours there is a tendency for changes in rectal temperature to be accompanied by changes in skin temperature of the toes of the frostbitten foot.

The temperature changes in the toes of the animal illustrated in Figure 4 and in other animals studied are brought about by changes in blood flow through the tissues. Tittel (5), by direct observation of rabbit ears frozen with solid carbon dioxide, has described a state of passive dilatation of arterioles in the injured region of the ear. This passive dilatation should be regarded as a relative dilatation, and, although constriction may not occur, the size of the vessels may be altered by changes in perfusion pressure. If the arterioles within the injured regions of the feet are in a state of passive dilatation similar to that described by Tittel in rabbit ears following freezing, then blood flow and hence skin temperature should be determined by the perfusion pressure and the patency of the arteries proximal to the level of injury. The rise of skin temperature in uninjured regions following general application of heat demonstrates the existence of adequate systemic arterial pressure. In the injured limb both the failure of signs of vasoconstriction after chilling and of vasodilatation after warming could be explained on the basis of severe spasm of the arteries proximal to the level of injury. Such arterial spasm has been described by Burdenko (6) in human frostbite of the feet where arterial spasm reached as high as the common iliacs. The measurements given in Figure 4 show that the temperatures of the toes of the frostbitten foot were persistently lower than the toes of the normal foot. The course of cooling of the toes in the injured foot shows that there was a progressive reduction of blood flow from 45 minutes after injury to about 2½ hours after injury. The slope of this line differs little from that describing the fall in temperature of the normal toes when vasoconstriction was induced by the application of cold. It is therefore probable that at the time of measurement, spasm of large arteries on the injured side was occurring and that the spasm was not capable of being relaxed by the usual reflex responses to the application of heat elsewhere on the body.

It should be emphasized that the abnormalities of thermovascular response described above are not interpreted as indications of later vasomotor abnormalities, but are restricted to the first few hours after injury. Studies of skin temperature over a longer period after injury (Figure 3) show that the temperature of the toes of rabbit feet injured by cold tend to stabilize at about 28° C. and that there is usually a slight rise until 48 to 50 hours after injury. The application of cold as illustrated in Figure 4 brought about sufficient reduction of blood flow to bring the toe temperature of the injured foot to approximately 24° C. while that of the uninjured foot did not fall below 29.5° C. Thus it is suggested that vasoconstrictor responses to cold may be potentiated locally by recent cold injury but that central inhibition of vasoconstrictor discharges over the vasomotor neurons supplying the vessels of the injured extremity is not evoked by the local or general application of heat.

SUMMARY

Rabbits' feet and ears, frostbitten by immersion in liquid at temperatures from − 15° to − 70° C. for varying lengths of time, undergo a series of changes which, for a given time and temperature, are constant and reproducible. Upon removal from the cold liquid the part is solidly frozen, but is not brittle. Massive edema develops with the

reestablishment of blood flow to the part. After 3 to 4 days, in those instances in which the injury is of sufficient severity, wet gangrene develops. Drying begins 4 to 6 days after injury, resulting in mummification of the foot or ear which eventually separates near the line to which it was immersed in the freezing mixture.

Observations of the skin color of the injured region and measurements of skin temperature indicate that for a time after injury blood flows through the injured region, often at a faster rate than in the normal foot or ear. During the first 50 hours after injury there is a progressive fall in skin temperature of frostbitten ears, until a level approximately equal to room temperature is reached coincidentally with the occurrence of wet gangrene. Comparison of skin temperature of the toes of frostbitten feet with the temperature of the normal foot indicates that in those animals in which the injury is of sufficient severity to result in subsequent loss of the toes, there is a significant decrease in temperature of the injured foot below that of the normal foot during the first 6 hours after injury. This difference becomes more marked with time.

STUDIES ON GANGRENE FOLLOWING COLD INJURY. III. EDEMA FOLLOWING COLD INJURY: ITS MAGNITUDE AND THE COMPOSITION AND SOURCES OF EDEMA FLUID[1]

By FREDERICK A. FUHRMAN and J. M. CRISMON

(From the Department of Physiology, Stanford University School of Medicine, Stanford University, California)

(Received for publication September 1, 1946)

One of the most prominent features of severe cold injury (frostbite) is the early and rapid development of edema of the injured part. We have described previously a method for the production of controlled injury by cold (1) and the general course of events ending in gangrene (2). The data presented here concern the edema following frostbite. Most of these observations were carried out during the first 24 hours after injury, at a time when swelling of the injured part occurs. The method used for the production of the injury by cold is the same as that described previously (1).

A. Magnitude and location of edema

The maximum increase in volume of ears and feet of rabbits following frostbite of different duration and at different temperatures is given in Table I. In ears the greater part of the fluid is found in the more distensible proximal part. The measurements were made by immersing as much as possible of the ear in water and measuring the volume of water displaced. In the leg most of the measurements were made as far proximally as the part was frozen (to the tuberosity at the base of the fifth metatarsal). The fluid, however, is not confined to this region, but is forced up the leg in a manner similar to that observed in ears. A few measurements of volume were made as far as the tuber calcanei (Table I). Twenty-four hours after injury of the foot, edema is apparent above the ankle and in some animals extends as far as the knee. Measurements of total fluid loss by estimation of the volume change of the entire leg were not made.

The appearance of the foot of a rabbit 2 hours after frostbite (3 minutes at $-55°$ C.) is shown

* Freezing did not occur.

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Stanford University.

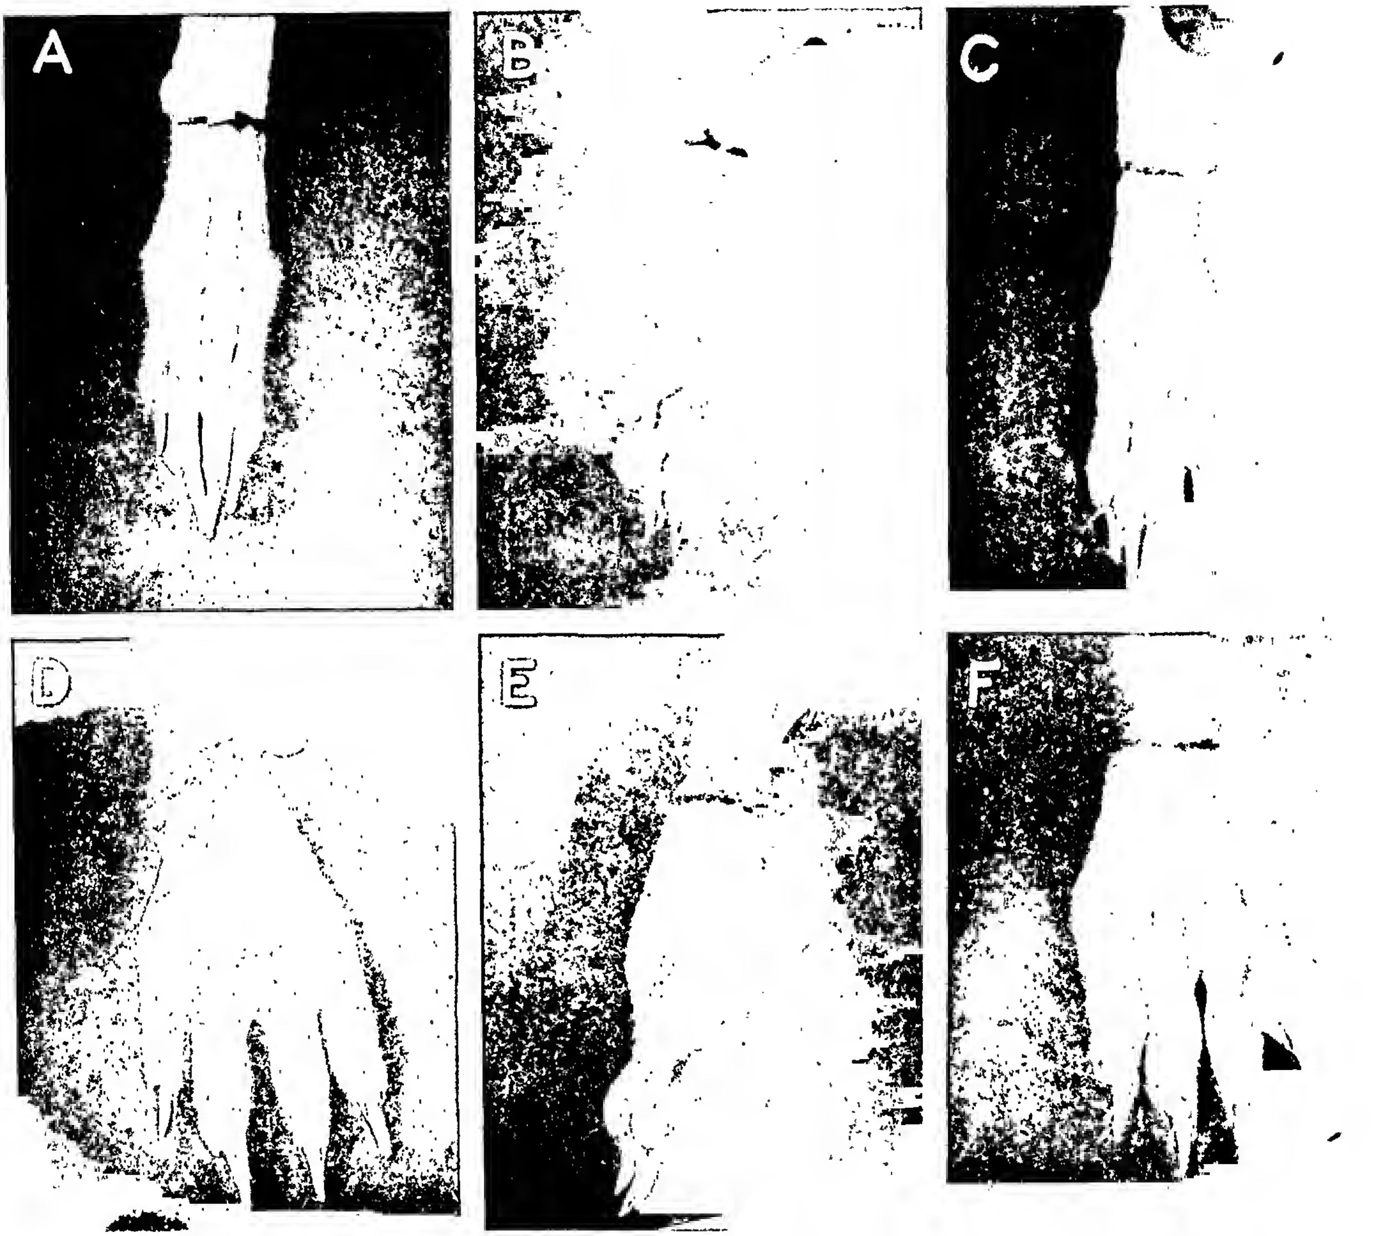

FIG. 1. EDEMA OF RABBIT FEET FOLLOWING SEVERE COLD INJURY

A, B and C show a right hind foot, with hair removed, before cold injury. D, E and F show the same foot 2 hours after injury by immersion for 3 minutes at − 50° C. Foot immersed to the point indicated by the ink line. Volume of edematous foot is 2.7 times that of the foot before injury.

in Figure 1. The toes are spread apart by the accumulation of fluid, and swelling is especially marked on the dorsal surface of the foot. Much less swelling is evident on the plantar surface where the skin is much more tightly bound to the underlying connective tissue. Upon incision of the dorsum of an edematous foot, the edema fluid may be seen to be distributed chiefly in the loose connective tissue underlying the skin. The fluid itself is viscous and drains slowly from the incision. It coagulates within a few minutes after withdrawal from the foot.

In order to determine whether any exudation of fluid occurred in the proximal, uninjured portion of a frostbitten ear, the distal, frostbitten part was amputated after injury in one experiment. Following frostbite for 90 seconds at − 55° C. a clamp was placed on the ear just proximal to the line of immersion. Two and one-half hours later the ear distal to the clamp was amputated, cauterized, and the clamp then released. On the following day there was very slight edema present in the distal part of the stump near the site of amputation. This had disappeared on the second day. No

edema approaching in magnitude that occurring after untreated frostbite was observed, and no evidence of edema was seen in the proximal part of the ear. It thus appears that the fluid loss occurs only in the distal injured part of the ear and that edema proximal to the frostbitten region is the result of forcing of fluid into that region after the limit of distensibility of the tip of the ear is reached.

B. Rate of swelling

In all animals in which the foot or ear actually became frozen during immersion (true frostbite), thawing and return of blood to the injured extremity were followed immediately by rapid and extensive swelling. Increase in the volume of a frostbitten foot could usually be demonstrated 20 minutes after injury. The relative increase in volume of feet frostbitten for 1, 2, and 3 minutes at − 55° C. may be compared in Figure 2, in which the maxima and minima for each duration of injury are plotted at various time intervals after frostbite. The volume was measured to the line of immersion (the tuberosity at the base of the fifth metatarsal).

If comparisons are made between rabbit feet immersed at − 55° C. for 1, 2, and 3 minutes, it is found that the rate of swelling increases with the duration of immersion and thus also with the severity of the injury. Although swelling begins within 20 to 30 minutes after exposure in all cases, it occurs most rapidly following 3-minute exposure and least rapidly after a 1-minute exposure. Following 1-minute immersion the maximum volume is reached in from 3 to 6 hours after injury. Following a 2-minute immersion the maximum occurs somewhat earlier, and after 3-minute immersion the maximum volume is attained in 1 to 2 hours in some animals. The maximum volume attained is similar following the different periods of immersion, although some feet showed only slight increase in volume following 1-minute exposure and others became as swollen as those exposed for 3 minutes. The great variability of the foot volume following 1-minute exposure (Figure 2) is an indication of lack of

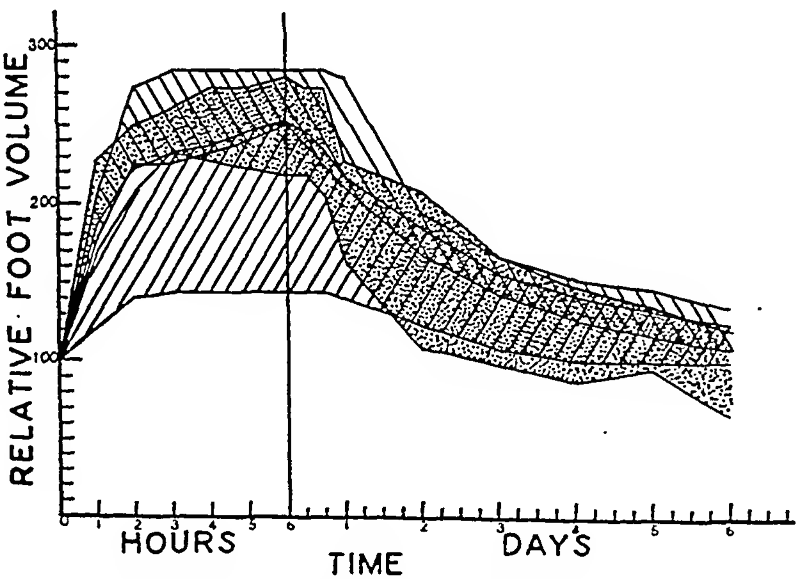

FIG. 2. COMPARISON OF VOLUME CHANGES IN RABBIT FEET AFTER EXPOSURE AT − 55° C. FOR ONE, TWO, AND THREE MINUTES

Initial foot volume expressed as 100. For each severity of injury the maximum and minimum values of foot volume at different time periods after injury are connected by straight lines. The area between the curves of maximum and minimum volume include all of the cases measured. Area shaded right—1-minute immersion. Area shaded left—2-minute immersion. Area spotted—3-minute immersion.

uniformity in injury following this length of immersion.

The decrease in foot volume begins about 1 day after injury and appears to be more rapid following the more severe injury. This decrease in volume results from dehydration of the foot, due to loss of fluid to the outside as well as internally. The external water loss is most rapid when necrosis and wet gangrene appear, and, since necrosis of most of the injured area is an invariable consequence of a 3-minute immersion at $-55°$ C., drying and shrinkage of the foot below its normal size are most rapid in this type of injury.

C. *Subcutaneous tissue pressure*

Subcutaneous tissue pressures in frostbitten feet were determined at varying times after injury by the method of Henderson (3) as modified by Wells, Youmans, and Miller (4). The needle was inserted through the skin on the dorsal surface of the foot into the edematous mass of underlying tissue, and the point adjusted so that it was approximately midway between the skin and metatarsal bones. Care was taken that only two punctures were made in each foot; repeated puncturing of the skin resulted in loss of fluid through the skin and consequent decrease in pressure.

The results of determinations of subcutaneous tissue pressure in the frostbitten feet of 9 animals

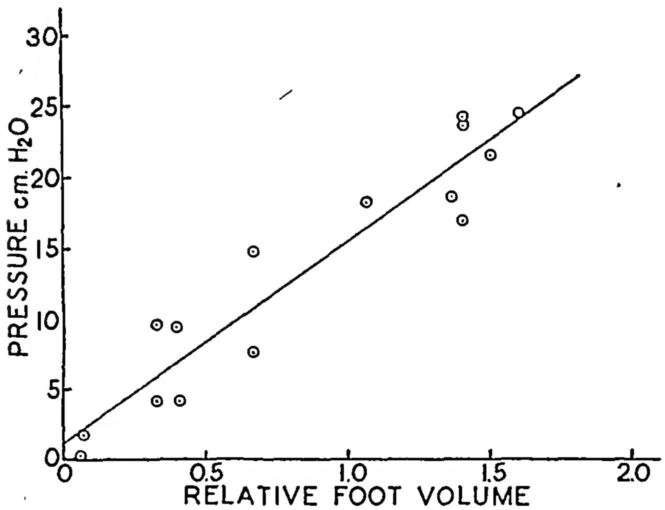

FIG. 3. RELATIONSHIP BETWEEN FOOT VOLUME AND SUBCUTANEOUS TISSUE PRESSURE AFTER FROSTBITE

Subcutaneous tissue pressure in cm. H_2O plotted as a function of relative increase in foot volume after exposure of one foot at $-55°$ C. for 3 minutes. Data from 9 animals. A maximum of two determinations was made on each animal.

are plotted against the foot volume at the time of pressure measurement in Figure 3. In all cases the frostbite was produced by immersion at $-55°$ C. for 3 minutes. The line drawn in Figure 3 was fitted to the data by the method of least squares and may be represented by the equation

$$P = 1.12 + 0.144\ V \qquad (1)$$

in which P is subcutaneous pressure in cm. of water and V is the relative increase in foot volume.

It may be seen from Figure 3 that as the volume of the foot increases the pressure is found to increase until, at maximum foot volume, the subcutaneous pressure is approximately 25 cm. H_2O. This pressure is of the same order of magnitude as the pressure inside capillaries. Landis (5, 6) found by direct measurement that the capillary pressures of arteriolar and venous capillaries were 30 cm. H_2O and 17 cm. H_2O respectively in the mesentery of the rat and 38.5 cm. H_2O and 17 cm. H_2O in the mesentery of the guinea pig. The importance of high subcutaneous pressure in relation to the functional pathology of frostbite will be discussed later.

When the foot has attained a volume 250 to 300 per cent of the initial volume, further increase measured to the line of immersion does not occur, but the pressure within the foot reaches such a level that fluid is forced in a proximal direction above the level of injury.

If the time course of increase in subcutaneous pressure in the foot following cold injury is considered, it is found that the pressure increases during the period of swelling (for the first 4 to 6 hours), and then reaches a maximum pressure coinciding in time with the maximum foot volume.

D. *Composition of edema fluid*

Determination of the protein concentration of edema fluid withdrawn from frostbitten feet and in fluid drawn from blisters on frostbitten ears was made at various times after frostbite. The protein concentration was calculated from the specific gravity of the fluid determined by the falling drop method (7). Protein concentration was calculated from the formula given by Weech (8):

$$Pr = (\text{Sp. Gr.} - 1.0069) \times 340.1 \qquad (2)$$

in which Pr is the protein concentration in grams per 100 ml.

1. *Protein concentration of ear blister fluid*

The protein concentration of blister fluid from frostbitten ears, withdrawn at various times after frostbite of 90-second duration at − 55° C., is given in Figure 4. In the greater number of these animals the blisters formed in the first 4 hours after injury, although in some cases blisters were not seen until 8 to 12 hours after injury. Fluid from the blisters was straw-colored and did not contain appreciable amounts of hemoglobin. It may be seen from the figure that there is a decrease in protein concentration of blister fluid with time. The line drawn in the figure, fitted to the data by the method of least squares, may be represented by the equation

$$Pr = 4.303 - 0.0254\ t \tag{3}$$

in which Pr is the protein concentration in grams per 100 ml. and t is the time in hours after frostbite. The coefficient of correlation between protein concentration and time after frostbite was calculated to be − 0.798.

Pochin (9) found a negative correlation between protein concentration and time after injury in edema fluid taken from rabbit ears following vascular occlusion. The initial protein concentration of the edema fluid after vascular occlusion and of blister fluid after frostbite injury are very

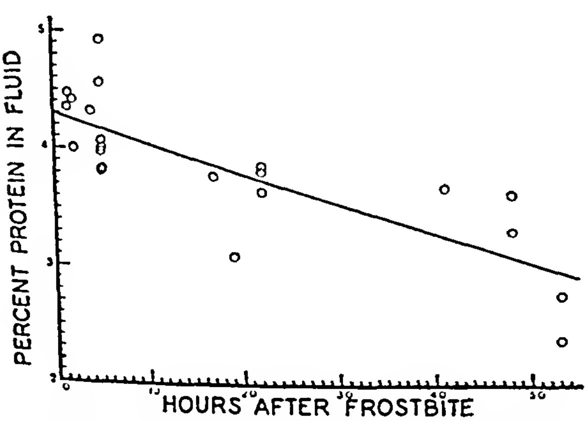

FIG. 4. TIME COURSE OF CHANGE IN PROTEIN CONCENTRATION OF EAR BLISTER FLUID FOLLOWING SEVERE COLD INJURY

Data from 12 animals. Frostbite was produced in all cases by immersion at − 55° C. for 90 seconds.

TABLE II

Protein concentration in edema fluid from frostbitten feet
Exposure at − 55° C.

No. of animals	Duration of exposure	Time after frostbite at which fluid was sampled	Mean protein	S. E. of mean
			per cent	
5	1	120–240 minutes	3.46	.668
22	3	90–240 minutes	4.13	.139
4	3	24 hours	3.01	.323
4	3	44 hours	3.91	.585

similar (4.5 per cent and 4.3 per cent respectively). Pochin's data show a more rapid decrease in protein concentration in the edema fluid after occlusion than that reported here in blister fluid after frostbite. This may indicate a more rapid removal of protein-containing fluid via the lymphatics in occlusion.

2. *Protein concentration of foot edema fluid*

The protein concentration of edema fluid taken from frostbitten feet under various circumstances is given in Table II. It may be seen from the table that the protein concentration after 1-minute frostbite is somewhat less than after 3-minute frostbite at − 55° C. This difference is, however, not significant ($P < 0.7$).

The data for the protein concentration of foot edema fluid taken at different times after injury are not sufficient to establish so definite a relationship as that in ear blister fluid. The correlation between protein concentration and time in hours after injury was − 0.494 and the straight line fitted to the data may be represented by the equation

$$Pr = 4.326 - 0.052\ t \tag{4}$$

in which the symbols are the same as those used in equation (3). This relationship is based upon 22 determinations made between 1 and 6 hours after injury and upon 4 determinations made 24 hours after frostbite. It is apparent that in frostbitten feet, as in frostbitten ears, the protein concentration of the edema-fluid is initially high, only slightly below that of the plasma, and that it decreases progressively with time after injury.

Table II also shows the protein concentration of foot edema fluid taken 44 hours after frostbite. In this case there was an apparent increase in protein concentration. It seems probable that this

increase is due to loss of water more rapid than loss of protein from the foot.

The protein concentration found in the foot edema fluid and in ear blister fluid following cold injury is in good agreement with the data reported by Harkins and Harmon (10) for protein concentration in edema fluid from severely frostbitten dogs. They report a mean edema fluid protein concentration of 3.6 per cent.

3. *Effect of edema fluid upon blood pressure and isolated smooth muscle.*

The frequent reports of the presence of a toxic substance in plasma and edema fluid after burns (11, 12) suggest that such toxic materials may be present in the edema fluid taken from extremities following cold injury. In order to test this possibility, edema fluid removed from frostbitten rabbit feet 2 hours after injury was examined in the following manner.

a. Effect upon blood pressure. Edema fluid was withdrawn from the feet of two rabbits 85 and 95 minutes after frostbite. In one case the fluid was used immediately and in the other it was held overnight in a refrigerator. This fluid was then injected intravenously into rabbits anesthetized with dial. Arterial pressure was recorded during and following the injection. Injection of the edema fluid in amounts up to 2 ml. in a rabbit weighing 2.4 kgm. produced no change in the level of arterial pressure.

b. Effect upon isolated guinea pig intestine. Segments of guinea pig ileum were suspended in oxygenated Tyrode solution containing 1:1,000,000 atropine. Addition of edema fluid withdrawn from frostbitten rabbit feet produced slight contraction in one instance. In this case 1.0 ml. of edema fluid was equal in activity to 0.1 μg. histamine. This activity may be accounted for entirely on the basis of the normal histamine content of the small amounts of blood present in the edema fluid, since rabbit blood contains 10 to 12 μg. histamine per ml. (13). In all muscle preparations the activity of the muscle was confirmed by contraction in response to additions of histamine.

c. Assay of edema fluid for histamine. Edema fluid withdrawn from frostbitten feet 2 to 4 hours after injury was prepared for histamine assay by the method of Barsoum and Gaddum (13) as modified by Anrep *et al.* (14). The extracts were tested upon the atropinized guinea pig ileum and upon atropinized rectal caecum of the fowl. No contractions of the isolated muscle were produced by the edema fluid extracts. Comparison with known concentrations of histamine showed that the histamine content of the edema fluid must be less than 0.2 μg. per ml. of original edema fluid.

d. Intradermal injection of edema fluid. Edema fluid from a rabbit foot, withdrawn 95 minutes after injury, was injected intradermally into the ears of two rabbits. The volumes injected were approximately 0.1 and 0.3 ml. Slight vasodilatation was seen immediately surrounding the sites of injection within 5 minutes. No edema developed and the slight hyperemia disappeared within 12 hours.

Histamine liberation from perfused limbs injured by high temperature has been described by Kellaway and Rawlinson (15). The edema fluid formed after frostbite, however, does not contain significant amounts of histamine. Failure to demonstrate the presence of toxic materials in this edema fluid by the methods outlined above is not interpreted to mean that chemical substances are not implicated in the local changes following frostbite. It is possible that such principles as those described by Shorr, Zweifach and Furchgott (16), which would not be detected by the methods used here, may play a part in the local circulatory changes following cold injury.

E. *Changes in blood composition coincidental with swelling*

1. *Plasma protein changes following cold injury.*

Plasma protein concentration was calculated from the plasma specific gravity, determined by the falling drop method of Barbour and Hamilton (7), by means of equation (2). In every case the plasma protein concentration decreased during the period of swelling of the frostbitten foot. The results obtained in a representative experiment are shown in Figure 5 (which also shows changes in foot volume, hematocrit, hemoglobin concentration, and blood specific gravity during the same time period). In this experiment the plasma protein concentration fell from an initial value of 5.34 per cent to a minimum of 3.96 per cent. Similar results were obtained in 13 other animals in which the plasma protein fell to 81.3 per cent of the initial 185 to 357 minutes after injury. Plasma protein concentrations before frostbite and at times ranging from 160 to 357 minutes after frostbite in 6 animals are given in Table III. It may be seen that in all cases there is a decrease in plasma protein concentration following frostbite, ranging from 0.98 to 1.57 grams per 100 ml. The relationship between the decrease in plasma protein concentration and the protein concentration in edema fluid will be considered below.

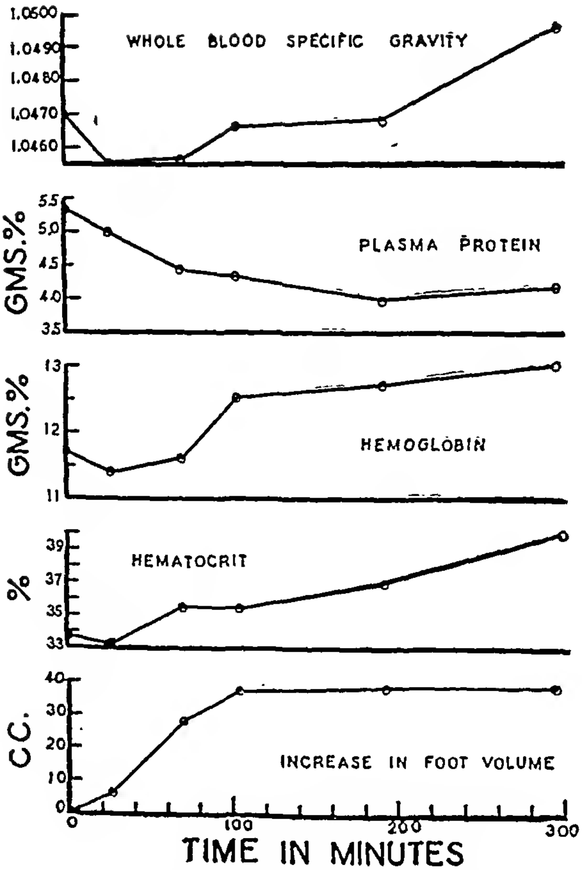

FIG. 5. TIME COURSE OF CHANGES IN WHOLE BLOOD SPECIFIC GRAVITY, PLASMA PROTEIN, HEMOGLOBIN, HEMATOCRIT AND FOOT VOLUME FOLLOWING SEVERE COLD INJURY

Representative data from one animal after exposure of one hind foot at − 55° C. for 3 minutes.

In order to determine the approximate duration of the decrease in plasma protein concentration following this type of frostbite, determinations were made 24 hours after injury in four animals. The results are given in Table IV. It is clear from the data given in the table that after this length of time the plasma protein concentration had returned to approximately the initial value. The data show no tendency toward a decrease in plasma protein concentration such as might result from leakage of protein into regions remote from the site of injury.

2. *Relationship of plasma protein changes to edema fluid protein concentration*

Information regarding the origin of the edema fluid in frostbitten extremities may be obtained by comparison of the protein content of the edema fluid with the plasma protein concentration before and after injury. Such a comparison has been made for the data given here on two bases: (1) comparison of the mean protein concentration of the edema fluid with the mean initial plasma protein concentration; (2) comparison, in individual animals, of the loss in total circulating protein with the total protein found in edema fluid.

Determination of the initial plasma protein concentration (before frostbite) in 23 animals gave a mean value of 5.42 grams per 100 ml. (Range 4.00 to 6.56; S.E. of mean = 0.137). The protein concentration of edema fluid taken from frostbitten feet and from blisters on frostbitten ears during the first few hours after injury were given previously as 4.13 grams per 100 ml. and 4.23 grams per 100 ml. respectively. If these values for protein concentration in the edema fluid are compared directly with the mean plasma protein concentration it may be calculated that for feet 76.2 per cent or for ears 78.0 per cent of the edema fluid is whole plasma and

* Four per cent of body weight.

the remainder must therefore be plasma ultrafiltrate.

The data given in Table III make it possible to calculate, for individual animals, the loss of total circulating protein as compared with protein in edema fluid from the foot of the same animal. In Table III are given the initial plasma protein concentration, and, after 160 to 357 minutes, the increase in foot volume and the plasma protein concentration at that time. In Table V are listed certain derived data from Table III, as well as the actual protein concentration of the foot edema fluid from these animals. The normal plasma volume of these animals is assumed to be four per cent of the body weight. It may be seen that the loss in total circulating protein ranges from 0.69 to 1.63 grams if it be assumed that no change in plasma volume occurs (Column 5). When this is divided by the volume of fluid measured to have accumulated in the foot during the time period given (Column 3), the theoretical protein concentration of the edema fluid may be calculated (Column 6). Good agreement is seen between this theoretical value and that actually determined (Column 7), indicating that the total loss of circulating protein may be accounted for by protein occurring in the edema fluid. It should be pointed out that this comparison involves, at best, a rough approximation of the actual changes. The determination of the exact volume of edema fluid cannot be made with great accuracy by the displacement method. Furthermore the assumption that no change in plasma volume occurs is not strictly valid, since data presented below indicate a reduction in plasma volume soon after injury, with a progressive replacement in plasma volume over a period of several hours.

3. *Changes in hemoglobin concentration and hematocrit during swelling.*

The hemoglobin concentration and the hematocrit were determined in arterial blood during the period of swelling of the foot following a 3-minute immersion at − 55° C.

The procedure was as follows: Heparin was used as an anticoagulant. Hemoglobin was determined by the acid hematin method using 0.05 ml. of blood. Hematocrit was determined in Van Allen tubes without dilution of the blood. In several animals the hematocrit was calculated from the hemoglobin concentration using a value of 33.9 grams hemoglobin per 100 ml. of packed erythrocytes (17). This was calculated assuming an oxygen capacity of 46.1 ml. of oxygen per 100 ml. packed cells (17) and 1.36 ml. oxygen to be bound by 1 gram hemoglobin (18). In a limited number of determinations on rabbit blood the mean corpuscular hemoglobin concentration was found to be 33.6 grams per 100 ml. of packed erythrocytes.

For the four animals in which both hemoglobin and hematocrit were determined on the same samples of blood, the mean corpuscular hemoglobin concentration was calculated for the initial sample and the sample taken at the time of attainment of maximum foot volume. It was found that a decrease occurred in two animals (34.7 to 32.8 and 35.3 to 33.5) and no change occurred in the other two. Since the difference found was not great and appeared in only two of four animals, swelling of erythrocytes during the development of edema is not considered to be an important or invariable consequence of cold injury under the conditions used here.

The hemoglobin and hematocrit values, together with the figures showing fluid loss to the injured foot and the whole blood specific gravity, are given in Table VI. As is to be expected from data given previously which indicated loss of about 77 per cent whole plasma, the hemo-

s = spleen removed from circulation before frostbite.

globin concentration and hematocrit are found to increase progressively during the period of swelling. These values are plotted in Figure 5 for one representative animal.

From a comparison of the initial and final hematocrit values, provided the loss of fluid to the injured foot is known, it is possible to calculate the extent to which plasma volume, reduced due to loss into the injured region, has been replaced by withdrawal of fluid from extravascular sources. These data are shown in Table VII. The cell volume is assumed to remain constant throughout the experiment. In two animals (Nos. 17 and 6) the spleen was excluded from the circulation before frostbite in order to exclude the addition of cells from this source. These animals did not appear to differ from the others in the series.

* Spleen occluded from the circulation before cold injury.

For Table VII the calculations involved are as follows: initial blood volume (Initial V_b) is assumed to be 7 per cent of the body weight, from which is calculated the initial cell volume (V_c) and the initial plasma volume (Initial V_p) by use of the hematocrit determined initially (Initial Ht).

$$V_c = (\text{Body weight} \times 0.07) \times \text{Initial } Ht$$
$$\text{Initial } V_p = (\text{Body weight} \times 0.07) \times (100 - \text{Initial } Ht)$$

If it be assumed that the fluid lost (X) into the injured region is plasma and that the plasma volume is reduced by the amount (X), then the following calculated values may be derived:

$$\text{Calc. Final } V_p = \text{Initial } V_p - X$$
$$\text{Calc. Final } V_b = \text{Cal. Final } V_p + V_c$$
$$\text{Calc. Final } Ht = \frac{V_c \times 100}{\text{Calc. Final } V_b}$$

If, now, the final determined hematocrit value (Final Ht) be compared in each case with the final calculated hematocrit (Calc. Final Ht), it is found that the determined hematocrit value is smaller in all the animals. This indicates that part of the plasma lost has been replaced by water withdrawn from the interstitial compartment and from the gut. The extent of this replacement may be estimated by calculation of the blood volume on the basis of the determined final hematocrit (Final Ht) and comparison of this figure with the calculated final blood volume (Calc. Final V_b) derived above.

$$\text{Final } V_b = \frac{\text{Calc. Final } Ht \times \text{Calc. Final } V_b}{\text{Final } Ht}$$

It is found (Table VII) that the replacement of plasma volume amounts to from 8 to 19 ml. in the time interval studied.

An examination of the hematocrit values following cold injury thus indicates a reduction in plasma volume which is partially replaced by extravascular fluid within a few hours. Further evidence for this is given in the next section.

4. *Measurement of plasma volume following cold injury*

In four animals the plasma volume was determined by the dye method immediately before frostbite and again after 2 to 4 hours. Preliminary experiments showed that intravenously injected T–1824 was readily lost from the circulation into the injured foot, so that the frostbitten foot must be excluded from the circulation before the second plasma volume determination is made in order to obviate fictitiously high values.

The procedure was as follows: Initial plasma volume was determined by the intravenous administration of 2 mgm. per kgm. T–1824; the determination of the dye concentration in plasma was made after 10 minutes (19). Plasma volume after frostbite was determined after first occluding the circulation to the injured foot by a tourniquet placed just above the knee. A blood sample was then withdrawn to serve as a control, an additional injection of 1 mgm. per kgm. T–1824 was made intravenously, and the dye concentration again was determined after 10 minutes. Concentrations of T–1824 were determined in undiluted plasma using a 620 μm. filter in a Klett-Summerson photoelectric colorimeter.

Table VIII shows the results of determinations of initial plasma volume and plasma volume after frostbite of one hind foot at − 55° C. for 3 minutes. It will be seen that the determinations made 120, 148, and 180 minutes after injury all show reductions in plasma volume, but that after 240 minutes (in one animal) the plasma volume is made up to its initial value. These results confirm those obtained by calculation of hematocrit differences in showing that the fluid lost from the plasma is rapidly replaced during the first few hours after injury.

at − 55° C. In a number of instances arterial samples were also obtained for comparison.

When serial samples of blood were taken, it was necessary to withdraw only very small volumes of blood in order that the blood volume be altered as little as possible. This was done by drawing blood directly from the vein into a Roughton-Scholander (20) blood pipette (1.0 to 1.5 mm. bore, containing 100 cmm.) which was first wet with heparin solution (10 mgm. per ml.). The pipette was fitted to a 26-gauge hypodermic needle by means of a rubber gasket in the needle hub. The pressure in the vein was sufficient to fill the pipette. After removal of the needle, samples of blood for the determination of hemoglobin (20 cmm.) and specific gravity (20 cmm.) were transferred directly to appropriate pipettes, enough blood being left in the original pipette for determination of oxygen content by the method of Roughton and Scholander (20).

The results of these determinations are given in Table IX. Data for an individual animal (No. 3) are plotted in Figure 6. As swelling of the injured leg occurs, the oxygen content of the venous blood flowing from the leg increases. In some cases the venous oxygen content actually exceeded the arterial oxygen content, due to loss of plasma in passage of the blood through the injured tissue. In all animals oxygen content of both venous and arterial blood increased during the period of swelling. In three animals (Nos. 3, 13, and 7) the hemoglobin concentration was also determined in the same blood samples in which oxygen content was determined.. By using a value for oxygen capacity of hemoglobin of 1.36 ml. per gram (18), the blood oxygen saturation has been calculated for different time periods after injury. These calculations all indicate that during the period of swelling the tissue of the injured limb is utilizing oxygen (that is, tissue death did not occur from the exposure at − 55° C.). The data are not extensive enough to permit definite conclusions to be drawn as to whether oxygen utilization is decreased soon after injury. Such decrease in coefficient of oxygen utilization occurred in two of the three animals studied.

DISCUSSION

It has been pointed out that, following vascular occlusion of the rabbit ear prolonged enough to lead to gangrene of the part (9), the protein concentration of the edema fluid is almost identical with that occurring after frostbite. Likewise the protein concentration of edema fluid and the changes in hemoglobin and hematocrit reported here agree with those found by Harkins and Harmon (10) after freezing approximately one-quarter of the body surface of dogs. The early hemoconcentration observed to follow severe burning, which resembles that found in this series of animals following frostbite, has been observed by many workers in both animals and man (11, 12). Both the tissue edema fluid (21) and blister fluid (22) from burned areas have been demonstrated to be exudates with a protein concentration approaching that of plasma. Presman *et al.* (23) report the protein concentration of blister fluid taken from burned human beings to be about 70 per cent that of plasma. This is in good agreement with the value of 77

per cent found in this series of animals after frostbite. The plasma protein changes following burning have been studied recently by Lischer *et al.* (24). Plasma albumin tended to fall in all animals, but plasma globulin fell only in less severely burned animals which survived. It has not been determined whether the fall in plasma protein following frostbite is due chiefly to decrease in the albumin fraction.

The significance of swelling, as one of the manifestations of injury following the exposure of parts of the body to severe cold, may be judged basically from two points of view: (a) its correlation with the extent of tissue loss and the course of healing; and (b) the information it may furnish concerning the nature of the injury produced. The experiments described above indicate that the magnitude of swelling alone is of relatively little help in affording a basis for describing the final outcome of injuries produced by cold. On the other hand, the rates of its appearance and its duration have a fairly consistent relation to the severity of injury. In those animals subjected to cold of sufficient degree and duration to produce complete gangrene and loss of the exposed part, the edema which appeared was more rapid in onset and disappearance than in the milder forms of injury. In no case did gangrene appear without the previous occurrence of massive edema in the injured region.

The demonstration that the fluid lost from the blood stream into the interstitial compartment of the injured regions contained large amounts of protein furnishes evidence of increased capillary permeability. Protein was found in quantities equalling that to be expected if as much as 77 per cent of the total volume of edema fluid were whole plasma. There occurred a massive loss of protein from the blood into injured feet and ears which recovered, as well as into those which became gangrenous. Thus, injury of capillaries sufficiently severe to induce increased permeability to plasma protein does not appear to be the determining event in the development of gangrene. However, the amounts of induration and persistent periarticular fibrosis which characterize the healing stage following injury by severe cold probably depend upon the protein centent of the edema fluid.

The loss of plasma from the blood stream during the course of swelling is sufficient to produce moderate increases in hemoglobin concentration and hematocrit during the first few hours after injury. Shock was not observed in any of the animals studied, probably because of the limited size of the injury. As plasma is lost into the injured region, the blood becomes diluted by fluid from the interstitial compartment and probably from the gut as well, so that the volume of fluid lost to the frostbitten part is greater than the quantity by which the plasma volume is reduced. While the replacement of plasma volume is sufficient to produce a fall in plasma protein concentration during the first few hours after injury, it is not enough to compensate completely for the fluid loss, and a moderate increase in hematocrit occurs.

SUMMARY

Following severe cold injury, produced by immersion of one hind foot of rabbits in liquid at − 55° C. for 3 minutes, massive local edema of the part is an inevitable consequence. Investigation of the specific details involved in the development of the edema permit the following conclusions to be drawn.

1. Swelling of the foot begins as soon as thawing is complete and reaches a maximum in about 6 hours. Decrease in volume begins about 24 hours after injury and continues progressively during the next 5 days until the foot dries and becomes mummified. The maximum foot volume is about 3 times the initial volume.

2. Subcutaneous tissue pressure in frostbitten feet increases as the feet swell, until a pressure of about 25 cm. H_2O is attained 4 to 6 hours after injury at a time when the volume of the feet is maximal.

3. Fluid withdrawn from frostbitten feet during the stage of maximal edema and fluid from blisters on frostbitten ears contain an average of 4.3 per cent protein. The protein concentration of the fluid decreases progressively with time after injury.

4. The presence of toxic materials in the edema fluid was not indicated by the following tests: application to isolated guinea pig and fowl intestinal smooth muscle; intradermal injection in-

to rabbit ears; intravenous administration to rabbits while arterial pressure was being recorded.

5. The mean protein concentration of edema fluid from frostbitten feet is equivalent to about 76 per cent of the protein concentration in plasma before injury.

6. Plasma protein concentration is reduced during the first 6 hours after injury but is restored after 24 hours.

7. Moderate increases in hematocrit and hemoglobin concentration of the blood occur during the period of swelling of the foot.

8. Calculation of the extent to which fluid lost into the injured limb is replaced by extravascular fluid indicates that plasma volume is first reduced and then progressively restored during the first 6 hours after injury. Determination of plasma volume by the dye method in four animals before and after injury agrees with the plasma volume changes calculated on the basis of changes in concentration of blood constituents.

9. During the period of swelling, loss of fluid consisting of about 76 per cent plasma is rapid enough to result in decrease in plasma volume. Progressive replacement of plasma volume during the first few hours after injury is sufficient to result in a fall in plasma protein cencentration, but is not great enough to compensate completely for the fluid loss to the foot; thus, moderate increase in hematocrit occurs.

10. In some cases oxygen content of venous blood draining from the injured limb during swelling exceeded arterial oxygen content due to loss of fluid into the injured area. Oxygen utilization by the injured limb occurs during the first 5 hours after injury.

STUDIES ON GANGRENE FOLLOWING COLD INJURY. IV. THE USE OF FLUORESCEIN AS AN INDICATOR OF LOCAL BLOOD FLOW: DISTRIBUTION OF FLUORESCEIN IN BODY FLUIDS AFTER INTRAVENOUS INJECTION[1]

By J. M. CRISMON and F. A. FUHRMAN

(From the Department of Physiology, Stanford University School of Medicine, Stanford University, California)

(Received for publication September 1, 1946)

The use of fluorescein as a means of determining the adequacy of blood flow and the degree of capillary permeability in both normal individuals and in those manifesting various pathological states has been described in a series of papers by Kurt Lange and his associates (1, 2, 3). In general, the method depends upon the introduction of fluorescein into the blood stream and its detection by exposing the region under study to ultraviolet light. Data have been obtained by direct observations, photographic recording, and photoelectric registration of the yellow-green glow which results from the excitation of fluorescein in the tissues. It is obvious that the appearance of fluorescence in tissues remote from the site of injection of fluorescein demonstrates the existence of circulating blood within the area under observation. However, the interpretation of the significance of gradations in the intensity of fluorescence, the rate at which maximum intensity is reached, and the rate at which it diminishes requires detailed knowledge of the properties of fluorescein and the manner in which it becomes distributed in blood and tissue fluid.

Changes in the time-intensity relationships of fluorescence after the intravenous injection of fluorescein have been used recently as the basis for explanations of certain abnormalities present in myxedema and in tissues subjected to severe injury by cold (4, 5). In both of these widely different abnormal states, certain of the divergences from normal in the distribution of fluorescein were attributed to changes in capillary permeability. While there is no doubt that the permeability of the capillary membranes must play an important part in determining the distribution of dye between the blood and the interstitial fluid, the influence of other factors affecting the blood-interstitial fluid equilibrium should not be overlooked. The recent important contributions of Zweifach and his coworkers (6) serve to illustrate how changes in the pattern of local blood flow may first alter, in a striking way, the freedom of exchanges between the flowing blood and the interstitial fluid and later give rise to stasis and changes in capillary permeability as secondary phenomena.

The experiments to be described below were undertaken to study in normal rabbits the distribution of intravenously injected fluorescein in blood and other body fluids, some of the factors influencing fluorescein equilibrium, and the extent of penetration of cells by the dye.

METHODS

Fluorescein was administered to normal adult rabbits by injection into the marginal ear vein. The dose used was 75 mgm. per kgm. body weight and was given as a 5 per cent solution of sodium fluorescein in distilled water. White rabbits were used in order to avoid errors due to skin pigment, and all areas for study were closely clipped. The source of the ultraviolet light used for the excitation of fluorescein was a Shannon unit No. 92 consisting of a mercury vapor spot lamp (HGCH4) mounted in a holder with adjustable trunnions on a transformer and fitted with two glass filters: a UV heat-resisting Red-Purple and a UV Blue Purple Ultra.

Photoelectric measurement of the intensity of skin fluorescence was accomplished by means of a photometer constructed from a General Electric light sensitive cell of the barrier layer type connected through a tap switch to a reflecting galvanometer. The cell was mounted in a light-shielded housing set at a distance of 10 cm. from the surface of the skin area to be studied. A metal shield, set in the plane of the skin surface, restricted the area, which served as the source of light falling on the cell, to a circle 37 mm. in diameter. The ultraviolet lamp

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Stanford University.

was held in a clamp with the surface of the globe at a distance of 11 cm. from the shield with the incident light directed on the skin at an angle of 45°, and at 90° to the path of the visible light from the skin surface to the light-sensitive cell. Light falling on the photo cell was restricted to the yellow-green region of the spectrum by means of a Wratten No. 61 filter mounted in the photocell housing.

The intensity of fluorescence was expressed in units of galvanometer deflection. Galvanometer readings, taken when the skin was exposed to ultraviolet light before fluorescein injection, were subtracted from those after fluorescein to yield the change due to the presence of dye. The blank reading amounted to about 5 per cent of the maximum deflection under full fluorescence in normal animals.

The concentration of fluorescein in blood and peritoneal fluid in most of the experiments was measured by adding 1 ml. of the fluid in question to 6 ml. of 95 per cent ethyl alcohol and separating the precipitated protein by centrifugation. The fluorescein dissolved freely in the alcohol used for dilution and precipitation. The resulting yellow color was measured in a Klett Summerson photoelectric colorimeter with a Wratten No. 44a filter. The concentration of the dye was calculated by the comparison of colorimeter readings with values obtained from a standard curve plotted from colorimeter readings made on alcoholic solutions of fluorescein of known concentration. Blanks were prepared from a mixture of alcohol and fluorescein-free blood to obtain a zero setting of the colorimeter. Comparison of readings from solutions containing known amounts of fluorescein dissolved in alcohol with readings obtained upon alcoholic extracts of blood to which known amounts of fluorescein had been added showed that the yield of fluorescein was complete and that no interfering pigment was retained in the extract.

A few of the analyses were carried out without extraction. Twenty cu.mm. of the blood or other fluids were diluted to 50 ml. with phosphate buffer at pH 7.0, and the concentration of fluorescein was measured in a Coleman Photofluorometer against solutions of known fluorescein concentration. Good agreement was obtained between the results from both methods of analysis.

RESULTS

1. *The relation between blood concentration of fluorescein and the fluorescence of the skin.*

The gross appearance of fluorescent skin under ultraviolet light after the intravenous injection of fluorescein indicated an initial distribution of dye in close relation to blood vessels. Within a very brief time fluorescence was uniform over the whole area in a manner consistent with the free passage of dye between the blood and the extravascular fluid. The time relations of this equilibrium were explored in normal rabbits by

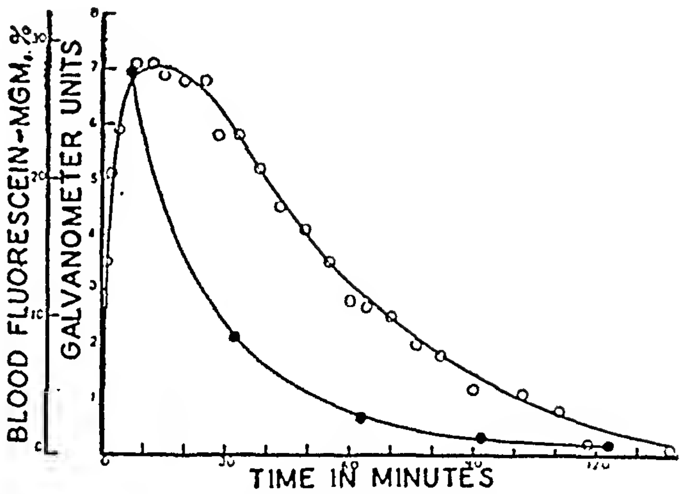

FIG. 1. CHANGE IN INTENSITY OF FLUORESCENCE IN NORMAL RABBIT'S EAR WITH TIME COMPARED TO DISAPPEARANCE OF FLUORESCEIN FROM THE BLOOD

Representative data from one animal. Open circles—fluorescence, in galvanometer units. Solid circles—concentration of blood fluorescein.

making serial measurements of both the concentration of fluorescein in the blood and measurements of the intensity of skin fluorescence. Figure 1 shows curves plotted from representative data from one animal. The curve describing the rate of disappearance of fluorescein from the blood is of the "die-away" type and indicates the dependence of rate of removal upon concentration gradients. Since fluorescein is excreted freely in the urine (3) at the same time as it is being moved from the blood stream to the extravascular fluid, this curve represents the change in concentration resulting from loss of dye as well as its dilution in the entire extracellular phase. The maximum intensity of skin fluorescence was reached at a time when the blood concentration was falling rapidly. Fluorescence declined very little over the following period of about 15 minutes. In this short interval the blood concentration of dye decreased sharply by 18 to 20 mgm. per 100 ml. In the period from 30 minutes after the injection of fluorescein up to 140 minutes, the decline of intensity of fluorescence exhibited an orderly decrease in rate with time. Thus, the curve describing decreasing fluorescence from 30 minutes after injection is qualitatively similar to that describing the change in blood concentration of dye.

The regularity of the rate of disappearance of fluorescein from the blood of rabbits is illustrated

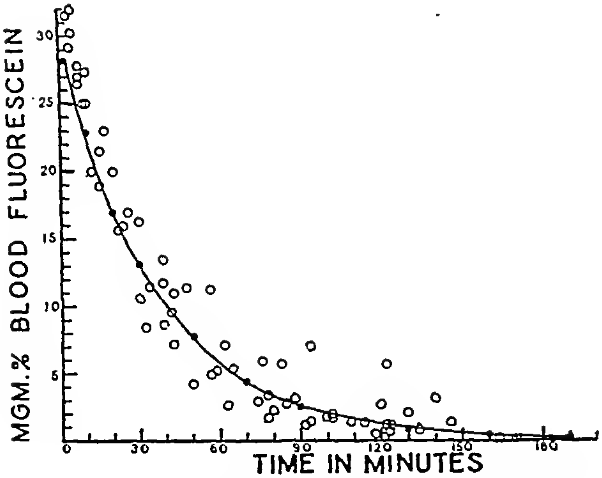

FIG. 2. CHANGE IN BLOOD FLUORESCEIN CONCENTRATION WITH TIME IN NORMAL RABBITS

Data from determinations in 14 animals after intravenous injection of 75 mgm. per kgm. sodium fluorescein. Open circles—individual determinations. Curve with solid circles fitted to data on a semi-log plot by method of least squares (Figure 3).

by the curve in Figure 2. The open circles represent individual measurements of blood fluorescein on 14 animals. The same data were plotted as the logarithm of the blood concentration against time in Figure 3. The rectilinear fit in Figure 3 was calculated by the method of least squares. The line drawn through the solid circles in Figure 2 was derived from the least square fit by the general formula

$$\log y = a + bx.$$

The constants for the line drawn in Figure 3 are: $a = 2.48$ and $b = 0.0118$.

A similar regularity in the rate of decrease of fluorescence is illustrated in Figure 4. This graph shows the distribution of the measurements on the ears of six normal rabbits of fluorescence intensity expressed as the log of the intensity in galvanometer units plotted against time. Each point represents an individual measurement. The straight line was fitted by the method of least squares. The constants are $a = 1.99$ and $b = 0.0087$. Statistical analysis of the slopes of the lines in Figures 3 and 4 showed that they are not significantly different.

These observations show that the maximum skin fluorescence does not coincide in time with maximum concentration of dye in the blood but rather occurs at a time when the blood fluorescein concentration has been sharply reduced. Thus, an important influence upon the rate of loss of dye from the blood stream is the rate at which it accumulates in the extravascular fluid, and the intensity of fluorescence in the skin must be considered an expression of extravascular fluorescein concentration rather than an expression of either blood flow rate or the concentration of fluorescein in the blood. However, it is clear that the rate at which the dye may enter or leave the extravascular fluid is dependent in some way upon concentration gradients. These data do not permit a decision as to the relative importance of diffusion or filtration as factors determining the rate of transfer.

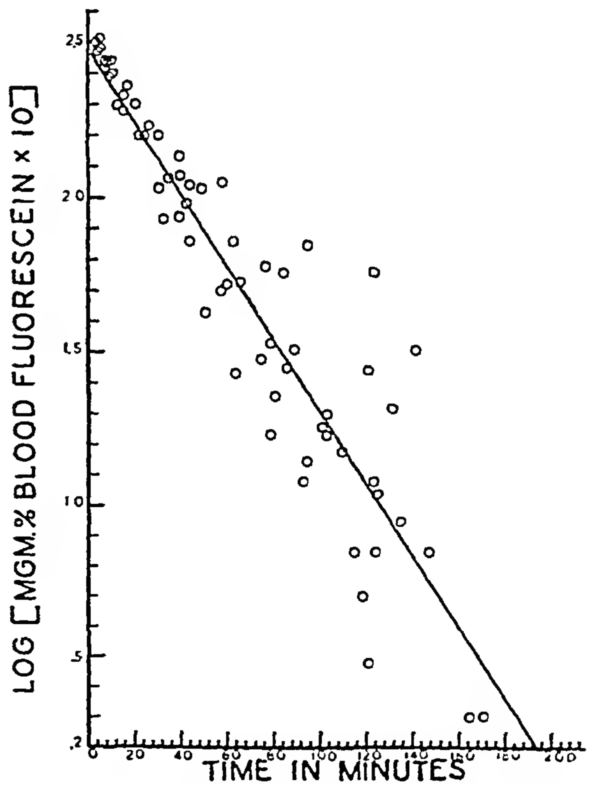

FIG. 3. CHANGE IN BLOOD FLUORESCEIN CONCENTRATION WITH TIME IN NORMAL RABBITS

Straight line calculated by the method of least squares. Data from 6 animals. Each symbol represents 1 animal. Fluorescein injected at zero time.

2. *The diffusion of fluorescein from the blood against a filtration gradient*

Although Lange and Boyd (3) have studied the role of diffusion and filtration in exchanges of fluorescein across membranes, their experiments were carried out *in vitro* with collodion membranes. In order to demonstrate *in vivo* the free passage of dye from the blood into extravascular fluid under circumstances where the net filtration gradient was bringing about a movement of fluid into the blood stream, fluorescein exchanges were studied in three rabbits which had received intraperitoneal injections of Ringer's solution before dye was administered.

Each animal received 50 ml. per kilogram body weight of Ringer's solution containing 0.2 per cent glucose. The Ringer's solution was injected intraperitoneally, and, immediately afterward, the usual dose of fluorescein was injected intravenously. Samples of blood and of fluid aspirated from the peritoneal cavity were taken at intervals and the concentration of fluorescein was determined. After 107 to 140 minutes, the animals were killed and the volume of fluid remaining in the peritoneal cavity was measured. Estimation of the protein concentration of plasma and of peritoneal fluid was made by the method of Barbour and Hamilton (7).

TABLE I

Changes in fluorescein concentration in blood and peritoneal fluid

75 mgm. per kgm. fluorescein injected intravenously
50 ml. per kgm. Ringer's solution injected intraperitoneally

Animal number	Weight	Time of sampling. Minutes after dye injection		Plasma protein	Fluorescein	
		Blood	Peritoneal fluid		Blood	Peritoneal fluid
	kgm.			*grams per 100 ml.*	*mgm. per 100 ml.*	
23	2.20	15	12	5.78	21.5	0.70
		42	39	5.37	9.6	0.80
		85	82	5.48	2.8	1.30
		122	118	5.52	1.2	1.45
		146	148	5.34	0.7	1.40
20	2.46	10	21	4.99	27.4	0.90
		39	45	5.03	13.5	1.20
		75	82	5.41	5.8	1.40
		122	126	5.07	2.1	1.30
28	1.80	11	16	4.45	23.0	1.10
		39	43	4.66	11.8	2.40
		65	71	4.52	5.4	3.20
		102	107	4.39	1.7	2.90

TABLE II

Diffusion of fluorescein against a filtration gradient

Terminal fluid volume and fluorescein concentrations after intraperitoneal injection of 50 ml. per kgm. body weight of Ringer's solution and intravenous injection of 75 mgm. per kgm. fluorescein.

Animal number	Mgm. dye injected at 75 mgm. per kgm.	Ringer's solution			Total time	Dye in peritoneal fluid		
		Injected	Recovered	Recovery		Final conc.	Total	Injected dye
		ml.	*ml.*	*per cent*	*min.*	*mgm. per 100 ml.*	*mgm.*	*per cent*
20	181	123	53	43	126	1.3	0.69	0.38
23	165	110	72	65	148	1.4	1.10	0.67
28	135	90	50	56	107	2.9	1.45	1.07

Data obtained from three animals are presented in Tables I and II. Figure 5 shows curves describing the time course, in a representative experiment, of the changes of dye concentration in the blood and in the Ringer's solution withdrawn from the peritoneal cavity. The intersection of the curves at 110 minutes after the injection of fluorescein shows the time at which the concentration of the dye was equal in blood and peritoneal fluid. For approximately 40 minutes thereafter, the concentration of dye in blood continued to decrease while that of the fluid in the peritoneal cavity decreased comparatively little. Since the change in fluid volume in the peritoneal cavity of all three animals (Table II) showed vigorous absorption during the time that dye was passing into this fluid, the net change in fluorescein concentration was one largely determined by diffusion pressure. The permeability of capillaries within the peritoneal cavity during the experiments was assumed to undergo no significant change, since the highest specific gravity measured on peritoneal fluid did not exceed 1.0066. The data in Table I show that the concentration of dye in the peritoneal fluid reached and exceeded the concentration in the blood in two of the animals tested. In the remaining animal (No. 20), the concentration of dye in the peritoneal cavity began to decline before it reached equilibrium with the blood.

Teorell (8) has made an extensive theoretical analysis of the kinetics of distribution of substances introduced into the body on the basis of the following relationships derived from Fick's law:

(a) the total *amount* of substance transferred between blood and the tissue is:

$$\underset{-dN}{\text{amount}} = \underset{D}{\text{diffusion coeff.}} \times \underset{dc/dx}{\text{conc. gradient}} \times \underset{A}{\text{surface}} \times \underset{dt}{\text{time}} \quad (1)$$

and

(b) since the diffusion coefficient is related to the net value of the friction coefficients encountered, it will be incorporated with the effective permeation surface (A in Eq. 1) and the boundary thickness in a "permeability coefficient" as k'_n in the following:

$$\text{Amount across boundary in the time unit } \frac{-dN}{-dt} = \underset{k_n'}{\text{perm. coeff.}} \times \underset{\frac{N_i}{V_i} - \frac{N_o}{V_o}}{\text{conc. diff.}} \quad (2)$$

where N_i, V_i and N_o, V_o are the amounts of the substance and the fluid volume respectively inside and outside the boundary, and "amount" is the number of gram molecules or grams or any unit.

Where it may be assumed safely that the dis-

tribution of the substance introduced into the blood is not complicated by selective accumulation in depots, reaction with blood constituents, by tissue inactivation or by changes in volumes of fluid concerned, Teorell's analysis, by the simple formulation given above, may be applied. His calculations show that, after the concentration of substances in the blood and in the extravascular phase have become equal, the removal of substances from both phases occurs at about the same rate but that the concentration of substances in tissue fluid remains persistently above that in the blood.

The conditions of the experiments reported here differ from those in Teorell's analysis in two ways: the dye leaves the blood and enters a large amount of fluid which is continuously changing in volume, and in addition, the blood is being continuously diluted by the fluid which is being absorbed. Zweifach (9) has pointed out that transfers of fluid across capillary membranes are "transfers of fluid in bulk." It may be assumed that the transfer of fluid from the peritoneal cavity involves also the removal of at least some of the fluorescein which had previously passed into this fluid from the blood stream.

The course of events in animal No. 20 serves to emphasize the effect of fluid filtration from the peritoneal cavity to the blood upon final concentration relationships. A simplified statement of the factors determining the concentration of dye in peritoneal fluid may be presented as follows:

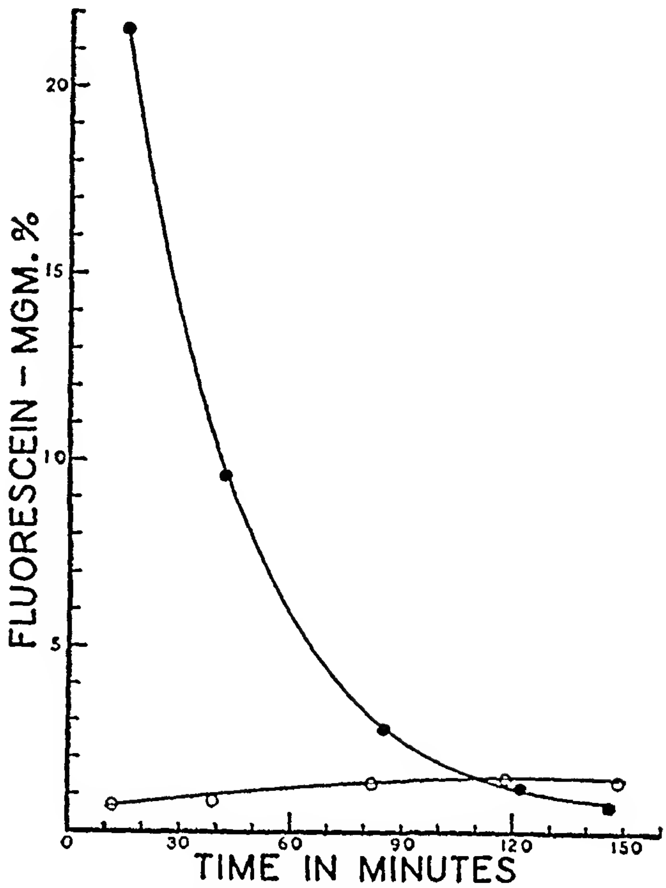

FIG. 5. TIME COURSE OF CHANGES IN FLUORESCEIN CONCENTRATION IN BLOOD AND PERITONEAL FLUID

Representative data from 1 animal. Fluorescein injected at zero time. Solid circles—concentration of fluorescein in blood. Open circles—concentration of fluorescein in peritoneal fluid.

$$\frac{(\text{dye entering mgm. per min.}) - (\text{dye leaving mgm. per min.})}{(\text{fluid entering ml. per min.} - (\text{fluid leaving ml. per min.})} = \frac{\text{mgm. gain or loss of dye}}{\text{ml. gain or loss of volume}} = \text{net change}$$

in conc. of dye and the concentration of dye in the peritoneal fluid may be expressed as

$$\text{mgm. of dye per 100 ml.} = \frac{\text{net change in conc. of dye}}{\text{volume of fluid in the peritoneal cavity}} \times 100.$$

Where the rate of fluid filtration from the peritoneal cavity is high, as it was in the case of animal No. 20, the rate of removal of dye along with the fluid may be sufficiently great to bring about a decline of fluorescein concentration in the peritoneal cavity before concentration equilibrium is established. We have no reason to believe that there was any qualitative difference in the processes involved in fluorescein exchange among the three animals tested in the manner described. The attainment of fluorescein equilibrium between blood and the Ringer's solution in the peritoneal cavity may not safely be considered to represent simple relationships of diffusion pressure and permeability. The magnitude of the equilibrium concentration and the time at which this concentration was reached depends upon the rate and direction of fluid exchange as well as upon the rate and direction of transfer of dye.

These observations show that, while fluorescein may diffuse out of the blood into extravascular fluid at the same time as fluid is being actively

taken into the blood in the same region, the movement of dye is not independent of the movement of water.

3. *The extent of cell penetration by fluorescein.*

A further examination of the distribution of fluorescein after intravenous injection was carried out by the analysis of blood and skeletal muscle from animals subjected to previous ligation of the renal pedicles. Three rabbits were anesthetized by the intraperitoneal injection of dial, 90 mgm. per kgm. body weight. After supplementary administration of ether the renal pedicles were ligated acutely either through lumbar incisions or by an abdominal approach. The wounds were closed and control blood samples were taken. An intravenous injection of fluorescein, 75 mgm. per kgm. body weight, was given. At intervals approximately one-half hour apart, three blood samples were taken. Following the last sample, the animals were killed and samples of skeletal muscle were excised. Plasma was analyzed for fluorescein by the methods described previously. The muscle samples were weighed, homogenized in a Waring Blendor and subjected to extraction for the determination of fluorescein. The muscle from the first animal studied was extracted directly with 95 per cent alcohol in the proportion of 1 gram of minced muscle to 6 ml. of alcohol. Although the muscle was grossly yellow in appearance this method of extraction yielded no detectable fluorescein when the alcoholic extract was subjected to colorimetric comparison. In the remaining two animals the muscle samples weighing approximately 50 grams each were extracted directly in 200 ml. of cold phosphate buffer at pH 7.0 or were subjected to repeated freezing and thawing before final separation of the extracting medium by centrifugation. The shapes of the curves describing the "dilution" of injected fluorescein indicated that even at the end of 150 minutes the blood concentration of the dye continued to fall slowly. Calculation of the volume of fluid in which the fluorescein would have to be dissolved, if solution alone were to account for the reduced concentration with time, showed that the apparent distribution volume of dye amounted to 39 to 45 per cent of the animal's body weight. Various investigators (10, 11) have found that the extracellular phase of most mammals including rabbits comprises between 20 and 30 per cent of the body weight. Therefore, the apparent distribution volume of fluorescein observed in the present studies must be accounted for by an appreciable penetration into the cellular compartment, or loss by some other route.

The analyses of muscle samples from the same animals yielded values for fluorescein concentration of 1.03 to 1.92 mgm. of dye per 100 grams of fresh muscle. On the assumption that even distribution of fluorescein existed throughout the extracellular phase, the comparison of plasma fluorescein with muscle fluorescein showed that the distribution volume of dye amounted to 8.4 to 11.4 per cent of the muscle weight. Others have reported that the extracellular phase of rabbit muscle is approximately 16 per cent by weight (10). It, therefore, seemed unlikely that the large total distribution volume of dye could be accounted for on the basis of a general penetration of dye into cells.

All of the animals were observed to have brightly fluorescent yellow dye in the gallbladder bile and in the lumen of the intestine. Analysis of the intestinal fluid for fluorescein in one animal showed that the concentration of dye was 45.75 mgm. per 100 ml. The apparent dilution volume of dye, estimated from the amount injected and the final concentration, was greatly in excess of the extracellular phase volume calculated as 25 per cent of the body weight; 925 ml. compared to 500 ml. The amount of dye which would be dissolved in the volume representing the difference between the two values given above at the final blood concentration of 16.25 mgm. per 100 ml. was

$$425 \text{ ml.} \times \frac{16.25 \text{ mgm.}}{100 \text{ ml.}} = 69.1 \text{ mgm.}$$

If all of this "lost dye" were in the intestinal tract at a concentration of 45.75 mgm. per 100 ml., the volume of fluid necessary to accommodate it would be:

$$\frac{69.1 \text{ mgm.}}{V} = \frac{45.75 \text{ mgm.}}{100 \text{ ml.}}$$
$$V = 151 \text{ ml.}$$

Since the brilliant fluorescence of gallbladder bile

indicated a concentration of dye even greater than that in the fluid in the lumen of the intestine, a dilution volume much less than the estimated volume of 151 ml. would actually accommodate the amount of "lost dye" indicated above. Carmichael, Strickland, and Driver (12) report data from which the water in the contents of various parts of the gastro-intestinal tract of rabbits may be calculated. The average water content of the small intestine, cecum and colon from six rabbits, weighing approximately 2 kilograms each, was 114 ml. Thus, it is reasonable to assume that the disparity between the measured distribution volume of fluorescein and that predicted for the extracellular phase may be accounted for by the amount of dye excreted into the bile and the lumen of the intestine.

The distribution of fluorescein between plasma and red blood cells was studied on blood samples from four rabbits by equilibrating heparinized whole blood *in vitro* at 37° C. with known amounts of fluorescein. The fluorescein concentration of the separated plasma was determined at intervals, and the distribution of dye between the cells and the plasma phase was calculated from these measurements and the hematocrit values. Within one minute after the addition of dye to the blood, only about 85 per cent of it could be found in the plasma, and over a period of 2 hours the plasma fluorescein diminished to 82.7 per cent of the amount predicted from the quantity of dye originally added to the sample. Thus, either penetration of fluorescein or its adsorption upon the surface of red blood cells removed from 15 to 17.3 per cent of it from the plasma.

When red cells were subjected to alteration of their normal surface volume relationship by suspending them in solutions of sodium chloride varying in concentration from 1.8 per cent to 0.54 per cent before equilibrating them with fluorescein, no differences were noted in the amount of dye recovered from the non-cellular phase of the suspension. Since there is little or no change in cell surface area and large change in cell volume under the above conditions, it seems likely that the disappearance of fluorescein from the plasma phase may be ascribed to surface adsorption rather than cell penetration.

CONCLUSION

1. The intensity of fluorescence of regions exposed to ultraviolet light after the intravenous injection of fluorescein depends more directly upon the amount of dye in the interstitial fluid than upon the concentration of dye in the blood.

2. The amount of fluorescein present in the interstitial fluid depends to an important degree upon filtration processes involved in the exchanges of plasma ultrafiltrate across capillary membranes as well as upon simple diffusion exchanges. The movement of dye across capillary membranes should not, therefore, be considered to be independent of the movement of water.

3. The distribution of fluorescein in the various water compartments of the body after intravenous injection extends throughout the extracellular phase. The dye is excreted in large amounts in the bile and small quantities, 15 to 17 per cent, become associated with the cellular fraction of the blood in a manner which suggests surface occlusion rather than penetration of the cells.

SUMMARY

The distribution of injected fluorescein, a fluorescent dye, was studied in normal rabbits. A consideration of the relation of dye concentration in the blood and the intensity of fluoresence of the animal's skin under ultraviolet light indicated that maximum intensity of fluorescence is reached at a time when the concentration in the blood is falling rapidly. Thereafter, the disappearance of dye from the blood and the decline of intensity of skin fluorescence occurred at about the same rate.

The exchanges of fluorescein injected into the blood stream with Ringer's solution introduced into the peritoneal cavity of rabbits showed that the concentration of dye rose in the fluid within the peritoneal cavity during the time that the fluid was being actively absorbed into the blood. The concentration of dye in the fluid within the peritoneal cavity at any time after injection depends upon the amount of it entering and leaving the peritoneal cavity as well as upon the direction and volume of fluid exchange. Therefore, in circumstances where the volume of extravascular fluid may be changing, the movement

of dye is not independent of the movement of water.

The distribution of intravenously injected fluorescein was tested in rabbits after ligation of the renal pedicles. Calculations of the apparent dilution volume of the dye yielded values equivalent to from 39 to 45 per cent of the animals' body weight. Determinations of the fluorescein content of samples of skeletal muscles from the same animals showed no evidence that the dye penetrated the intracellular phase. If the amounts of dye in muscle were assumed to be in equilibrium with the fluorescein in the blood, the volume of muscle water in which the dye was dissolved equalled 8.4 to 11.4 per cent of the total weight of muscle. Sufficient amounts of fluorescein were found in the bile and in the lumen of the gut to approximate the amount which had disappeared from the extracellular phase.

When heparinized whole blood was equilibrated for 2 hours *in vitro* at 38° C. with known amounts of fluorescein, approximately 83 per cent of the amount of added dye could be recovered from the separated plasma. Since osmotic manipulation of red cell volume without change in the surface area did not change the amount of dye recovered from the fluid phase, the loss of dye was tentatively attributed to surface adsorption rather than cell penetration.

STUDIES ON GANGRENE FOLLOWING COLD INJURY. V. THE USE OF FLUORESCEIN AS AN INDICATOR OF LOCAL BLOOD FLOW: FLUORESCEIN TESTS IN EXPERIMENTAL FROSTBITE [1]

By J. M. CRISMON and FREDERICK A. FUHRMAN

(From the Department of Physiology, Stanford University School of Medicine, Stanford University, California)

(Received for publication September 1, 1946)

The application of the fluorescein test to the study of frostbite has been described recently by Lange and Boyd (1). In the course of studies of experimental frostbite carried on in this laboratory, certain of the results obtained with the fluorescein test have been difficult to explain on the basis of interpretations suggested by the proposers of the method. Two groups of experiments were undertaken in order to study certain aspects of fluorescein exchange not already reported in the literature. The first group of experiments consisted of studies on normal rabbits of skin fluorescence and fluorescein distribution in body fluids: these have been presented previously (2). The present paper reports the second group of studies carried out on normal rabbits and on rabbits subjected to severe cold injury.

METHOD

The techniques employed in the fluorescein test, the measurement of skin fluorescence after the injection of fluorescein, and the analysis of body fluids for fluorescein were described previously (2). Skin fluorescence under ultraviolet light was photographed with a Kodak Recomar having a Kodak anastigmat lens, f. 4.5 of 105 mm. focal length. Black and white photographs were taken at f.8 on Ansco Superpan Press film with exposure times of 15 seconds through a Wratten No. 15 filter or 90 seconds through a Wratten No. 62 filter. The animals used in all of the experiments were adult New Zealand white rabbits from a uniform strain.

RESULTS

1. *Fluorescence in normal skin*

When the intravenous injection of fluorescein was made while the animals were exposed to ultraviolet light, bright greenish-yellow fluorescence was detectable in hair-free areas of the skin within a few seconds after the beginning of injection. The intensity of color became maximal in about 15 minutes. The decline of intensity was, at first, rapid and then progressively more gradual over a period of 2 to 2½ hours. In the rabbit ear, the regions which glowed most intensely were those relatively free of large blood vessels. The larger blood vessels stood out as dark streaks which could be obliterated by prescure with a glass slide. The areas rendered ischemic by pressure showed no decrease of fluorescence.

2. *Fluorescence in frostbitten ears of rabbits*

The influence of injury by frostbite upon the distribution of fluorescein after intravenous injection was studied on rabbits' ears. Frostbite was produced by immersing the distal 3 to 4 cm. of the ears in a freezing mixture consisting of alcohol, ethylene glycol, and water with sufficient solid carbon dioxide added to bring the temperature between − 52° C. and − 70° C. The details of the method of producing standard cold injury and the general course of changes following such injuries have been described in previous reports (3, 4).

Abnormalities in the distribution of fluorescein in the frostbitten portion of rabbits' ears included decreased rate of entrance of dye, slower rate of removal, and lower maximum intensity of fluorescence than was observed in the normal ear. Observations made at varying intervals after injury showed that the local changes, which were responsible for the abnormalities of fluorescein distribution, undergo modification with time. The photographs in Figure 1 illustrate the delayed penetration and exit of the dye as well as the differences in results of identical tests made immediately after inquiry and repeated

some 18 hours later. Figure 1A shows a photograph of the normal ear of a rabbit taken under ultraviolet light before the injection of fluorescein and before the ear was frostbitten. The small bright spot near the tip of the ear is the fluorescence from a drop of lubricating oil which was smeared on the skin from the electric clipper. Figure 1B was taken 15 minutes after the ear was re-

moved from the freezing mixture. The exposure to cold was 1 minute at − 70° C.[2] Fluorescein was injected intravenously in the opposite ear 10 minutes before the photograph was taken. The depth of immersion in the freezing mixture is clearly indicated by the virtual absence of fluorescence in the distal 3 cm. of the ear. The larger vessels of the distal part of the ear are faintly fluorescent at this time, with an appreciable spread of dye about the central artery for a distance of about 8 mm. into the injured area. Some lack of sharpness in the junction between the brightly fluorescent, normal part and the injured region suggests that limited penetration of fluorescein was taking place at that point. Figure 1C is a photograph of the same animal taken 30 minutes after frostbite and 25 minutes after the injection of dye. It will be noted that the intensity of fluorescence had diminished to a considerable degree in the normal part of the ear, while that in the injured area had reached a brightness almost equal to that observed at 10 minutes in the uninjured areas, and that the fluorescence almost obscures vascular detail. Figure 1D, photographed 18½ hours after the first injection of fluorescein, shows the complete removal of dye from all parts of the ear at that time. Figure 1E illustrates the appearance of the ear at 18 hours and 50 minutes after frostbite and 10 minutes after the second injection of fluorescein. In this photograph the vascular detail, which was easily made out in the normal part of the ear at 10 minutes after the first injection of dye, is almost completely obscured by the massive edema and the distribution of fluorescein in the skin. The penetration of dye into the injured region can be seen only faintly outlining the major vascular

[2] The results were the same when the temperature of the freezing mixture was − 52° to − 56° C.

channels. Figure 1F, photographed 25 minutes after the second injection of fluorescein, shows a striking reduction in the amount of dye in the injured region as compared with the amount which accumulated during an identical interval after injection when the injury was only 30 minutes old.

3. *Time intensity relationships of fluorescence in normal and frostbitten ears of rabbits*

Photoelectric measurements were made of the change in intensity with time of fluorescence in 6 normal rabbit ears and in 17 ears at various times after frostbite. Figure 2 shows the results of these measurements in curves plotted with the intensity of fluorescence on the axis of ordinates in terms of galvanometer units and time in hours after the injection of fluorescein on the axis of abscissas. In normal ears, the change in itensity of fluorescence with time was characterized by a very rapid rise to a maximum within 15 minutes and a somewhat less rapid decline in intensity, with final disappearance of glow occurring between 2 and 3 hours after injection of dye. The rate of increase in intensity measured in frostbitten ears when the dye was injected immediately or at 1 hour after injury is slower than that observed in normal ears. When the injection of fluorescein was made at successively longer intervals after frostbite, further slowing of both the entrance and exit of dye occurred. At intervals of 1 and 2 days after frostbite the maximum intensity reached was only a little over a third of that reached in normal ears. The tendency for exit of fluorescein from the frostbitten region to be slower than its entrance, a phenomenon noticeable in the comparison between measurements made when the dye was injected immediately after frostbite with those made at 1 hour, was greatly exaggerated in the tests made at intervals of 1 and 2 days. While no striking differences were noticeable between the measurements made on the first and second days after injury, the tests on the third day showed only a feeble fluorescence. The maximum occurred about 2 hours after the injection of dye and was followed by a greatly prolonged course of removal. In some cases fluorescence was detected by direct observation as long as 24 hours after dye injection.

Since the rates of entrance and removal of dye were shown to become progressively slower as the interval between injury and the test was increased, only the earliest tests were subjected to statistical comparison. The significance of difference in rates of fluorescein exchange between that in normal ears and that in ears tested immediately after frostbite was calculated (5). Table I presents measurements of fluorescence at 10 minutes after the injection of dye and at 2 hours after injection in 5 normal ears and in 5 frostbitten ears of rabbits receiving fluorescein immediately after frostbite. Comparison of the intensity of fluorescence in both series at 10 minutes after injection shows that the brilliance is significantly greater in normal ears. Analysis at this time interval was considered to be free of differences which might be attributed to gross deficiencies of blood flow in the frostbitten ears because skin temperature measurements taken at this time showed that the temperature was rising very rapidly. The pink color of the skin and the large size of major blood

TABLE I

Measurements of intensity of fluorescence in normal and frostbitten ears of rabbits at intervals after injection of fluorescein

Data from 5 animals

Column	Normal ears				Frostbitten ears 90-second exposure at −55° C.

	7.1	7.1	7.0	9	0.3	3.5	2.5	60
	4.0	4.8	3.7	20	0.2	2.0	1.5	84
$\bar{X}$ =	6.78		6.74		0.82		1.90	
$SE_{\bar{x}}$ =	0.752		1.163		0.285		0.344	

$\bar{X}$ = Mean.

$SE_{\bar{x}}$ = Standard error of mean.

* Difference in galvanometer units between maximum readings and readings taken two hours after injection of fluorescein. Comparison of mean values at the base of columns 1 and 5 indicates difference in rate of entrance of dye in normal and frostbitten ears. Standard error of the difference between means of columns 1 and 5 is 1.213 and $P < 0.01$ Comparison of columns 3 and 7 indicates difference in rate of exit of the dye Standard error of the difference between the two means is 0.804 and $P < 0.001$. P expresses the probability that such differences would be encountered by errors of random sampling.

vessels also furnished evidence of rapid blood flow.

The fluorescence at 10 minutes, at the maximum, and the decrease in 2 hours following the injection of dye (see Table I) was greater in normal ears than in those injured by cold. Statistical comparison of the mean values for columns 1 and 5 showed a significant difference. Therefore, since the most rapid rate of entry of dye into frostbitten ears is significantly slower than the rate of entry into normal ears, the still slower rates of entry encountered at longer intervals after injury must also be lower than the rate in normal ears. The slowing of removal of dye from frostbitten ears as compared with the rates of removal from normal ears was found to be significant by means of a similar assessment of the difference between the means of values given in columns 3 and 7. The data in columns 3 and 7 were obtained by subtracting from the galvanometer deflection measured at the peak of fluorescence, the galvanometer deflection measured 2 hours after the maximum was reached. The difference between these amounts of change over a period of 2 hours in the two groups is consistent with the marked difference in the general slopes of the curves of declining intensity of fluorescence. Progressive flattening of the curves is noted with increase in the interval between injury by cold and the injection of dye. Hence, the validity of the difference established between measurements on normal ears and on frostbitten ears tested immediately after frostbite may be presumed to extend to the greater differences observed at longer time intervals.

TABLE II

Comparison of fluorescein concentration in blood and edema fluid

75 mgm. per kgm. fluorescein given intravenously 10 minutes after exposure of one foot at −55° C. for 3 minutes

Animal number	Time after fluorescein	Blood fluorescein concentration	Plasma fluorescein* concentration	Edema fluid fluorescein concentration
	min.	*mgm. per 100 ml.*	*mgm. per 100 ml.*	*mgm. per 100 ml.*
78	120	1.78	2.92	5.10
74	140	3.20	5.25	10.78
81	175	0.20	0.33	8.25

* Plasma fluorescein concentration calculated from whole blood fluorescein concentration assuming a hematocrit of 39 per cent (mean of 9 animals) and no penetration of fluorescein into red blood cells.

4. *The concentration of fluorescein in edema fluid and in blood*

In order to determine whether the delayed removal of fluorescein from frostbitten regions was a phenomenon restricted to layers of the skin near the surface or one involving the deeper layers also, analyses of blood and of edema fluid from frostbitten feet were made in three animals. One hind foot of each of three rabbits was frostbitten by immersion for 3 minutes in the freezing mixture at − 55° C. (3). Intravenous injection of fluorescein, 75 mgm. per kgm. body weight, was given at 10 minutes after frostbite. At intervals from 120 to 175 minutes after the injection of dye, samples of blood and of edema fluid were taken for fluorescein analysis. Data from these experiments are presented in Table II. The low concentrations of dye found in the blood of these animals is similar to that observed in normal animals at comparable times after fluorescein administration (2). Edema fluid, withdrawn from the frostbitten feet at the same time as the blood samples were obtained, contained dye at several times the concentration found in the blood. On the basis of an estimated hematocrit value of 39 per cent in rabbit No. 78, where the smallest difference is shown, the calculated plasma concentration of dye was 2.92 mgm. per 100 ml., only a little more than half of that in the edema fluid from the foot of the same animal.

5. *The influence of increased blood flow upon fluorescein exchanges in frostbitten rabbit ears*

Measurements of skin temperature in frostbitten ears and feet of rabbits have shown that the blood vessels of the injured regions do not participate in thermovascular reflex changes in diameter (4). However, the vessels of parts of ears proximal to the injured region show both tonic constriction and the ability to dilate in response to local application of heat or following procaine block of the stellate ganglions (6). The flow of blood into the injured area of frostbitten ears is, in part, determined by the degree of dilatation of the major arteries proximal to the line of frostbite. Direct observation of blood flow in frostbitten ears

treated by rapid thawing in warm water or by procaine block of the stellate ganglion showed that the irreversible stage of stasis was delayed when blood flow was increased, whether the increase was brought about by heat or by sympathetic paralysis (6). If stasis was allowed to progress without treatment for 20 to 50 minutes, the subsequent increase of blood flow was ineffective in restoring movement of blood in true capillaries as determined by direct observation.

The influence of increased blood flow upon the distribution of fluorescein in the frostbitten ears of rabbits was tested in the following manner. Both ears of each of three rabbits were frostbitten by immersion for 1 minute in the freezing mixture at − 55° C. At intervals varying from 54 to 125 minutes after frostbite, 1 to 2 ml. of 2 per cent procaine hydrochloride solution were injected into the region of the stellate ganglion on one side. Five minutes later fluorescein was injected by vein in the usual dose of 75 mgm. per kgm. body weight. Over the ensuing 2 to 6 hours, the intensity of fluorescence was measured in both ears. The curves presented in Figure 3 show that in all three animals the fluorescence of the ear on the side subjected to sympathetic block reached a higher maximum intensity than that measured on the injured, untreated ear. While the rate of increase in fluorescence was higher on the blocked side, the rate of removal was about the same for both.

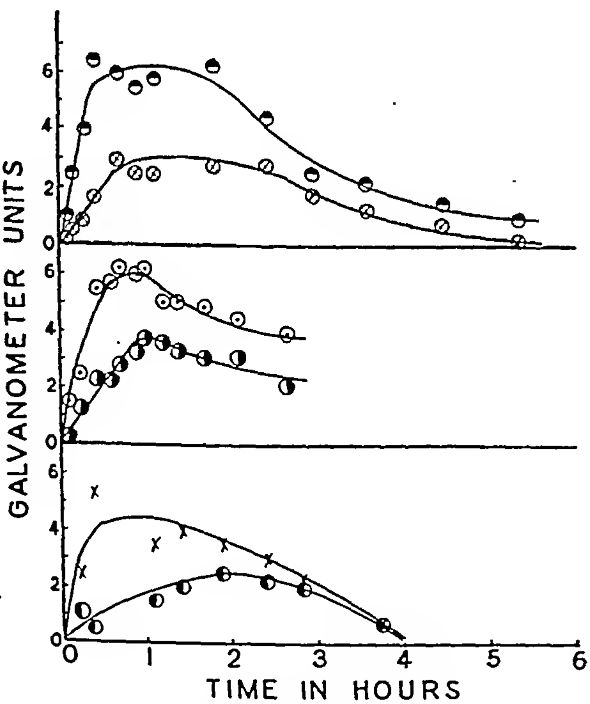

FIG. 3. INTENSITY OF FLUORESCENCE OF RABBITS' EARS AFTER FROSTBITE AND PROCAINE BLOCK OF RIGHT STELLATE GANGLION

Both ears of each rabbit exposed at − 55° C. for one minute. Procaine injected 2 hours after frostbite. Fluorescein injected .5 minutes after procaine (zero time on figure). Upper curves in each figure—right frostbitten ear, ganglion blocked. Lower curves in each figure—left frostbitten ear. Each figure represents one animal.

The increase in fluorescence, observed in frostbitten ears under the circumstances described above, was measured at a time after injury when stasis in true capillaries was completely developed. Paralysis of the sympathetic nerve supply to the ear, at comparable times after injury in other experiments, had been found to be incapable of restoring blood flow in these vessels (6), even though the rise in skin temperature indicated an increased total blood flow. Since the exposure to cold of both ears in each animal was the same, the difference in intensity of fluorescence following procaine block of the stellate ganglion should be attributed to alteration of the minute volume or local pattern of blood flow rather than to differences in capillary permeability.

DISCUSSION

Observations of skin color, skin temperature, arterial pulsation, and movement of blood watched under the microscope, at least in some vascular channels, in the frostbitten ears of rabbits show that total blood flow is for a time greater than that in normal ears and does not become completely arrested until more than 50 hours after injury (4, 6). During the intervals characterized by rapid blood flow, tests with fluorescein show both delayed entrance and delayed exit of dye from the skin of the injured region. Lange's recently reported observations in which similar fluorescein tests were used upon accidental and experimental cold injury also point out the paradox of impaired dye exchange in the presence of good blood flow (1). He observed diminished fluorescence in regions injured by mild cold and was able to show that capillary blood obtained from poorly staining regions contained as much fluorescein as that from normal, brightly fluores-

cent skin. Two possible explanations were offered to account for the differences observed: namely, that capillary permeability had decreased as the result of cold injury and that local vasoconstriction resulted in reduction of filtration pressure. The second of these explanations was considered to be a local change probably not involving more than axon reflexes, since the difference could not be abolished by local anesthesia or by sympathetic block. Severe cold, sufficient to freeze the tissues, resulted in delayed entrance of fluorescein and apparent hyperfluorescence when observations were made at successively longer intervals after dye injection.

The present studies on gangrene resulting from cold injury include several observations which are difficult to reconcile with Lange's assumption that reduced capillary permeability was the factor responsible for the abnormal distribution of fluorescein in tissues injured by cold. The rapid swelling of frostbitten parts, which begins virtually with the return of blood flow after thawing, and the high protein concentration of the edema fluid are changes not consistent with decreased capillary permeability. The delayed penetration of fluorescein into frostbitten regions also seems difficult to explain upon the basis of Lange's second suggestion, decreased filtration pressure, since this would have to coincide with the appearance of massive edema and the rise of subcutaneous tissue pressure to levels as high as 25 cm. of water (7).

An attempt to explain the abnormal distribution of dye upon the basis of simple changes in capillary permeability would require the additional assumption that the permeability changes be selective with respect to the plasma constituents as well as to the direction of their free passage. If decreased capillary permeability were responsible for the delayed entrance of dye into the skin of the frostbitten region, the capillaries would have to be capable of passing large quantities of plasma protein into the interstitial fluid during the time that the loss of fluorescein from the blood in the same region was being restrained. Data presented in a previous report (7) furnish ample evidence of protein loss from the blood into the frostbitten ears and feet of rabbits.

Comparison between the fluorescence of frostbitten regions and the adjacent, uninjured areas at about 1 hour after the injection of dye shows that the glow from the injured region is much brighter than that from the normal area. This is an example of the "hyperfluorescence" of skin subjected to severe cold injury, described by Lange and Boyd (1). However, serial measurements made from the time of injection of dye furnish evidence on two important points: (a) the maximum brightness of the two areas does not coincide in time; and (b) the intensity of fluorescence at maximum for injured areas is lower than the maximum intensity reached in normal skin. Thus, what, on first inspection, might seem to be a hyperfluorescence of the injured area is actually less than the maximum intensity reached at an earlier time in normal skin. The appearance of hyperfluorescence is the result of removal of dye from adjacent uninjured areas at a faster rate than from the frostbitten area. This circumstance again poses the problem of apparently selective changes in permeability. If it be assumed that the hyperfluorescence is an expression of increased capillary permeability (1), then it must be a selective form of change in permeability, manifesting a decreased restraint of dye as it leaves the blood stream in the injured region and then failure of fluorescein to move into the capillaries when the diffusion gradient has become reversed by the decline of concentration of dye in the blood. Some form of permeability change, which is peculiarly selective with respect to particle size and which operates only in one direction, must be postulated to account for the facts. Such a postulate departs widely from the accumulated experience of investigators who have studied the nature of exchanges across capillary membranes (8, 9, 10).

Both theoretical considerations (10) and measurements on normal animals (2) indicate that fluorescein should become distributed in a manner similar to that observed for other relatively small molecules, *i.e.,* largely by diffusion. The major factors involved in such transfers of dissolved material include the diffusion gradient, the permeability of capillaries, the blood flow rate, and the surface area available for diffusion. The evidence presented above shows that the dye is slow in entering and still slower in leaving areas injured by severe cold. At the same time, other evidence indicates that the diffusion gradients, the minute

volume blood flow, and the degree of capillary permeability are all such that faster rather than slower transfer of dye would be expected. As to possible alteration of the surface area available for diffusion, direct observation of blood flow in frostbitten, transilluminated ears of rabbits has shown that stasis begins early in the true capillaries and is complete within 10 minutes of the return of blood flow after thawing. Flow persists in arteriovenous anastomoses and arteriolarvenular capillaries. Since protein loss into the edema fluid is high in the early period and lower at later stages, it is not difficult to conceive of the early loss as occurring via abnormal leakage from these capillaries, which later are prevented from participating as exchange surfaces by having been blocked by silting red blood cells. Thus, blood flow persists at large minute volume and relatively high pressure in the channels remaining patent. This circumstance serves to explain both the rapid production of edema fluid by filtration and the interference with fluorescein distribution; there is a sharp reduction in the area available for diffusion. The dye, which is filtered out from the arteriorlar-venular capillaries, finds its way back into the blood stream, not by the usual reversal of gradient as the concentration of dye in the blood declines, but by slower removal via lymphatics and by movement of dye into adjacent uninjured regions where stasis has not occurred.

The above interpretation of phenomena observed in the aplication of fluorescein tests to the study of frostbite is consistent with other manifestations of altered blood flow and fluid exchange occurring after severe cold injury. Information about the degree of involvement of capillaries by stasis and its resolution may provide helpful guides in treatment and prognosis. Thus, in addition to the use of fluorescence as a clear-cut indicator of the presence or absence of blood flow, the estimation of rate of dye exchange in injured tissues may be of clinical value.

SUMMARY

Analyses were made of the distribution of intravenously injected fluorescein in normal ears of rabbits and in ears severely injured by cold. The results showed that both the dye's entrance into and its exit from the injured regions were slower than the exchanges observed in uninjured tissues. The maximum intensity of fluorescence reached in frostbitten skin was lower than the maximum recorded in normal skin. Repeated tests on the same animal showed that the exchanges of dye became progressively slower with time after injury.

When both ears of rabbits were frostbitten and procaine block of the stellate ganglion was produced on one side, the tests with fluorescein showed earlier and higher maximum intensity of fluorescence in the frostbitten ear on the side blocked. This maneuver had been shown in other experiments to be followed by delay in the onset of stasis. The greater intensity of fluorescence on the side having increased blood flow as the result of blockage of the stellate ganglion was attributed to the longer persistence of blood flow through true capillaries and, hence, greater opportunity for exchange of dye between the blood and interstitial fluid.

Edema fluid was taken from frostbitten feet of rabbits at a sufficiently long interval after the intravenous injection of fluorescein to permit the concentration of dye in the blood to fall to very low levels. Analysis of the edema fluid showed that the fluorescein concentration was at least twice as great as that in the blood.

The mechanisms of impaired dye exchange in frostbitten tissues are discussed, and a hypothesis is presented in which the impairment of dye exchange is attributed to reduction of available surface for diffusion by the development of stasis in the true capillaries following cold injury.

EFFECT OF CREATINE ON THE PAIN OF MUSCLE ISCHEMIA

By F. B. CULP and F. W. KINARD

(From the Departments of Chemistry, and Physiology, Medical College of the State of South Carolina, Charleston)

(Received for publication September 8, 1946)

The stimulus of the pain which arises from exercising ischemic muscle has been ascribed to a "factor P" (1). It has been suggested that this factor may be lactic acid, a compound of phosphorus, or creatine, or ammonia (2); phosphoric acid (3); potassium (4); lactate ion (5); or histamine (6). On the other hand, conclusions have been reached that potassium, sarcolactate, and ammonium ions are probably not responsible (6).

No investigations of the relation of creatine to the pain of muscle ischemia have been reported although such a relationship has been suggested (2). In the present study, the pain in exercising ischemic muscle was studied before and during creatine administration in order to observe the effect of creatine upon the pain process.

METHODS

Healthy male medical students were used as subjects with 6 in the control group and 8 in the experimental group. Each subject ate the usual diet of his choice and collected his total 24-hour output of urine. At 3:00 P.M. each day the subject brought the urine to the laboratory and submitted to a standard procedure (7) for the determination of the duration of exercise before the appearance of "definite" pain in the exercising ischemic muscle. The endpoint chosen was the first appearance of a definite sensation of pain in the forearm or hand after exercise had been executed at the rate of one contraction per second. The time, in seconds, was recorded by a stop watch concealed from the subject. The right arm alone was used in all experiments. Instead of simple flexion of the fingers to form a fist, the subject squeezed a gripping device against a spring tension of 1.1 kgm.

The urinary creatine and creatinine were determined in duplicate by the method of Peters (8), using the Evelyn photoelectric colorimeter for the color comparisons. Urine studies were made during both the preliminary control and the experimental periods.

Following a period of several days during which the subject became familiar with the procedure, single observations were made daily for a control period of 2 days before creatine administration was begun.

Creatine, C.P., was dissolved in water, chilled, flavored with citric acid and saccharin, and administered in daily doses of 10 grams for a period of 4 days. Creatine was given only after 2 days of preliminary studies. The control subjects were given flavored water, from a flask labelled "creatine," and were led to think that they were being given creatine. No one was informed of the grouping of subjects or of the exact nature of the experiments.

RESULTS

The exercise duration, in seconds, until the appearance of a definite sensation of pain in the exercising ischemic muscles was recorded during the 2-day preliminary period. For each subject the mean of these two values is plotted in Figures 1 and 2 on the zero line of the control period. Each of the two values is then plotted in terms of per cent variation from the mean value. During the experimental periods, the time of appearance of pain is plotted as per cent variation from the mean value of the preliminary control period.

Control subjects. In each of the 6 subjects, the time of appearance of definite pain in the preliminary control period did not vary more than 5.5 per cent from the mean of the two values (Figure 1).

On the first day after receiving the flavored water, to be designated hereafter as "placebo," only 2 subjects (C. H.; R. M.) observed definite pain within the time range of the preliminary control period. One of these, R. M., again observed pain within the control range on the second day. The only definite trend toward uniformity of response was the relatively delayed pain appearance in five of the subjects on the fourth day of the experimental period, as shown in Figure 1.

Creatinuria was not observed in any of the control subjects at any time.

Subjects receiving creatine. On the first day of the experimental period, 5 of the 8 subjects observed definite pain either within the limits of the preliminary control period or earlier. By the fourth day, when creatine retention was at a maximum, 6 subjects observed pain later than it

* Urine specimen lost.

had appeared during the control period, as shown in Figure 2.

Creatine retention. The subjects were on their usual diets, which were not creatine-free; so an arbitrary method of calculation was adopted. The creatine retained was considered to be the difference between that which had been fed and that excreted through each successive day of the experimental period. This value is recorded as the retained creatine and is plotted in Figure 3. The maximum retention was 22.60 grams of creatine in subject M. P., and the lowest was 13.79 grams in subject F. C.

DISCUSSION

It has been reported (9, 10) that the creatine concentration of muscle is increased by the feeding of creatine. In our subjects, there was a definite trend toward delayed appearance of pain in exercising ischemic muscle as the quantity of retained creatine increased. Perhaps, then the pain-producing phenomenon in ischemia is related to the creatine content of the muscle. However, a similar delay in pain appearance occurred in the control subjects. Since the two groups reacted in a similar manner and since the controls were not receiving creatine, it appears definite that increased creatine storage is not the fundamental cause of the delayed pain response. Training, or possibly some psychological factor, may be involved but this is mere speculation.

In comparing the amount of exercise required to produce pain in the two arms of 7 subjects, Katz, *et al* (11) found that pain appeared earlier in the left arm. The difference in the two arms was ascribed to training, as the right hand had been used much more frequently in the clenching exercise. We have used the right arm alone in all experiments and have made a single determination daily for not longer than 8 days. It would seem that training, under these conditions, would play not more than a minor role. In addition, several subjects showed marked shortening of the period of exercise on the first, second, or third days of the experimental period. If training is the major factor in producing the general tendency toward the longer toleration of exercise, it certainly does not influence the results in a graded uniform fashion.

SUMMARY

There was a definite trend toward delayed appearance of pain, in a majority of 8 subjects, as the quantity of retained creatine increased. However, the same tendency was observed in the control group which was receiving a placebo only. It is concluded that increased concentration of muscle creatine is not the primary cause of the delayed appearance of pain. Training may be involved in the delay but some unexplained factor, or factors, seems more likely.

SCLEROMA: AN ETIOLOGICAL STUDY

By MILTON GJELHAUG LEVINE, ROBERT E. HOYT, AND JOHN E. PETERSON

(From the Institute of Experimental Medicine and the Department of Medicine, College of Medical Evangelists, Los Angeles, California)

(Received for publication September 28, 1946)

Rhinoscleroma was discovered in 1870 by von Hebra (1) who considered it an unusual form of skin cancer. Geber (2) later characterized the lesion as a chronic inflammatory process accompanied by perivascular cellular infiltration and connective tissue proliferation. Mikulicz (3) clearly described the histological picture including the diagnostic "foam" or "lace" cells which have been named after him.

Since the disease is not confined to the nose as von Hebra originally assumed in using the prefix "rhino," the more inclusive term scleroma was officially adopted at the Second International Congress of Otorhino-laryngology (4) held in Madrid in 1932.

PATHOLOGY

Scleroma is a disease which clinically is well defined. It is a granulomatous lesion primarily localized in the upper respiratory tract. Secondarily it may appear about the pyriform aperture of the vestibule of the nose. In the respiratory tract, scleroma is most often localized in the anterior portion of the nose, in the vestibule or the posterior nares. In the larynx, the lesions are found usually in the subglottal space.

The pharynx and throat are the seat of lesions in a third of the cases. These are found in the mesopharynx, the posterior surface of the soft palate, the uvula, the pillars, and the lateral portion of the posterior wall. The trachea is occasionally involved.

The gross lesion most frequently described is the circumscribed nodular type which may appear as a single nodule or in groups. Each nodule may appear as a single nodule or in groups. Each nodule may vary in size from 1 to 10 mm. Their consistency varies; the early infiltrates are soft while those of longer standing are harder.

Histologically, the picture is that of a granuloma. The ciliated epithelium is transformed into stratified pavement cells. In the deeper layers of the cornea, the protoplasm becomes more dispersed and partially disappears; vacoules and pyknotic nuclei are seen. Perivascular infiltration is found in which the Mikulicz cell stands out.

Clinically, the nodular type is easily recognized. However, one may assume the existence of a prenodular stage which is less likely to be recognized since there have been no *accepted* specific tests for the disease. Szmurlo (5) has actually described this form of scleroma as the "diffuse" stage. This first "appears as atrophic rhinitis characterized by atrophy of the nasal mucosa with abundant secretion and gray crusts on the surface."

The clinical course of the disease is benign, the onset is insidious, and the duration may be from twenty to thirty years. There is little effect on the general health except for the mechanical obstruction of the air passages which may in extreme cases lead to asphyxia.

INCIDENCE

Scleroma was once thought to be confined to Central and Southeastern Europe, but it is now recognized more often and is generally acknowledged as world-wide in occurrence. In a comprehensive report, Cunning and Guerry (6) in 1942 reported that 102 cases had been described to that date in the American and Canadian literature. Streit (7) contends that an endemic area exists in Central Europe especially Poland. Lasagna (8) feels that it is becoming more common in Italy, and there is some evidence that the disease is seen frequently in Central and South America.

ETIOLOGY

The problems of scleroma are clouded by the confusion associated with its etiology. In 1882, von Frisch (9) described an organism which he asserted to be the cause of the disease. Due to inadequate morphological studies inherent in the embryonic state of the science of bacteriology and due to the lack of an experimental lesion in

animals resembling the disease in human beings, Frisch's organism was not universally accepted. The belief expressed by the American, Perkins (10), that the scleroma bacillus was not related to the disease, has been echoed periodically since then, and the current opinion may be seen in the comments of two outstanding bacteriological texts. Gay (11) states, "*K. rhinoscleromatis* bears some as yet obscure relationship with the disease rhinoscleroma. It appears, however, commonly to be a secondary invader in the lesions characteristic of the disease." Wilson and Miles (12) state, "There is very little evidence to show that this organism is primarily responsible for it. There is no means by which it can be distinguished with certainty from other members of the capsulated group; and since we know that members of this group may be present in the nose of healthy persons, it is difficult to prove that they play any part in production of rhinoscleroma. The probability is that they are mere secondary invaders, which grow freely in the nose of patients suffering from the disease."

Much of the etiological difficulty encountered is due to the alleged presence of the scleroma bacillus or related organisms in normal throats. To test this hypothesis, we must establish a criterion for the characteristics of the scleroma bacillus, then we must study its occurrence in the normal throat. The very early literature must be discarded since the required facts about the related Friedlander bacillus and the coli-aerobacter group were not available to these first investigators. There is, however, a remarkable uniformity which has been overlooked in the description of the rhinoscleroma bacillus by a number of reliable investigators in recent years. Figi and Thompson (13) in 1928, described 3 strains isolated from patients at the Mayo Clinic. Morris and Julianelle (14), apparently unaware of Thompson's report, studied 9 strains from cases in Sumatra and this country. Both of these workers found their strains to ferment glucose, maltose, and mannite with the production of acid only. Sucrose was fermented slowly by some strains, lactose never. Indole was not formed, nitrate was reduced. Other reactions are noted but are not essential to the differential identification of the organism. Gonsiorowski and Meisel (15), two

TABLE I

Cultural characteristics of scleroma strains

Strain	Mannite	Maltose	Dextrose	Lactose	Sucrose	Nitrate	Indole
1L	A	A	A	–	A	+	–
2F	A	A	A	–	–	+	–
3J	A	A	A	–	–	+	–
4M	A	A	A	–	–	+	–
5R	A	A	A	–	–	+	–
6C	A	A	A	–	–	+	–
7CA	A	A	A	–	–	+	–
8T	A	A	A	–	–	+	–

Polish workers with a large number of freshly isolated strains at their disposal, reported the fermentation of glucose (acid only) but not of lactose, the only sugars tested.

We have isolated seven strains from cases to be described later in this paper and have obtained one culture from the American Type Culture Collection. The results of cultured studies on these organisms are given in Table I.

From the above it is evident that there is a remarkable uniformity in the reactions of our organisms identical with those obtained by the workers mentioned above. We feel that the characteristics described in Table I, including the variable, slow fermentation of sucrose should be considered specific for these organisms. If we include the colony characteristics (large translucent, mucoid, coalescing colonies on blood agar, nutrient agar, and E. M. B. medium), we have a sufficient differential description to identify this organism.

No other related gram negative rod found on the human being has been reported which gives the same pattern of reactions. This is true even of the variable Friedlander group. Julianelle (14), who has done most of the work on the classification of this genus, found no strain in any of the groups A, B, C or the unclassified Friedlander group to give reactions similar to those described for the rhinoscleroma bacillus. We have studied strains of the Friedlander bacillus obtained from the American Type Culture Collection, and find no resemblance of any of these to the scleroma organism (Table II).

From the above and from Julianelle's findings, we concluded that it should be possible to separate the mucoid Friedlander from the mucoid scleroma bacillus.

TABLE II

Cultural characteristics of Friedlander strains

Strain	Mannite	Maltose	Dextrose	Lactose	Sucrose	Nitrate	Indole
132	AG	AG	AG	AG	AG	+	−
8044 A	AG	AG	AG	AG	AG	+	−
4727	AG	AG	AG	AG	AG	+	−
8045 A	AG	AG	AG	AG	AG	+	−
8046 A	AG	AG	AG	AG	AG	+	−
6540	AG	AG	AG	AG	AG	+	−
7380 B	A	A	A	A	A	+	−
9997	A	A	A	A	A	+	−
4208	A	A	A	A	A	+	−

We next tested the assumption that the scleroma bacillus is found in normal throats. A total of 204 normal individuals and 63 with various nose and throat ailments were cultured. The procedure used was found to the satisfactory in the isolation of the rhinoscleroma organisms in the known infected cases. Nose and throat swabs were streaked on blood agar and E. M. B. in all infected individuals. Since the results on the blood agar and E. M. B. were similar, we employed only the latter in our studies of the normal, and the nose and throat cases.

Gram negative organisms (which morphologically are related to the scleroma bacillus) in the nose and throat that will grow on E. M. B. include members of the coli-aerogenes and Friedlander groups, Proteus, Pseudomonas and Alkaligenes. Most noses and throats did not show a sufficient number of any of these to give a positive culture. Of a total of 267 individuals tested, only 34 gave positive cultures; the results of cultural studies of these organisms are presented in Table III.

TABLE III

Cultural characteristics of gram negative bacilli isolated from normal individuals or nose and throat cases

Mannite	Maltose	Dextrose	Lactose	Sucrose	Nitrate	Indole	Number of strains
AG	AG	AG	AG	AG	+	−	13
AG	AG	AG	AG	AG	+	+	2
AG	AG	AG	AG	AG	−	−	1
AG	AG	AG	—	AG	+	+	1
AG	AG	AG	AG	−	+	+	2
AG	A	A	AG	AG	+	−	1
AG	AG	AG	A	AG	+	−	1
AG	AG	AG	A	−	+	+	1
AG	AG	AG	−	−	+	−	2
AG	AG	AG	−	−	+	+	1
A	A	A	A	A	+	−	1
−	−	A	−	−	−	−	1
−	−	AG	−	−	+	+	1
−	−	A	−	−	+	+	1
−	−	−	−	−	−	−	4
−	−	A	−	−	+	−	1

Although we have not as yet speciated the above strains, it is obvious that none has the pattern we have found to be characteristic of the scleroma bacillus. Further work is in progress to name these organisms as to species.

SEROLOGICAL STUDIES

In order further to relate the organism to the disease in question, serological studies should be of value. There are many references in the literature to such studies. As is true of the cultural studies, the early serological reports are confusing, and for the same reasons mentioned previously. However, more recent studies, if correlated, certainly are not to be disregarded. Goldzieher and Neuber (16), Brault and Masselot (17), and Quast (18) have all agreed that serum from patients with scleroma or from rabbits immunized with the organism is capable of fixing complement. Fitzgerald (19) showed that a rabbit immune serum agglutinated specifically the decapsulated organism. Prasek and Prica (20) and Morris and Julianelle (14) have both demonstrated the specific antigenicity of the organism.

We have employed the complement fixation test in our studies. Seven patients suffering from scleroma have given positive reactions with antigen consisting of heat-killed (65° C. for 30 minutes) organisms grown on nutrient agar slants.

Over 500 sera from normal patients and from individuals with an assortment of other diseases have been tested with only occasional positive reactions. However, we find such "false positive reactions" to be a function of the concentration of antigen and antiserum. We are now in the process of standardizing the procedure to obtain maximum accuracy. Details of the test will be published elsewhere.

CASE STUDIES

One further controversial question concerning scleroma has been its contagiousness. Its endemic nature has been suggested previously. Familial occurrence would indicate an infectious etiology. Lasagna (8) Robertson and Secretan (21), and Gerber (22) have reported duplicate cases occurring in the same family. We have studied seven cases, six of which have occurred in the same family.

Case 1. L. M., male, age 20, of Mexican descent, was referred to the clinic because of dyspnea and a cough productive of a thick yellow mucoid material.

About one year ago he began to notice that his nostrils were "plugged up" and that a sticky yellow discharge was chronically present. The significant physical findings related to the respiratory tract. A hard granulomatous mass filled the nares, nasopharynx, and the pharynx. In some places the mass was covered by dirty, green, malodorous crusted material which was occasionally expectorated. The voice was hoarse and there was some granulation involving the epiglottis and aryepiglottic folds. The patient complained that the dyspnea interfered with normal activity. There were no other significant laboratory or physical findings.

Biopsy of the lesion demonstrated a typical granuloma with plasma and lymphoid cells. Hyalinization was present. Mikulicz cells were numerous and easily demonstrated. Staining with the Krajian modification of the Gram-Weigert method showed numerous bacilli present, extra- and intracellularly.

The patient has been treated with sulfadiazine, penicillin, and streptomycin. Only the last was really effective against the organism *in vitro* and caused a decrease in the number of rhinoscleroma bacilli in the throat, but did not affect the lesions after 10 days of treatment with 10 grams of the drug. Deep x-ray is being used at the present time.

From the above patient we isolated the scleroma bacillus in twenty consecutive throat cultures on blood agar and E. M. B. agar. The organism grows as a large, mucoid, flowing colony easily picked from the usual throat contaminants after 24 hours of incubation.

On questioning this first patient, we found that his father has similar symptoms, of longer duration. His history follows:

Case 2. L. M., age 37, was essentially well until his nose was broken about 10 years ago. After this his nose became progressively "stuffy" and a thick yellow discharge developed. Rhinoscleroma was diagnosed clinically elsewhere one year after onset and x-ray therapy was given. At present, there is adequate airway, but the lining of the nose and pharynx is hard, irregular, and studded with foul smelling, greenish crusts.

Biopsy findings were typical and identical with those of Case 1, including the presence of the small bacilli in stained sections of the tissue. Organisms identical with the scleroma bacillus have been isolated repeatedly in cultures from the nose and throat.

After seeing that the father and son both were suffering from the same disease, we thought that other members of the family might show symptoms of a similar nature. From our discussion with father and son, we knew that they were suffering from vague symptoms associated with the upper respiratory tract. In addition to the son (Case 1) the family consisted of four daughters, a young son age 9, and the wife of the oldest son (Case 1). The mother of the children has been separated from the family for the past four years and is not available.

The wife of Case 1 and the youngest son are free of symptoms and culturally negative. The four girls seem to show various stages of an infection of the nasopharynx which resembles the "diffuse" type of scleroma described by Szmurlo, and mentioned previously. Their case histories follow:

Case 3. J. M., age 19 (sister of Case 1), is asymptomatic except for frequent "head colds" and a watery nasal discharge which has been chronically present for two years. There is marked atrophy of the inferior and middle turbinates and the nose contains crusts and casts of greenish-yellow matter that has the same foul odor noticed in others of her family.

Biopsy sections show inflammation and the presence of many monocytes. The mucous glands are hyperplastic. The sections stained for bacterial examination were inadequate in this case. Cultures revealed the presence of the scleroma bacillus in the throat and nose.

Case 4. C. M., age 17 (sister of Case 1), is asymptomatic except for a chronic cough which she attributes to a thick, sticky, nasal and postnasal discharge. She had "lobar pneumonia with empyema" three years ago. Recovery followed open drainage. Physical examination of the upper respiratory tract showed marked atrophy of the inferior and middle turbinates with some thickening of the septum superiorly and anteriorly, and the presence of greenish crusts.

Biopsy sections show a diffuse infiltration, granulomatous in type, under the epithelium. Occasional cells of the macrophage variety are present. There are present also large foamy cells not typical of the Mikulicz cell. Bacterial stains show bacilli to be present extracellularly. Repeated cultures of the nose and throat show the presence of the scleroma bacillus.

Case 5. M. M., age 14 (sister of Case 1), complains of increased nasal "stuffiness" of a year and a half duration, with no visible discharge. Physical examination shows almost complete obstruction due to the involvement of the anterior and of the inferior turbinates. The hypertrophied tissue causing obstruction has the appearance of granulation tissue and bleeds easily on touching. There was some crusting due to greenish-yellow purulent exudate.

Biopsy sections show tissue consisting of large strands of hyaline material, and of compact masses of small round cells, mostly the macrophage type. In some areas the tissue appears necrotic with the cells staining faintly. One area shows mucous vacuoles which resemble fat tissue; these are surrounded by round cells of macrophage type. Some of the cells show foamy cytoplasm and some

are binucleate. No typical Mikulicz cells are seen. No bacterial stain was done. Repeated cultures of the nose and throat showed the presence of the scleroma bacillus.

Case 6. R. M., age 11 (sister of Case 1), is asymptomatic although her sisters complain that she is always clearing her throat. Examination showed considerable hypertrophy of the tonsils. No atrophy, granulation or crusting was present in the nares.

Biopsy of a slightly injected area of the pharyngeal mucosa reveals the presence of stratified and ciliated epithelium below which there are occasional areas of infiltration of macrophages. Small granulomatous lesions are found here and there around capillary vessels. Noticeable is the presence of large cells with peripheral nuclei and foamy cytoplasm. The bacterial stains show bacilli inside the macrophages. The scleroma bacillus was repeatedly isolated from nose and throat cultures.

The last four cases, in our opinion, resemble varying stages of rhinoscleroma. In none of these cases were the symptoms sufficiently severe to result in the patient being referred to a doctor, yet physical examination reveals lesions which at least in three of the cases are suggestive of the disease. In one case, R. M., the youngest sister, there are practically no gross pathologic lesions and yet the microscopic picture in all the cases including the last confirms the existence of the disease syndrome, which, together with the isolation of the scleroma bacillus in each case, gives extremely presumptive evidence that here we have a family in which six members are afflicted with various stages of the disease rhinoscleroma. Serological findings in each of these cases gives further evidence for this contention, although until the complement fixation test, mentioned previously, is standardized, emphasis on the serology must be avoided.

One further case will be presented although it is unrelated to the family mentioned above. This case also gave a positive culture for the scleroma bacillus and a positive complement fixation test.

Case 7. L. C., age 63, female of Mexican descent. The patient was seen first fourteen years ago when she complained of obstruction to her breathing of four months' duration. At that time, "granular pharynx" and hypertrophy of the right mid-turbinate accompanied by postnasal purulent discharge were reported. The patient was not seen again until recently at which time in addition to the previously mentioned symptoms the inferior turbinate on the right also was reported to be hypertrophic and irregular with the appearance of fungating granulation tissue.

Biopsy sections show the presence of shreds of epithelium, dense fibrous strands, and compact masses of round cells. Under high power the cells appear to be mostly plasma cells and lymphocytes, but here and there are seen numerous macrophages with foamy cytoplasm. An occasional large cell with peripheral nucleus and pink cytoplasm is seen. No hyaline globi are visible. Lesions seem to be of the granulomatous type.

CONCLUSION

Six cases of scleroma in the same family are described showing varying stages of the disease. The etiologic agent is suggested to be the scleroma bacillus first described by Frisch. Its characteristics are given. The incidence of this organism in the normal population has been studied. Suggestive serological findings are reported.

STUDIES ON A VIRUS FROM A PATIENT WITH FORT BRAGG FEVER (PRETIBIAL FEVER)

By HUGH TATLOCK[1]

(From the Respiratory Disease Commission Laboratory,[2] Regional Station Hospital, Section 2, Fort Bragg, North Carolina; the Division of Virus and Rickettsial Diseases, Army Medical School, Washington 12, D. C.; the Children's Hospital Research Foundation and Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati 29, Ohio[3])

(Received for publication October 8, 1946)

During the summer of 1942, an outbreak of a dengue-like illness of unknown etiology occurred at Fort Bragg, North Carolina. The disease, described by Daniels and Grennan (1), was characterized by moderate prostration, fever, splenomegaly, a rash localizing particularly on the anterior aspects of the legs, and a short course. The localization of the rash gave rise to the name "pretibial fever." Epidemiological information indicated that all of the patients in this outbreak were quartered in the same area of the post and that the incubation period was 10 days or longer. Serological tests served to exclude endemic typhus, infectious mononucleosis, brucellosis, and the typhoid-paratyphoid group of diseases. A commission was assigned by the Surgeon General of the United States Army to investigate the epidemiology and etiology of the disease. Working with frozen material in the form of blood, nasal washings, and urine from the patients, the members of the commission concluded: "All tests on this material proved negative as far as isolating or determining the nature of the infectious agent responsible for this disease was concerned" (2).

Similar outbreaks appeared during the summers of 1943 and 1944. The present report describes the recovery of an infectious agent from a patient having Fort Bragg fever in 1944 and summarizes observations on the biological characteristics of this agent. In addition, it presents the results of neutralization tests which indicate that the agent is related to the human infection; and finally, it describes the reproduction of the clinical disease picture in human subjects inoculated with the agent.

PART I

RECOVERY OF A VIRUS AND ITS CHARACTERISTICS

Recovery of the agent from a patient

On August 16, 1944, a 22-year-old white soldier noted a sudden onset of headache, feverishness, and generalized aching. In spite of these symptoms, he continued on duty until August 19 when his symptoms increased following a stimulating injection of tetanus toxoid, and he was hospitalized. Physical examination showed an acutely ill patient with a fever of 102° F., whose only other abnormal physical finding was a questionably palpable spleen. The leukocyte count was 5,750 per cubic mm. An indistinct maculopapular eruption was noted over the pretibial areas on August 21. This rash faded after 2 days. During his illness the patient showed a remittent temperature which reached 103° to 104.5° F. for 5 days. A blood culture taken shortly after the appearance of the rash proved sterile. Two days after defervescence he was completely recovered and was discharged from the hospital. The clinical diagnosis was Fort Bragg Fever.

Two Syrian hamsters and two guinea pigs were injected intraperitoneally with blood freshly drawn from this patient on August 21, 1944, 5 days after onset, when his temperature was 104.5° F. Both hamsters were found dead on the tenth day. No macroscopic abnormalities were found at autopsy and the viscera were bacteriologically sterile. Passage to other hamsters was

[2] Work done at Fort Bragg, North Carolina, was supported in part through the Commission on Acute Respiratory Diseases, Army Epidemiological Board, Preventive Medicine Service, Office of the Surgeon General, United States Army, and by grants from the Commonwealth Fund, the W. K. Kellogg Foundation, the John and Mary R. Markle Foundation, and the International Health Division of the Rockefeller Foundation to the Army Epidemiological Board for the Commission on Acute Respiratory Diseases.

[3] The studies in Cincinnati were supported by the Commission on Neurotropic Virus Diseases, Army Epidemiological Board, Preventive Medicine Service, Office of the Surgeon General, U. S. Army.

not attempted. Both guinea pigs developed fever (105°–106° F.) 8 days after inoculation. On the second day of fever, one of the animals was sacrificed; citrated blood, suspensions of brain, pooled liver and spleen, and tunica vaginalis were obtained and each injected into two guinea pigs by the intraperitoneal route. Cultures of the blood and organs of the guinea pig showed no growth. After a 7-day incubation period, fever developed in guinea pigs of the groups which had received blood and pooled liver and spleen; but no disease appeared in the other animals. A febrile illness was regularly induced in passage animals inoculated with citrated blood from affected guinea pigs. A similar febrile illness was induced and maintained by passage in guinea pigs injected with suspensions of liver and spleen of such animals; after the fourth serial passage, this line was abandoned for convenience. The stock colonies of the guinea pigs and hamsters were free from intercurrent disease at the time, as evidenced by several negative experiments employing intraperitoneal injections of blood from patients with other diseases.

Pathogenicity for animals and eggs

GUINEA PIGS: Guinea pigs developed fever following intraperitoneal injection of citrated blood or intracerebral injection of serum taken from passage animals on their first day of fever. The incubation period was from 4 to 8 days and the febrile course was from 2 to 4 days. Young guinea pigs (200 grams body weight) showed a more prolonged febrile reaction and a shorter incubation period than adult animals. Convalescent animals remained afebrile when reinoculated with infectious passage material. Fever was the only clinical evidence of infection in guinea pigs; none of the several hundred animals used in the 90-odd passages of the agent ever appeared sick. No macroscopic or microscopic pathological changes were consistently noted in guinea pigs sacrificed at various stages of the infection. Inclusion bodies and rickettsiae were searched for in sections and smears of organs stained by Giemsa's method and other techniques; none was found.

RABBITS: The disease induced in rabbits injected with infectious guinea pig material by the intraperitoneal or intracerebral route was essentially identical with that seen in guinea pigs injected with passage material. This mild febrile illness was maintained during four serial passages in rabbits.

HAMSTERS: Adult hamsters which were inoculated intraperitoneally with blood from guinea pigs of the sixth and subsequent passages died after about 8 days. However, the disease was only irregularly reproduced in adult hamsters which were injected with blood from moribund animals of this species. Young hamsters, 40 to 60 grams body weight, proved more susceptible to the experimental infection since the agent was readily maintained by serial intracerebral passage in them. Cerebral tissue from a young hamster used for the fourth transfer titered 10^{-4} when tested in hamsters.

A characteristic, rapidly progressing disease developed in inoculated hamsters following an incubation period of 7 to 16 days. Some hours preceding death, these animals became abnormally irritable and showed slight ataxia. They assumed a hunched position in the darkest corner of the cage, apparently having photophobia associated occasionally with a seropurulent discharge from the eyes. Generalized tremors, but no true convulsions, were occasionally noted. The initial ataxia rapidly progressed to complete paralysis of all four extremities and death usually ensued within a few minutes. Gross and microscopic findings at autopsy were consistently normal except for areas of fresh hemorrhage in the lungs which were frequently observed and were regarded as agonal manifestations. No inclusion bodies or rickettsiae were seen in the histological sections of the central nervous system or viscera.

MICE: Infectious material injected by various routes into mice of different ages and breeds induced no obvious disease. Furthermore, serial "blind" passages were unsuccessful.

EMBRYONATED EGGS: The intravenous injection of 11-day embryonated eggs with infected serum from passage guinea pigs resulted in the death of most embryos after about 7 days of incubation at 96° F. The agent was subsequently maintained for 23 serial transfers in embryonated eggs by the intravenous injection of suspensions of infected embryo liver diluted from 10^{-2} to 10^{-4}. The embryo livers were often dark green in color, but no other abnormalities were noted. No inclusion bodies or rickettsiae were seen in stained smears of embryo viscera, yolk sac, or chorio-allantoic membranes or fluids. Embryonated eggs survived the injection of infected guinea pig plasma into the yolk sac or the chorio-allantoic sac, or onto the chorio-allantoic membrane. However, it was

possible to demonstrate the presence of the agent in yolk sac tissue of embryos which had been injected intravenously with infected egg material and to propagate the agent thereafter by the yolk sac route. Titrations in hamsters of fresh suspensions of infected embryo liver or yolk sac usually yielded end points of 10^{-4}.

Filterability

Plasma from febrile guinea pigs was employed in a few preliminary filtration studies on the agent. For this purpose, the plasma was diluted with an equal quantity of physiological saline solution and passed through Seitz or Corning UF filters. Virus was demonstrated to be present in the filtrate of a Corning fritted glass filter (UF) but not in that from a single Seitz pad. Materials were tested for infectivity by intravenous injection into embryonated eggs, and the presence of the virus in tissues of embryos which died was confirmed by passage to hamsters and guinea pigs. The glass filter used in the experiment did not permit the passage of *Staphylococcus albus* which was added to the infected plasma.

Neutralization tests

Sera from patients convalescent from Fort Bragg fever and sera from recovered guinea pigs were tested for neutralizing antibody against the new agent. Virus for these tests consisted of undiluted guinea pig plasma or dilutions of infected chick embryo liver covering the range of 10^{-1} to 10^{-3}. The technique was as follows: Equal amounts of undiluted serum to be tested and the appropriate dilution of virus were mixed and incubated for 1 hour at room temperature and then injected into groups of two or three adult hamsters. Each animal received 0.5 ml. of the mixture intraperitoneally. The animals were observed for a period of 21 days and deaths recorded.

The results of such neutralization tests carried out on acute and convalescent sera from five cases

of Fort Bragg fever and two experimental guinea pigs are summarized in Table I. It is evident from the data that the convalescent sera from Patients A and B and from both guinea pigs contained neutralizing substances which protected the hamsters from death.

Storage

Considerable difficulty has been encountered in preserving the agent. Infectivity of blood, whole tissues, or tissues suspended in broth was lost after storage for 24 hours at 20° C., 4° C., or at − 70° C. in sealed glass ampoules. However, viability has been maintained when 20 per cent suspensions of infected embryo tissue were prepared in sterile skimmed milk media, pH 7.2, frozen rapidly in glass sealed ampoules and stored at − 70° C.; in one instance the agent was active after 8 months storage under these conditions. In one experiment, the infectivity of a chick embryo liver suspension diminished after storage at − 70° C. for 24 hours from a titer of 10^{-4} to 10^{-2}; both titrations were made in hamsters. The lability of the virus was further suggested in the tests with human subjects (see Part II). It was found that plasma taken from these patients during the febrile illness and proved to be infectious (actually whole blood was used here) by injection into other human beings, was not infectious for man after storage at − 70° C. for 12 days.[4] Fresh plasma was known to be infectious from work with hamsters.

Relation to other infectious agents

The available data are insufficient to identify this agent with any known pathogen. Sera of guinea pigs convalescent from the experimental disease failed to fix complement with the soluble antigen of lymphocytic choriomeningitis. Recovered guinea pigs were fully susceptible to infection with the Balkan Grippe strain of the rickettsia of Q fever (3). Convalescent sera from three of the patients described in Part II failed to fix complement with the antigen of Rocky Mountain spotted fever; in addition, no significant titers developed in the Weil Felix reaction with OX19, OX2, and OXK. The new agent was clearly different from the rickettsia-like organism which had been previously encountered in guinea pigs used in studies on Fort Bragg fever (4). Subsequent unpublished work indicated that the infection caused by the rickettsia-like agent was enzootic in the guinea pig colony and bore no relation to Fort Bragg fever in human beings.

PART II

PATHOGENICITY OF THE AGENT FOR HUMAN BEINGS [5]

In order to test the disease-producing capacity in man of the virus which had been maintained in guinea pigs and embryonated eggs, the inoculation of human subjects was next undertaken. The plan was to determine whether or not any disease could be produced by the injection of a suspension of infected egg embryo liver and, if infection occurred, to study the resistance to the new agent of individuals known to have recovered from dengue fever and from sandfly fever.

METHODS

Preliminary physical examinations were performed on all subjects; in addition, the results of x-ray examinations of the lungs, routine blood counts, urinalyses, and daily rectal temperatures indicated that they were, with few exceptions, in good general physical condition; all were free of intercurrent infection. Particular attention was given to examination of the skin, where long-standing blemishes might be confused later with the appearance of specific rashes. No attempt was made to isolate the patients because of the lack of epidemiological evidence for cross infection in naturally occurring Fort Bragg fever. It may be mentioned now that subsequent experience in the present studies likewise failed to suggest that the disease is contagious.

The first group of three patients were injected with a 10 per cent suspension of infected embryonated chick liver in saline. The material for this purpose was harvested from living embryos on the sixth day after intravenous injection with the 23rd egg passage, at a time when 50 per cent of the embryos had already died. This egg line had been started from the infectious serum of a guinea pig of the 80th serial passage in this host. Aerobic and anaerobic cultures of the inoculum for patients showed no growth on the usual bacteriological media. This same embryo liver emulsion was infectious at a dilution of 10^{-4} when titrated intracerebrally in hamsters. Mice given a

[4] This might explain the failure in 1942 of the group who investigated Fort Bragg fever to recover the agent from the blood of patients. All of the materials were stored in the frozen state for some days before injection into animals (2).

[5] The human subjects used in this study were part of a group undergoing fever therapy at the Longview State Hospital in Cincinnati.

combined intracerebral and intraperitoneal injection remained well. Guinea pigs which were also injected intraperitoneally with this inoculum developed the characteristic febrile reaction and the agent was readily transmitted to a second group of guinea pigs by inoculation of blood. It is evident that the infectious agent injected into the first group of human subjects had characteristics typical of those previously described for the virus.

The three individuals who made up the first group of subjects received 3.0 ml. intramuscularly and 0.4 ml. intracutaneously of the chick embryo liver suspension described above. Subsequent transfers of the agent to other individuals were made with blood which was drawn from the patients within 24 hours after the onset of fever. This was defibrinated, pooled, and immediately injected into the new subjects who received 5.0 ml. intramuscularly and 0.4 ml. intracutaneously.

RESULTS

A short febrile illness developed in all three of the subjects following injection with the suspension of infected chick embryo liver. The three individuals of the second group, who received pooled defibrinated blood of the first patients, developed a similar short febrile illness. Accordingly, the plan to carry out immunity studies was put into effect in the third group which consisted of two normal individuals, two persons recovered from sandfly fever, and four recovered from dengue fever. All of the patients, with one exception, in this third group developed the febrile reaction, and the majority exhibited the clinical picture of Fort Bragg fever with rash and leukopenia. The single exception was a normal subject who failed to show any fever over a 23-day period of observation. He had not been out of the state of Ohio, as far as could be determined, and his failure of response remains unexplained. The results of these studies in man are summarized in Figures 1 and 2. Figure 3 illustrates the types of rash which were seen. More detailed information concerning the various clinical features of the disease produced in man is given below.[6]

Incubation periods. The three individuals in the first group, inoculated with infected embryo liver suspension, came down sharply with fever on the ninth day after inoculation. The second group developed fever from the 11th to the 14th day after inoculation with defibrinated blood from the first group. The third and largest group, consisting of eight individuals, had incubation periods varying from 8 to 14 days, averaging 11. These were quite in accord with the estimate of 10 days or longer in the naturally occurring disease at Fort Bragg (2).

Fever. The temperature curves of the patients were spiking, such as occurs in the natural disease (1). Daily physical examinations failed to reveal evidence of the occurrence of intercurrent disease. The clearcut temperature elevations, ranging from 101° to 105.5° F. (rectal) and extending over a period of 1 to 6 days, average 3.2, stood out sharply from the preliminary temperature base lines. In four patients, a slight rise in temperature appeared 4 days preceding the main bout of fever. While no isolation of virus was attempted at this time, it will be noted in a subsequent paragraph that this agent circulates at least 2 days prior to the onset of the typical disease. The possibility was considered that this mild fever might represent the onset of viremia. Figures 1 and 2 show the variations in febrile response in the group of fourteen patients.

Other clinical signs and symptoms including rash. An evaluation of symptomatology in these patients was not too reliable. During the first 2 days of fever the majority complained of mild to moderate headache and aching in the back and thighs. Three individuals had mild but definite chills. There was loss of appetite, and occasional vomiting occurred. None of the patients appeared critically ill at any time, and soon after defervescence all were out of bed and had a rapid return of appetite and strength. During the course of illness, physical examination was not remarkable except for fever, splenomegaly, and rash. Three of the thirteen febrile individuals developed a definitely palpable spleen, and in two more there was questionable enlargement. A few cases developed injection of the sclerae with photophobia. There were no signs of respiratory or of meningeal involvement, and there was no significant lymphadenopathy.

No unequivocal rash was seen in any of the patients in the first two groups. However, five of the eight members of the third group developed

[6] One additional individual, not included in the 14 mentioned above, was injected intracutaneously with only 0.4 ml. of pooled serum from the first group of patients. He failed to develop fever during the following 20 days. Whether this person, like patient 7, was resistant to the virus or whether larger doses of virus were required for transmission remained undecided.

rashes of varying extent which appeared from the second to the fifth day after the onset of fever. For the most part these were limited to the anterior and lateral surfaces of the legs. The lesions were transitory and faded rapidly after the second day with evidence of residual pigmentation and small hemorrhagic areas in two of the cases.

Some of these patients were seen by Dr. Ashley A. Weech, Professor of Pediatrics, University of Cincinnati, who described their skin lesions in this manner: "The following description of the rash in experimental pretibial fever is the result of inspecting three patients, one with presumably early lesions on the fifth febrile day, another with better lesions on the third day, and the third with lesions on the seventh day. The three cases are sufficiently similar to permit one description. Lesions were present in the skin over the lower half of the tibiae in all cases; in one subject, similar lesions were present on the dorsal surface of the left forearm. The involved areas show an erythematous blush and vary in diameter from a few millimeters to a few centimeters. The borders are well defined, but the shapes are irregular. The areas are slightly elevated above the surrounding unaffected skin and on palpation feel mildly indurated. In two lesions over the tibia of one patient there was a small ecchymosis in the center. The appearance was that of fresh hemorrhage."

In one individual (patient 12), a large erythematous blush first appeared on the right shin, followed two days later by erythema and edema at the site of intracutaneous inoculation of the virus suspension. Two days after this, maculopapular erythematous lesions appeared over both shins. None of the other cases showed any reaction at the intracutaneous inoculation site. The rashes seen in the five subjects were sufficiently similar in appearance and distribution to the rashes described in the naturally occurring disease to leave little doubt but that the clinical picture of Fort Bragg fever had been reproduced in these human subjects.

Five of the thirteen positive cases showed a slight leukocytosis with a relative increase in granulocytes which appeared late in the incubation period and persisted for a day or so after the onset of fever (see WBC in Figures 1 and 2). Beginning about the third day of the febrile phase, a slight leukopenia with a relative lymphocytosis appeared and persisted for a few days. Further interpretation of the available data did not seem warranted. Average daily values of the leukocyte counts for these five cases are shown in Table II. The hematological findings in these individuals were similar to those in patients with Fort Bragg fever.

IMMUNOLOGICAL RELATIONSHIP BETWEEN FORT BRAGG FEVER, SANDFLY FEVER, AND DENGUE FEVER

Sabin (6) found that there are distinct immunological types of dengue virus which are sufficiently related to give rise to group specific cross immunity during the first 4 to 8 weeks, although at a later date the immunity is type-specific. Similarly in sandfly fever, one strain of virus isolated from an outbreak in Italy was completely unrelated (*i.e.*, there was no cross immunity even during the first weeks) to two other viruses which were isolated in the Middle East and Sicily. The last two agents were identical in so far as yielding complete cross immunity even 2 years after a single experimental attack (6). The patients used in these tests (see Figure 2) were selected by Dr. Sabin from among those he had previously inocu-

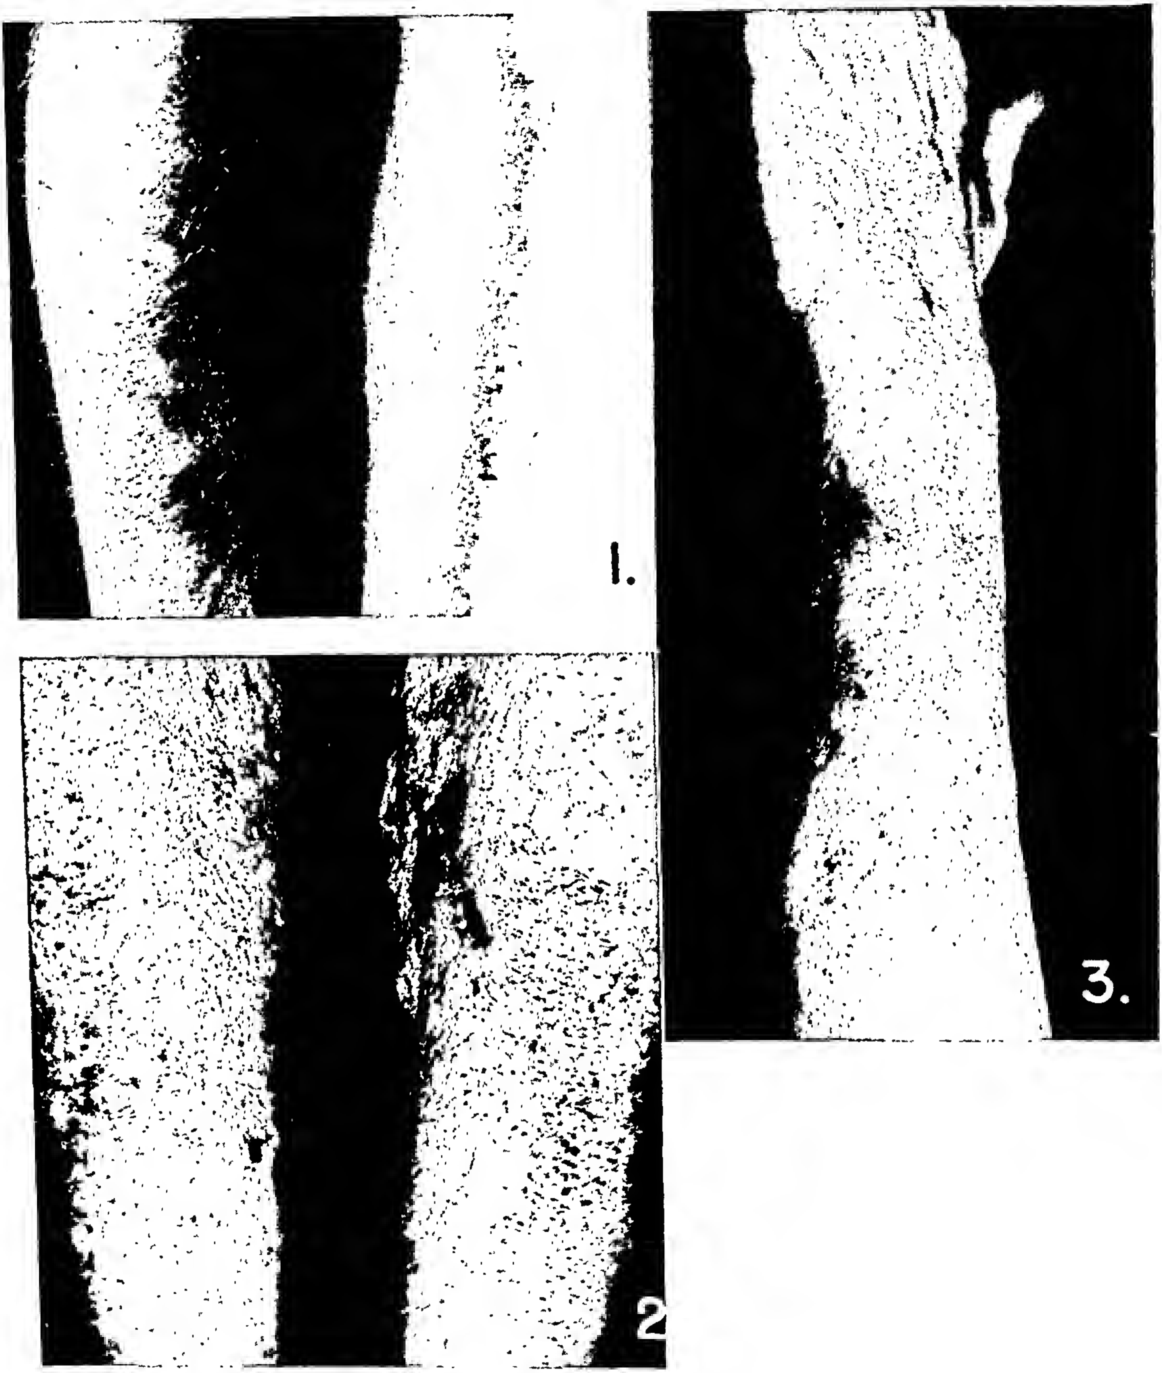

FIG. 3. ILLUSTRATION OF THE DIFFERENT TYPES OF RASH SEEN IN EXPERIMENTAL FORT BRAGG FEVER IN HUMAN BEINGS

Figures 3(*1*) and 3(*2*) show the early and late appearance, respectively, of the anterior shin lesions in patient 10. Figure 3(*3*) illustrates the raised macular lesions which appeared on the forearm of patient 13.

lated with dengue or sandfly fever viruses. Thus, patients 11 and 12, who had had typical experimental attacks of dengue following inoculation with the "New Guinea C" strain of virus 1 month before the present test, were selected since they would be expected to be immune to both "Hawaii" and "New Guinea C" strains of dengue. Patients 13 and 14, who had had experimental dengue fever following inoculation with the "Hawaii" strain of virus, 7 and 6 months, respectively, prior to the present test, would resist only an agent immunologically identical with the "Hawaii" type of virus. Similarly, patients 9 and 10 could indicate a relationship only between the new agent and the "Middle East—Sicilian" type of sandfly fever virus (5) but not with sandfly fever in general. Patient 9 had had his first attack in November, 1943 (2½ years prior to the present test) and was immune when challenged with the homologous virus in October, 1945. Patient 10 had had his experimental attack in October 1945, or 7 months before the present test. Since all six patients developed the experimental disease produced by the new agent, it can be concluded that it possesses neither a group relationship with the known dengue viruses nor any relationship with one strain of sandfly fever virus. It may be stressed, furthermore, that neither the dengue nor the sandfly fever viruses possess the pathogenic properties of the new agent for hamsters and guinea pigs.

DETECTION OF VIRUS IN THE BLOOD OF PATIENTS

Information on the time of appearance and duration of viremia in experimentally infected human subjects was obtained in the following manner. Blood was drawn from the patients at various times during the disease, immediately defibrinated, and injected into young hamsters. In certain instances the animals received 2.0 ml. of undiluted blood intraperitoneally. In others, serial tenfold dilutions of serum were injected intracerebrally in order to determine the infective titer. Those hamsters which died between the seventh and sixteenth days were assumed to have succumbed to infection with the virus under investigation. The results of these tests in patients 1, 2, and 3, Figure 1, clearly showed that virus was present at least 48 hours before the onset of fever and was still detectable on the second day of fever, but not on the fourth day or thereafter. Patient 8, Figure 2, had detectable virus circulating 24 hours before and 24 hours after the onset of fever, but not 4 days before nor 3 days after the onset of fever. In two instances, undiluted blood from patient 8 was lethal for hamsters but failed to kill in dilutions of 1:10 or greater. It may be concluded that the virus appeared in the blood of these patients shortly before the onset of fever and disappeared promptly; furthermore, it did not occur in large amounts.

SUMMARY AND CONCLUSIONS

An infectious agent was recovered from guinea pigs injected with blood from a soldier suffering from Fort Bragg fever in August, 1944 at Fort Bragg. The agent induced a febrile non-fatal illness in guinea pigs and rabbits and a lethal disease in hamsters. It was maintained by passage in animals or embryonated eggs, but storage even at − 70° C. was unsatisfactory unless special precautions were taken. The agent was filterable under conditions which were adequate to retain staphylococci.

The virus, after prolonged passage in guinea pigs and embryonated eggs, was able to induce the clinical picture of Fort Bragg fever in some of the inoculated human beings, while the majority exhibited only fever for 1 to 3 days.

The new virus appears to be unrelated in its properties or immunologically to the agents of lymphocytic choriomeningitis, Q fever, Rocky Mountain spotted fever, sandfly fever, and dengue fever. It does not resemble the rickettsia-like agent previously encountered in work on Fort Bragg fever and subsequently shown to be enzootic in guinea pigs.

ACKNOWLEDGMENTS

The author wishes to thank the Commission on Neurotropic Virus Diseases and particularly one member of the Commission, Dr. Albert B. Sabin, for his help in carrying out the human transmission studies. Grateful acknowledgment is made to Brig. General George C. Beach, USA, Commanding General, Army Medical Center, for granting the author detached service for the work on human subjects, to Brig. General S. Bayne-Jones, USA, and Colonel Worth B. Daniels, MC, for their interest and encouragement, and to Lt. Colonel Joseph E. Smadel, MC, for his help with the manuscript. The cooperation of Dr. Douglas Goldman, Medical Director of the Longview

State Hospital in Cincinnati, and of Dr. E. A. Baber, Superintendent of the institution, is gratefully acknowledged.

(From the Hospital of the Rockefeller Institute for Medical Research, New York City, and the Cairo Unit of the United States of America Typhus Commission)

(Received for publication October 9, 1946)

In an earlier communication (1) attention was called to the marked depressions of albumin: globulin ratios that frequently occur in the course of louse-borne typhus fever. Serum globulin concentrations in a number of cases were found to be higher than 5 grams per 100 ml. Because of the consistent rise in serum globulins in this disease, possibly a feature of the immune response, it was of interest to determine which globulin components were increased and to observe the sequence of changes associated with the clinical course.

The electrophoretic analyses to be described were made on serum samples taken from a patient with clinically typical severe typhus fever, included in the group previously reported. It will be seen that the depression of his albumin: globulin ratio was associated with a striking increase in the γ globulin component.

PROCEDURE

Sera were stored in sterile tubes at 4° C. without preservative. After the collections were complete they were brought from Egypt to New York City, refrigerated in transit.

The electrophoretic analyses were made in diethylbarbituric acid buffer (μ 0.1, pH 8.6) as previously described (2).

OBSERVATIONS AND DISCUSSION

A. S. M. (No. 2501), a 21-year-old Egyptian man, was admitted to the Typhus Commission ward on the third day of disease, acutely ill. There was no history of previous typhus, nor had he received anti-typhus vaccine.

During the first three weeks of hospitalization he had a sustained high fever. Delirium, vomiting, and a typical rash were present during the first week; intractable diarrhea during the second, and attacks of bronchial asthma during the third. In the latter part of his febrile course, dysarthria appeared with periods of emotional depression, increased tendon reflexes, spasticity of extremities, and adiadokokinesis. These neurological signs gradually disappeared during the subsequent five weeks of convalescence. At the time of discharge on the fifty-ninth day of disease, he was underweight, but the physical examination in other respects was normal.

On the fifth day of disease the Weil-Felix and complement fixation reactions were negative. On the forty-seventh day these tests were positive in dilutions of 1/320 and 1/1280 respectively.

OBSERVATIONS AND DISCUSSION

The results of electrophoretic analysis and the associated clinical data are charted in Figure 1.

The total protein, low during the early febrile stage, rose to abnormally high values in convalescence.

The relative proportion of albumin, and with it the albumin to globulin ratio, was found to be markedly depressed even on the fourth day of disease. Similar, but lesser, early depressions of albumin have been observed in patients with malaria (3) and with scarlet fever (4). Presumably this is a non-specific reaction to an acute febrile illness.

The relative proportion of α_1 globulin was not significantly disturbed; α_2 globulin showed a slight sustained increase. The practical absence of change in these components contrasts with the conspicuous increase found in patients with scarlet fever (4).

β globulin was on the low side of normal throughout the illness.

Most interesting is the early marked elevation of γ globulin. If it be assumed that the patient had a normal distribution of serum protein components prior to illness, this phenomenon would appear to indicate that there is a considerable release of γ globulin protein during the acute reaction to typhus infection. It would seem unlikely that the increase in γ globulin on the fourth day of disease could have been due to production of

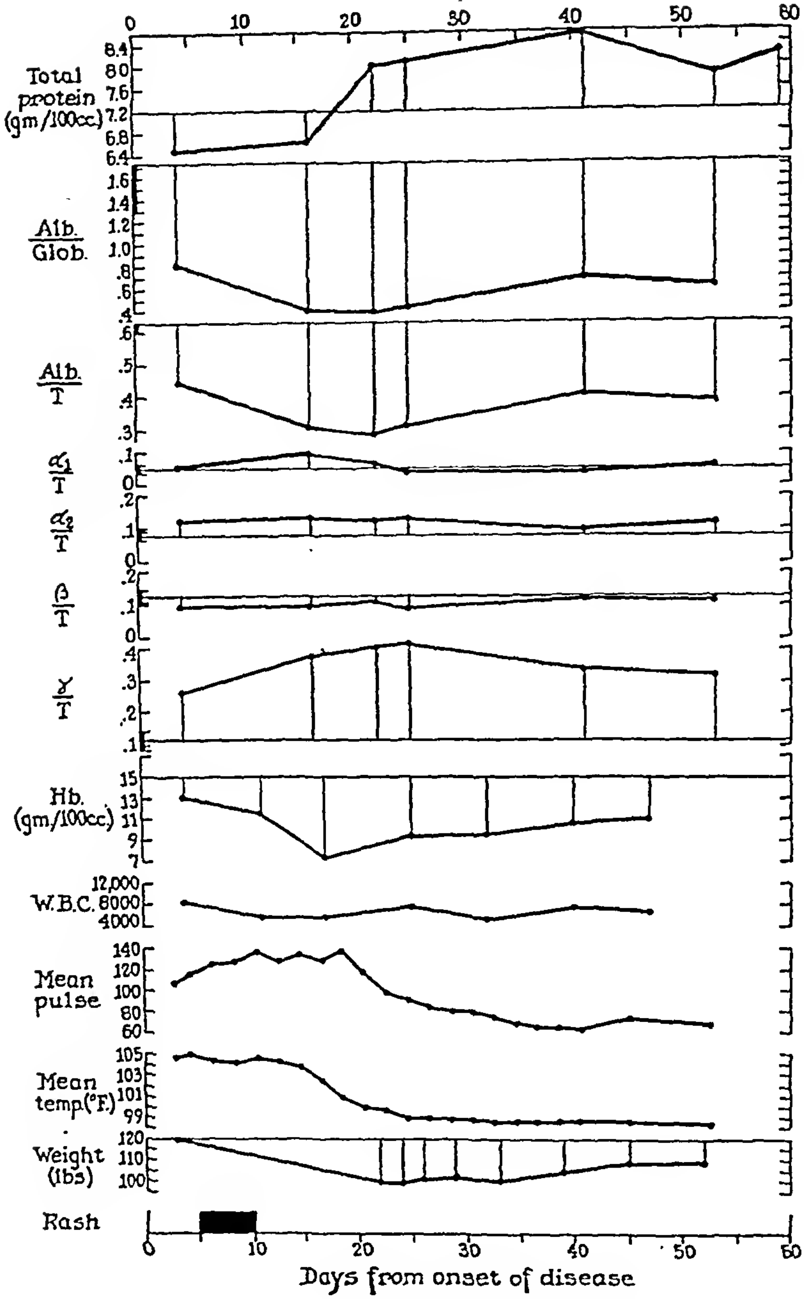

FIG. 1. ELECTROPHORETIC AND CLINICAL DATA DURING THE COURSE OF TYPHUS FEVER

From above downwards the ordinates show total protein concentration, the albumin: globulin ratio (measured electrophoretically), the fraction of the total protein (T) included in the different electrophoretic components, and the clinical data indicated. Horizontal lines show normal values, with the range of one standard deviation about the normal indicated by the heavy vertical brackets.

specific antibodies at that early date in a person without previous exposure to the antigens concerned. The available data, moreover, indicate that at least some of the antibodies which appear in the course of typhus fever were not then present, since the Weil-Felix and complement fixation tests were negative at that time, although later positive in high dilutions. It would further appear probable that protective antibodies were not present in significant concentration on the fourth day since the patient continued to be severely ill for over two weeks subsequently.

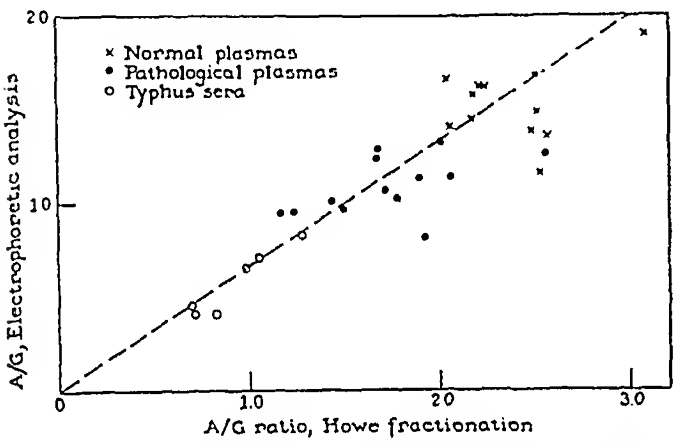

FIG. 2. CORRELATION OF ALBUMIN: GLOBULIN RATIOS MEASURED BY ELECTROPHORETIC ANALYSIS AND BY HOWE SODIUM SULFATE FRACTIONATION

Open circles show the new data.

The exceptionally low albumin: globulin ratios encountered in these sera presented an opportunity to extend the previously reported (2) correlation between the ratios determined by electrophoretic analysis and by the customary Howe sodium sulfate fractionation. It may be observed in Figure 2 that the newer data (open circles) approximate the same line drawn to fit earlier values. It would thus appear proper to infer from the more extensive study on typhus fever serum proteins (1) that the marked depressions observed in albumin: globulin ratios by salt fractionation would imply comparable abnormalities in the electrophoretic ratios.

SUMMARY

1. The relative proportion of albumin and the albumin: globulin ratio were markedly reduced on the fourth day of typhus fever and through the convalescence.

2. The α and β globulins were practically unaffected.

3. γ globulin was increased to a striking degree on the fourth day and to an even greater extent in convalescence.

4. A previously described relation between the albumin: globulin ratios determined electrophoretically and by salt fractionation was found to remain valid for the lower ratios encountered in this study.

THE ABSORPTION, EXCRETION, AND PHYSIOLOGICAL EFFECT OF IODINE IN NORMAL HUMAN SUBJECTS

By NORTON NELSON, EDWARD D. PALMES, CHARLES R. PARK, PATRICIA P. WEYMOUTH, AND WILLIAM B. BEAN

(*From the Armored Medical Research Laboratory, Fort Knox, Kentucky*)

(Received for publication October 13, 1946)

Although iodine has been used as a therapeutic agent for many years, information concerning its absorption, excretion, and physiological effect in normal men is not extensive. Several investigators have studied the uptake of iodine in the normal and pathological thyroid (1, 2, 3, 4, 5) and others, in balance studies, have sought to measure the daily iodine requirement of the body as a whole (6, 7, 8, 9). In general, very small amounts of iodine were used in these studies and the results cannot be applied readily to the fate of large quantities of iodine. This study deals with the absorption and excretion of iodine in quantities ranging from 20 mgm. to 440 mgm. per day, more than a thousand times the estimated daily requirement (4, 10), but within the range of clinical administration for syphilis, roentgenography, and for use as an expectorant, and only slightly above the commonly administered dosage of Lugol's solution for the treatment of thyroid disorders (11).

Two toxic effects of iodine in normal human subjects are well known, the direct toxic action of free iodine in aqueous or alcoholic solution on tissue protoplasm, and iodism or iodine sensitiveness, occurring in a small percentage of cases (12, 13, 14). It was formerly thought that iodine could give rise at times to hyperthyroidism (15, 16, 17), but more recently the consensus is that iodine has no effect on the basal metabolic rate of normal persons (4, 18, 19, 20, 21). Studies in this regard, however, have been limited. The few subjects used were not closely observed or were not followed for more than one or two weeks. Iodized salt has been used in large population groups without ill effect (22) but the amount of the halogen ingested daily was very small. In rabbits, a fall in metabolism due to Lugol's solution has been noted, reaching minimum values on the third day, and followed by a return to normal (23). Other animal studies have been equivocal in this regard (24, 25, 26, 27, 28). Iodine has been thought to increase nitrogen excretion in dogs and in man. (29).

In the present study a group of 13 healthy soldiers ingested large quantities of water containing an average of 34.8 mgm. per liter of iodine over a period of 38 days.[1] Iodine absorption from the gastrointestinal tract, excretion in the urine, sweat, and feces, and the concentration of iodine in the plasma were determined. A rough balance study was possible. The subjects worked and lived throughout the test in a hot humid environment. This led to the consumption of large amounts of iodine containing water and facilitated the study of iodine excretion in the sweat. The men were subjected to severe physical stress and observations were made on general health, work performance, acclimatization to heat, and basal metabolic rate.

METHODS

Experimental conditions. The subjects were divided into groups A and B, of 3 and 10 men respectively, on the basis of physical characteristics and work performance during a preliminary control period of 6 days. The environmental temperature at this time was kept at 80 degrees F. dry bulb and 30 to 50 per cent relative humidity. The test period in which iodine was administered followed immediately and lasted 45 days. During this time the environment of the laboratory room was maintained at a dry bulb temperature of 90 to 91 degrees F. and 95 per cent relative humidity from 8:00 A.M. to 4:30 P.M., but was returned to the relatively cool environment of the control period in the remaining hours of the day and night. The test period was followed by a final control

[1] This report is derived from a study of Bursoline, an iodine-containing agent for the disinfection of water. A Bursoline tablet contains 8.2 mgm. of free iodine and 8.2 mgm. of iodine combined as diglycine hydroiodide. On addition to water Bursoline yields a solution of free and ionic iodine.

period of 3 days, identical with the first period. All men, unless incapacitated, walked 5 hours each day except Sunday, 3 hours in the morning and 2 hours in the afternoon, at an average pace of 2.8 miles per hour. They wore shorts and regulation army shoes only, and carried 20-pound packs. They remained in the laboratory room day and night.

Group B drank iodine-containing water in the first 38 days of heat exposure while group A drank salted tap water. During the last 6 days of heat exposure, group A drank iodine-containing water and group B drank salted tap water (Table I). On Sundays when the men did not work, water requirements were low and the iodine ingestion consequently was reduced.

The final iodine content of the drinking water averaged 34.8 mgm. per liter of which 34 per cent was free iodine and 66 per cent iodide.

TABLE I

Regimen of exposure to iodine and heat

	Cool control 6 days	Iodine and moist heat 45 days			Cool control 3 days
	Days 6 through 1	Days 1 through 38	Day 39	Days 40 through 45	Days 46 through 48
Group A	T	S	S	I & S	T
Group B	T	I & S	S	S	T

T = Tap water, untreated.
S = Tap water, salted to 0.1 per cent.
I & S = Iodine water, salted to 0.1 per cent.

Experimental procedures. All water was dispensed by a trained technician and the consumption recorded. Twenty-four hour urine collections were made on all subjects throughout the study. During the period of iodine intake, blood samples were obtained on Monday morning and afternoon,

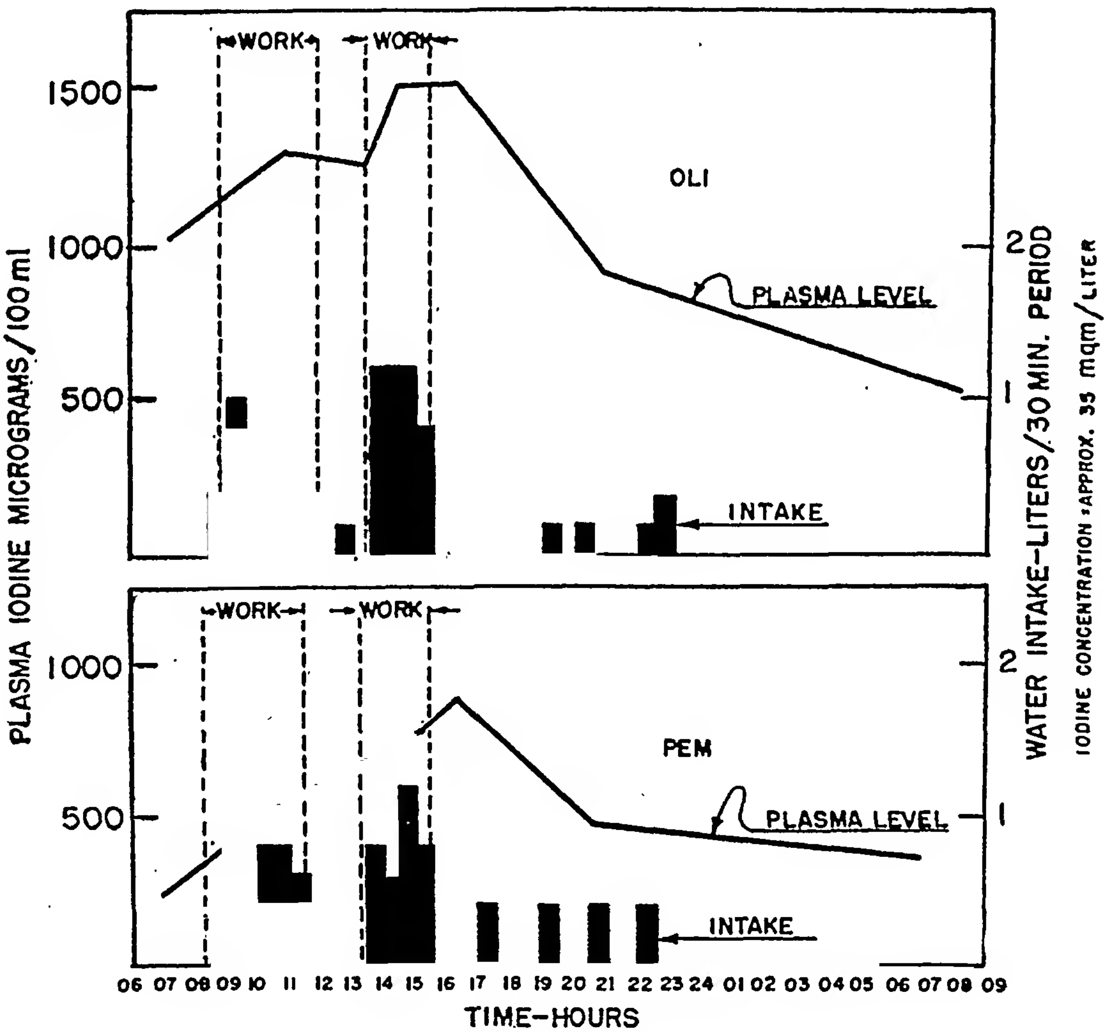

FIG. 1. PLASMA IODINE VERSUS IODINE WATER INTAKE

Wednesday afternoon, and Saturady morning and afternoon. After stopping iodine, only morning specimens were collected. Sweat collections were made at intervals by using dry suits of clothing for total sweat, or arm length rubber gauntlets for arm sweat. Feces were collected from 2 men for 7 consecutive days.

Details of the chemical methods will be given in a separate report (30).

Plasma rather than whole blood was chosen for analysis because of the simplified technic of determination and the expectation that, since the distribution of the iodide ion is similar to that of chloride (31), the plasma would give a more stable index of iodide concentration than whole blood. In addition, since the protein bound and organic iodine are removed with the protein precipitate (32, 33) a protein-free filtrate provided a homogeneous source of iodide ion. The available evidence (33) indicates that ingestion of iodine or iodide primarily influences the ionic iodide fraction of plasma. Iodine present in body fluids is believed to exist exclusively in the reduced form. This is suggested both by the redox potential of these fluids and by demonstration (34) that iodine is absorbed only after reduction to iodide. Unless iodine or iodides are being taken, only minute amounts of ionic iodide are found in plasma (4), certainly less than 3 or 4 μg. per 100 ml. which is the lower limit of detection by the method of analysis used here.

During the 38 days in which Group A drank salted tap water, the plasma collected from these men was uniformly negative for iodine (less than 10 μg. per 100 ml.); in four instances small amounts of iodine were found in the urine (probably contamination), but otherwise all were negative.

Observations were made on flushing, vigor, alertness, and the general reaction of subjects to work in the heat. Symptoms of headache, dizziness, nausea, palpitation, and gastrointestinal cramps were noted. Pulse rates and rectal temperatures were taken before, during, and after the periods of work. Sweat loss was calculated from the weight difference between the beginning and end of work periods, corrected for water intake, urine output, and sweat unevaporated at the time of weighings. Blood pressures were noted at frequent intervals.

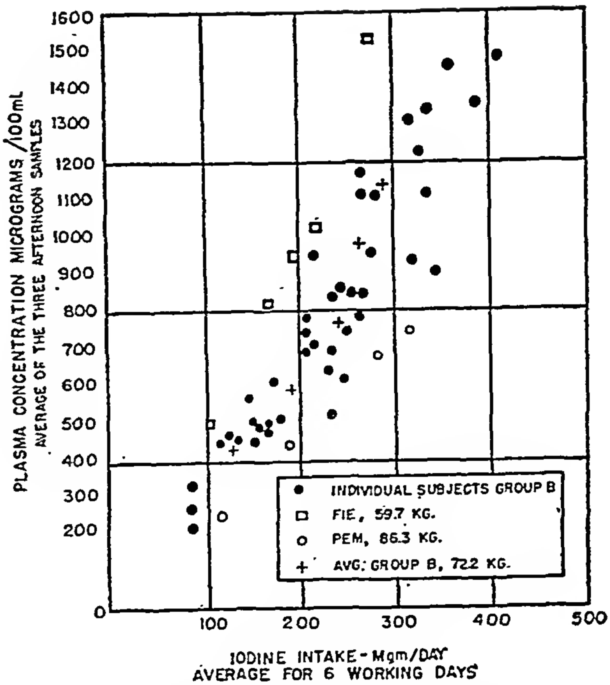

FIG. 2. RELATIONSHIP BETWEEN IODINE INTAKE AND PLASMA IODINE CONCENTRATION (GROUP B)

Basal metabolism was measured by the closed circuit Sanborn Waterless and Benedict-Roth machines. The tests were made before 8:00 A.M. when the subjects with rare exceptions had not moved from their cots. Twenty determinations were made on each subject, 13 of them in the period of exposure to iodine and heat.

RESULTS

Absorption of iodine. Iodine was rapidly absorbed from the gastrointestinal tract. This is apparent in Figure 1 in which iodine ingested and plasma iodine concentrations are plotted as functions of time. A rise of plasma level occurred after each period of iodine intake. The dip in the climbing portion of the plasma concentration curve which appeared in subject Oli indicated that within a period of 1 to 2 hours after cessation of intake the peak of absorption had been passed. Absorption was complete since no significant quantity of iodine was recovered from the stools of the subjects on high intakes. The level of plasma iodine was directly related to the intake as is best seen in Figure 2.

This proportionality over longer periods of time appears in Figure 3 where plasma concentrations

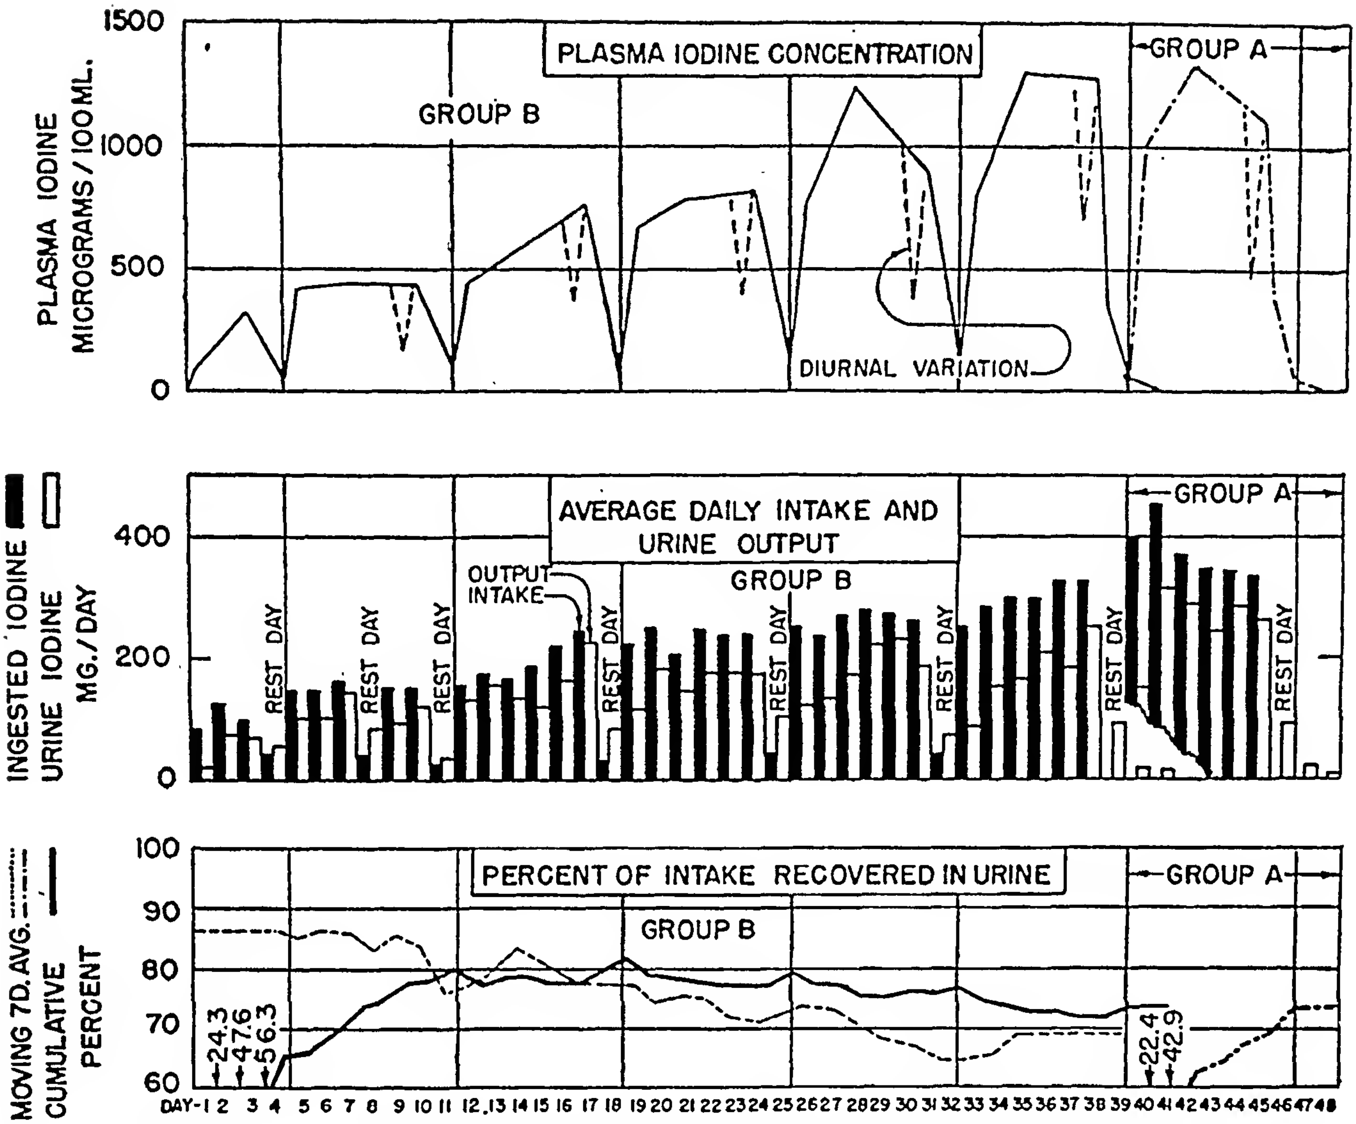

FIG. 3. PLASMA IODINE CONCENTRATION, IODINE INTAKE, AND URINE OUTPUT (GROUP A—AVERAGE OF 3 MEN; GROUP B—AVERAGE OF 10 MEN)

are shown in the upper panel, and intakes, plotted as solid columns for individual days, appear in the middle panel. The broken lines extending as V's from the solid envelope of plasma concentrations indicate the extent of diurnal variation.

Excretion of iodine. The uniformity and rapidity of the disappearance of iodine from the plasma are indicated in Figure 4 where iodine level is plotted on semilogarithmic scale against time. The linear plots suggest that a uniform rate of disappearance, proportional to the concentration, prevails during the elimination of iodine. From the slope of the average line, it is seen that if no more iodine is taken, plasma iodine concentration falls by 83 per cent (to 17 per cent of its initial value) in 24 hours.

The chief route of iodine elimination was in the urine. As shown by the solid line in the lower panel of Figure 3, 74 per cent of all iodine given was recovered in the urine in Group B and the same percentage subsequently in Group A. In each man, excretion in considerable amounts continued through the third day after cessation of intake, but only in insignificant quantities thereafter. This delay in excretion prevented a useful calculation of daily yield, for, on the rest day of each week, in which little iodine was taken, there occurred nevertheless a fairly large iodine excretion (Figure 3). This lag was due to the iodine content of the extracellular fluid. To compensate for the lag, the device of calculating urine return in terms of a moving 7-day average was used.

Thus in each 7-day average the excretion from 1 day in which the intake was low was included. This average yield is shown on the bottom panel of Figure 3 as a broken line. The decrease in per cent recovered in the urine which is apparent can be correlated with the increase in sweat output (weight loss) over the experimental period (Figure 5), and reflects the increased loss of iodine in sweat at high sweat outputs.

An attempt was made to obtain short-time measurements of the rate of iodine excretion in the urine in order to define the characteristics of urinary excretion as a function of plasma level and other factors. However, the tendency of all subjects to lag behind their water requirements during the period of active sweating led to low rates of urine flow and made accurately timed collections of urine very difficult. The available data indicated clearance rates from 10 to 25 ml. of plasma per minute with a tendency toward higher rates with increasing urine flow. Such clearances are consistent with the slopes of the plasma iodine disappearance lines in Figure 4.

The sweat was of next importance in the elimination of iodine. In Figure 6 it is apparent that sweat iodine concentration is related to plasma iodine concentration; roughly, the concentration of sweat iodine is 35 per cent of the concentration of plasma iodine. It can be seen that while the iodine level in arm sweat was of the same order of magnitude as the whole body sweat, it was nevertheless uniformly higher in relation to the

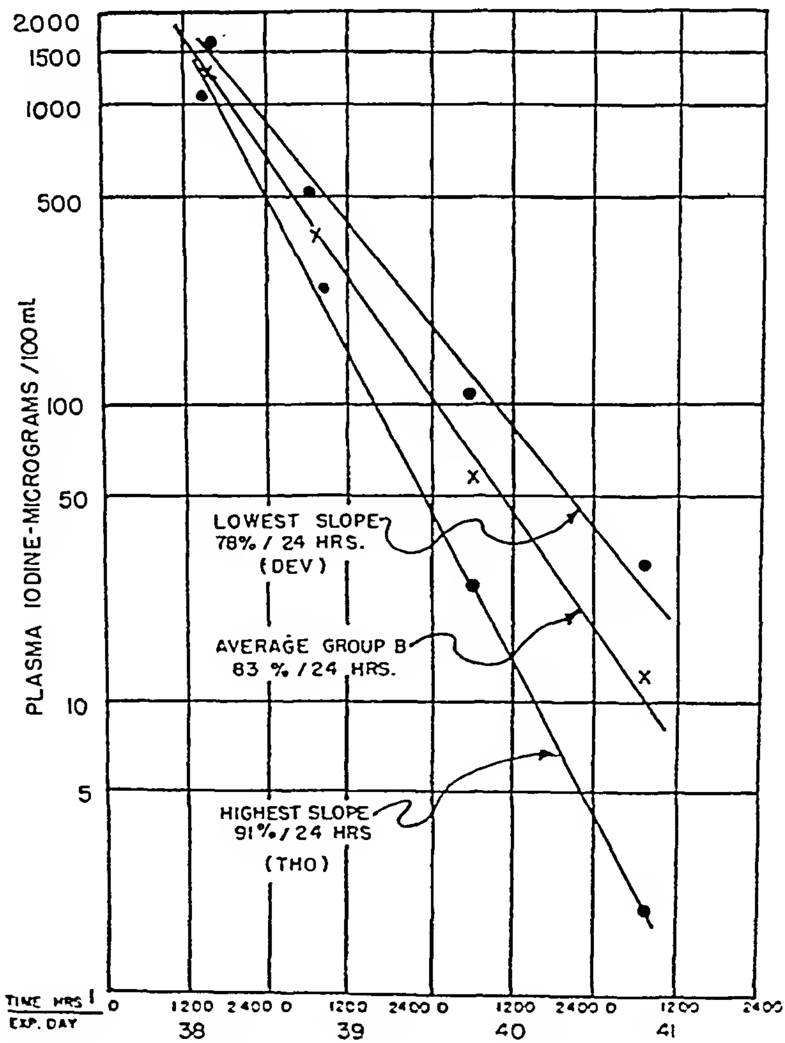

FIG. 4. RATE OF DISAPPEARANCE OF IODINE FROM THE PLASMA (GROUP B)

plasma level than whole body sweat by 25 per cent to 30 per cent. This may be due in part to regional differences in concentration.

Data pertinent to the question of analogy in sweat excretion between chloride and iodide were obtained in two experiments each on subjects Del and Bur. The results of these experiments are given in Table II. It appears that the concentration of both iodide and chloride in the sweat depends on the plasma concentrations in much the same way.

Relative to the amount ingested, only minor

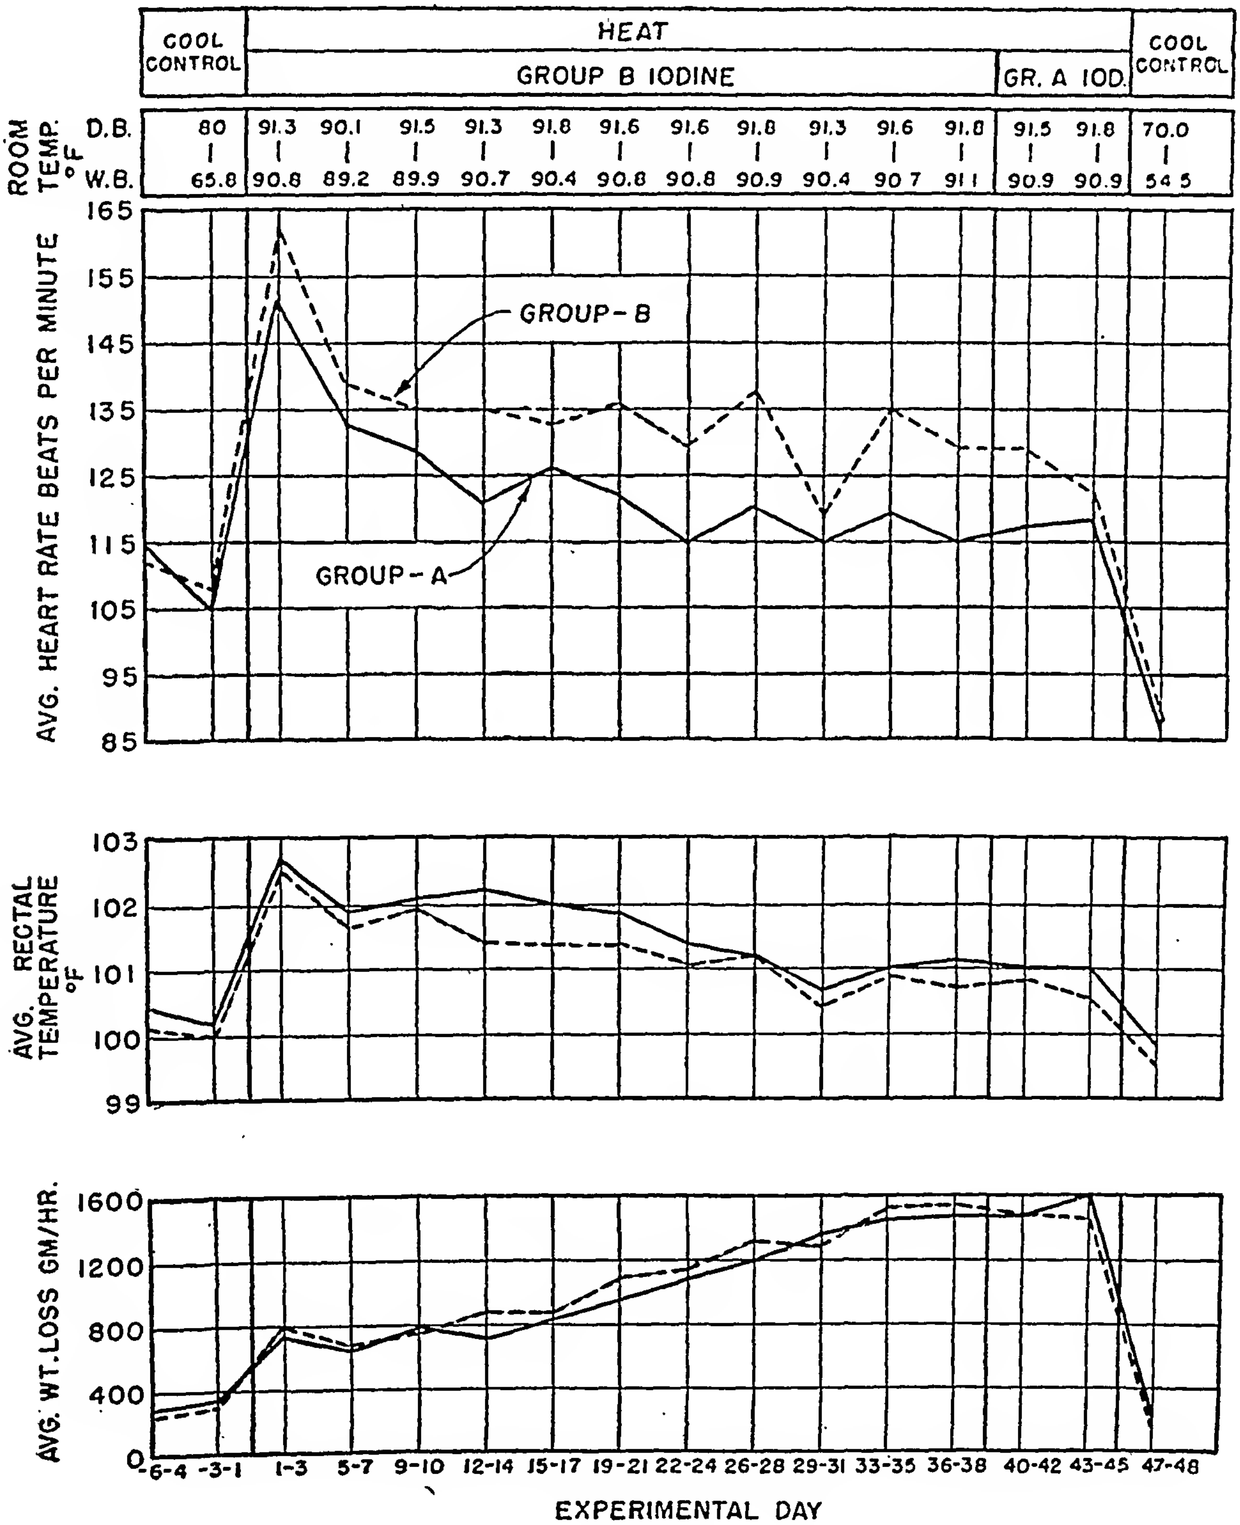

FIG. 5. HEART RATE, RECTAL TEMPERATURE, AND HOURLY WEIGHT LOSS BY 3-DAY PERIODS

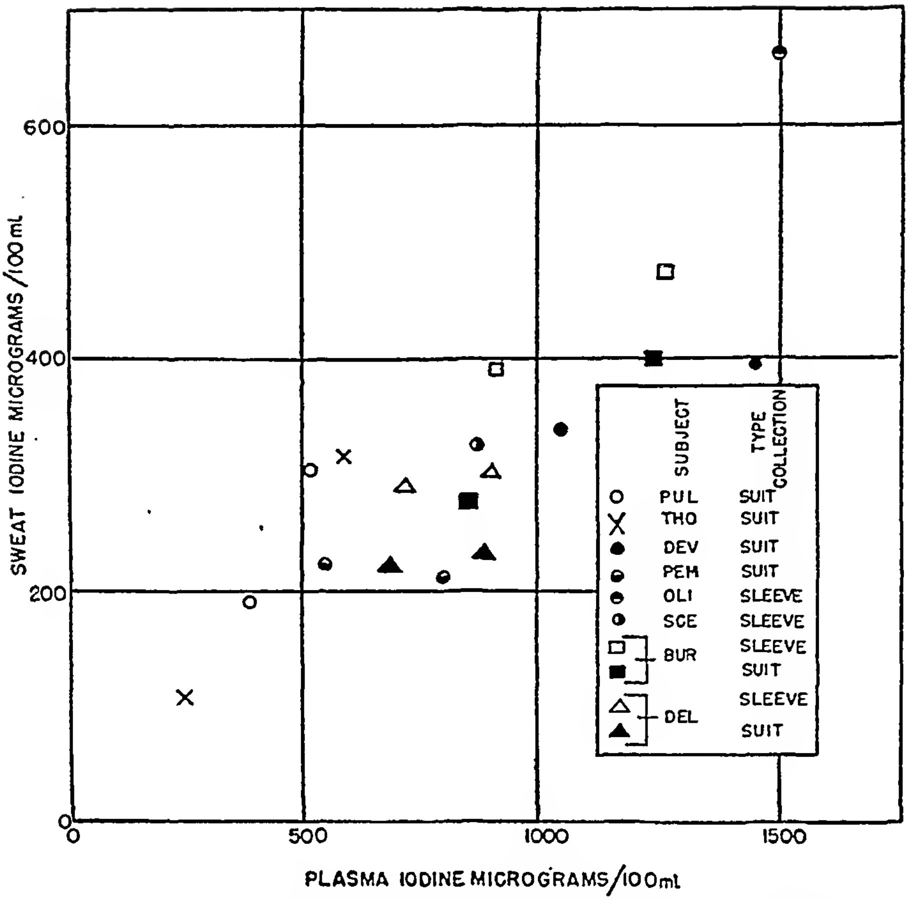

FIG. 6. CONCENTRATION OF IODINE IN SWEAT AS A FUNCTION OF PLASMA IODINE CONCENTRATION

amounts of iodine were found in the feces. Complete collections during 1 week made on subjects Pul and Tho led to recoveries of 0.32 per cent and 0.38 per cent respectively of ingested iodine.

Iodine balance. With the information available on the urine, sweat, and feces, it was possible to assemble the partial balance shown in Table III. The basis of calculation of the various components was as follows: the intake and urine output were taken from the sources already mentioned; sweat iodine was calculated from the total sweat excretion and an estimated iodine concentration derived from the correlation in Figure 6 (Sweat I = 0.35 plasma I, where plasma I was taken as 0.77[5] average peak plasma concentration); fecal output was calculated as a percentage of the total intake based on the results from the subjects Tho and Pul of 0.38 per cent and 0.32 per cent respectively.

The resulting balance, though based on crude estimates, gives a fair picture of the relative importance of the various paths of iodine loss under the circumstances of this experiment.

TABLE II

Iodide and chloride excretion in the sweat as a function of plasma concentration

Arm sweat collected for 40-minute period; plasma values interpolated to midpoint of period

Subject	Iodide			Chloride		
	Plasma	Sweat	Ratio I_s/I_p	Plasma	Sweat	Ratio Cl_s/Cl_p
	µg. per l.	*µg. per l.*		*meq. per l.*	*meq. per l.*	
Bur 1	910	3.94	0.433	95.5	41.5	0.434
2	1,260	4.75	0.377	93.5	34.5	0.369
Del 1	720	2.95	0.410	101.7	36.8	0.362
2	900	3.05	0.339	98.7	29.2	0.296

[5] The factor 0.77 was derived from curves of the type shown in Figure 1 to approximate an integrated average concentration for the work periods, the time of high sweat output.

	All	7,143	5,283	73.9	430	6.0	25.0	0.35	5,738	80.3

Physiological effects. The subjects ingested an average of 88 mgm. of iodine daily and attained blood plasma concentrations ranging from 75 to 1,300 μg. per 100 ml. during the 38-day period of exposure (Figure 3).

No deleterious effect on performance of work and no unusual hardships during acclimatization to heat were noted in those men taking iodine when compared with the control group or in comparison with other groups of normal subjects under similar conditions of stress (35, 36). The measurement of final postwork heart rate, rectal temperatures, and hourly sweat rates for the control and test periods are presented in Figure 5. It is apparent that the responses of both groups of men were parallel, regardless of the intake of iodine.

The results of the basal metabolism tests are presented in Figure 7. The group averages showed no trend, nor was any trend noted in the analysis of the results of individual subjects. No apparent change in basal metabolic rate due to heat exposure alone under the conditions of this experiment could be found. No change was observed in the size or consistency of the thyroid gland, and the neck circumference did not alter. There was an insignificant weight loss in both groups.

Blood and urine examinations before and after exposure to heat and iodine revealed only a slight fall in blood hemoglobin, similar to that noted in other groups of subjects exposed to heat alone.

The general symptomatology of the men in both groups was similiar and was that of acclimatization as has been described elsewhere (35, 36). Blood pressure measurements were not remarkable. Of

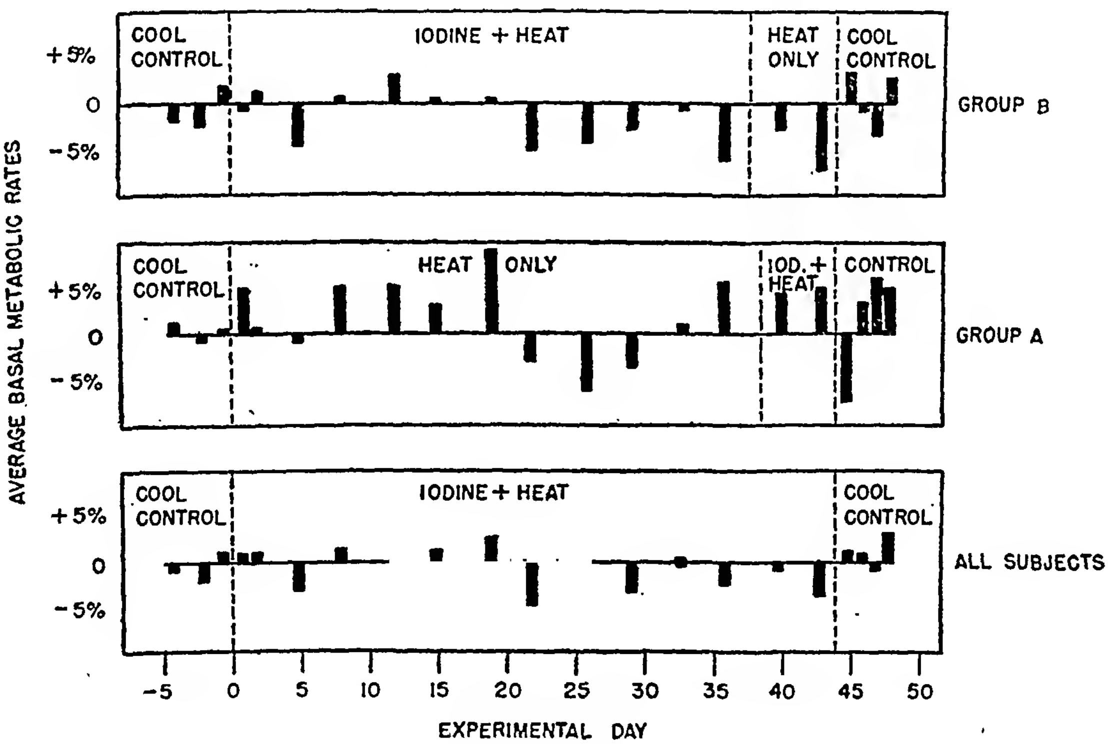

FIG. 7. EFFECT OF IODINE AND HEAT ON THE BASAL METABOLIC RATE

incidental interest was the fact that the taste of iodine water, found quite disagreeable at first, was preferred by the subjects to salted tap water at the end of the period of exposure.

The men were tested for skin sensitivity to iodine during and at the conclusion of the experiment but the small number of subjects precluded drawing any useful conclusions in that regard.

SUMMARY

(1) Inorganic iodine was rapidly and completely absorbed from the gastrointestinal tract.

(2) The plasma concentration of iodine was directly proportional to the quantity ingested.

(3) The iodine plasma level fell rapidly after cessation of iodine intake reaching near basal levels within 72 hours.

(4) Excretion of iodine was chiefly in the urine but an appreciable fraction appeared in the sweat. Sweat iodine concentration was 35 per cent of plasma concentration. Fecal excretion was negligible.

(5) No effect on general health, acclimatization to heat, vital signs, basal metabolism, blood, or urine could be ascribed to the ingestion of iodine by normal subjects over a period of 6 weeks.

We wish to thank T. C. Swigert, J. L. Gray, R. J. Bloom, and F. W. Urbush for technical assistance.

OBSERVATIONS ON MEN PERFORMING A STANDARD AMOUNT OF WORK IN LOW AMBIENT TEMPERATURES

By STEVEN M. HORVATH [1] and H. GOLDEN [2]

(*From the Armored Medical Research Laboratory, Fort Knox, Kentucky*)

(Received for publication October 21, 1946)

The activities of the various armies engaged in this last war have made evident the necessity for adequate information on the responses and reactions of man to the stresses of widely differing environmental conditions. During the past few years great emphasis has been placed upon investigations attempting to delineate the reactions of man to hot environments. Only a very limited number of studies were made in regard to cold weather despite the fact that greater divergences from normal (temperate zone) temperature conditions occur in sub-arctic and arctic areas.

Physiological investigations at these very low temperatures are hampered to some extent by the necessity for excessive amounts of clothing, which makes analysis of the role of the body temperature-regulating apparatus difficult. Even though investigators have been forced to consider only very practical matters, a certain amount of basic information has accrued,—primarily concerning the most adequate means of providing external heat or retaining body heat through the medium of protective clothing. In this report the responses of men working in environments as low as − 46.7° C. are presented. This complements earlier data (1) on men who sat quietly for long periods of time at similar ambient temperatures.

METHODS

All experiments were conducted from the months of August through December in the laboratory cold room described in a previous report (1). The environmental temperatures were maintained within ± 0.5° C. Air movement during test periods was practically zero. Exposure of subjects to the environments from − 3.3° to − 46.7° C. was made in a random manner. Two to four tests were made on each subject in the various environments except on subject JO., who was not available for ambient temperatures of − 16.1° and − 20.4° C. The physical characteristics of the five subjects are presented in Table I. The men were dressed in either of two clothing combinations,[3] arctic or herringbone twill uniforms.[3] In general only a single test was made on each subject during the day and that between 9 and 12 o'clock. The occasional 2- and 3-hour walking periods were conducted in the afternoon. The test procedure was as follows: each subject rested for 1 hour in a cool room (24° C., 50 per cent RH), donned a thermocouple harness, and was dressed in one of the uniforms. Rectal and skin temperatures were taken and the subject, entering the cold room, stepped onto the moving belt of the treadmill. At the completion of the hour work period, the man left the cold room and did not re-enter until another experiment on the following day.

TABLE I

Kl.	19	175	70.8	1.83

The treadmill in use had a walking surface provided by a roughened rubber belt sliding on a rigidly supported maple slipway. All tests were conducted at a speed of 3.0 miles per hour and a grade of 3.3 per cent. Skin temperatures were measured at 10-minute intervals at five or ten points with copper constantan thermocouples, and the mean skin temperature was calculated by the procedure suggested by Hardy and DuBois (2). Rectal temperatures were obtained either by calibrated clinical

thermomters or by indwelling rectal thermocouples. Expired air was collected in compensated gasometers and analyses of aliquot gas samples collected over mercury were performed in duplicate using the Haldane machine. These machines were checked by daily analysis of outdoor air. Calculations for the oxygen consumption, respiratory quotient, and caloric expenditure were made in the usual manner. Inspired air was at the same temperature as the environmental. During the work periods, the respiratory exchange was determined after 10 and 45 minutes of walking. Collections of expired air were made for 10-minute periods. Heart rate by palpation was obtained on four occasions, before work and at 20, 40, and 55 minutes from the onset of walking.

RESULTS

The subjects were given preliminary training on the treadmill for a period of 12 days. Control studies were made at 24° C. on the 2 days prior to the first cold room exposure and again on the 2 days following the last low temperature day. No after-stimulating effect of cold was noted, the results being very similar to the pre-cold tests. Consequently all four tests at 24° C. were averaged to give the single control value in the tables. The data obtained on the men when dressed in the arctic uniform and working in the following eight low temperatures, − 3.3°, − 16.1°, − 20.4°, − 24.8°, − 27.2°, − 31.0°, − 37.2°, and − 46.7° C., are to be found in Tables II and III. Additional information is shown graphically in Figures 1 to 4.

Regardless of the type of clothing worn, the energy expenditure for the standard work load was always higher in the cold environments,—the average increase being approximately 12 per cent. The greater caloric expenditure was not due to

* Wore herringbone twill uniform.

the additional clothing worn, since the weight of the herringbone twill uniforms was the same at 24° C. as at the lower temperatures. For some inexplicable reason the highest values were always obtained at the envinronmental temperature of − 27.2° C. The smallest increase in caloric output was observed in the least cold environment, − 3.3° C.; in fact, when the herringbone twill uniform was worn, no differences from the control values were noted. However, in environmental temperatures above this, the increases were roughly similar for both garment assemblies. Cold appeared to provide a small but definite stimulus to the metabolic processes.

The average oxygen consumption of all the subjects at the different environmental temperatures is plotted in Figure 1, and, in Figure 2, a smiliar plot is presented for subject JO. These latter data, unfortunately not for every ambient temperature, are presented because his oxygen consumption at 24° C. was the same as the average for the group. Furthermore, JO, showed the greatest change of the five men at the ambient temperature of − 3.3° C.

The ventilation rate was also raised but in approximately the same proportion as the oxygen consumption. The frequency of breathing was not increased, the larger ventilation being compensated by adjustment in depth of respiration. Barcroft and Verzar (3) noted some irregular gasping in the breathing pattern of their subjects exposed to low temperatures, but no abnormalities were noted in this study, even at the lowest environmental temperature, − 46.7° C. The respiratory quotient exhibited no consistent change, being higher at some environments, lower at others, and the same as the control (24° C.) in the remainder.

The heart rate during work showed no significant changes with varying ambient temperatures, and the amount of clothing worn made no significant difference.

The changes in skin and rectal temperatures were quite different with the two types of clothing worn and will be discussed separately in the following sections.

Arctic clothing. This clothing combination has an insulative value between 4 and 5 Clo. and was

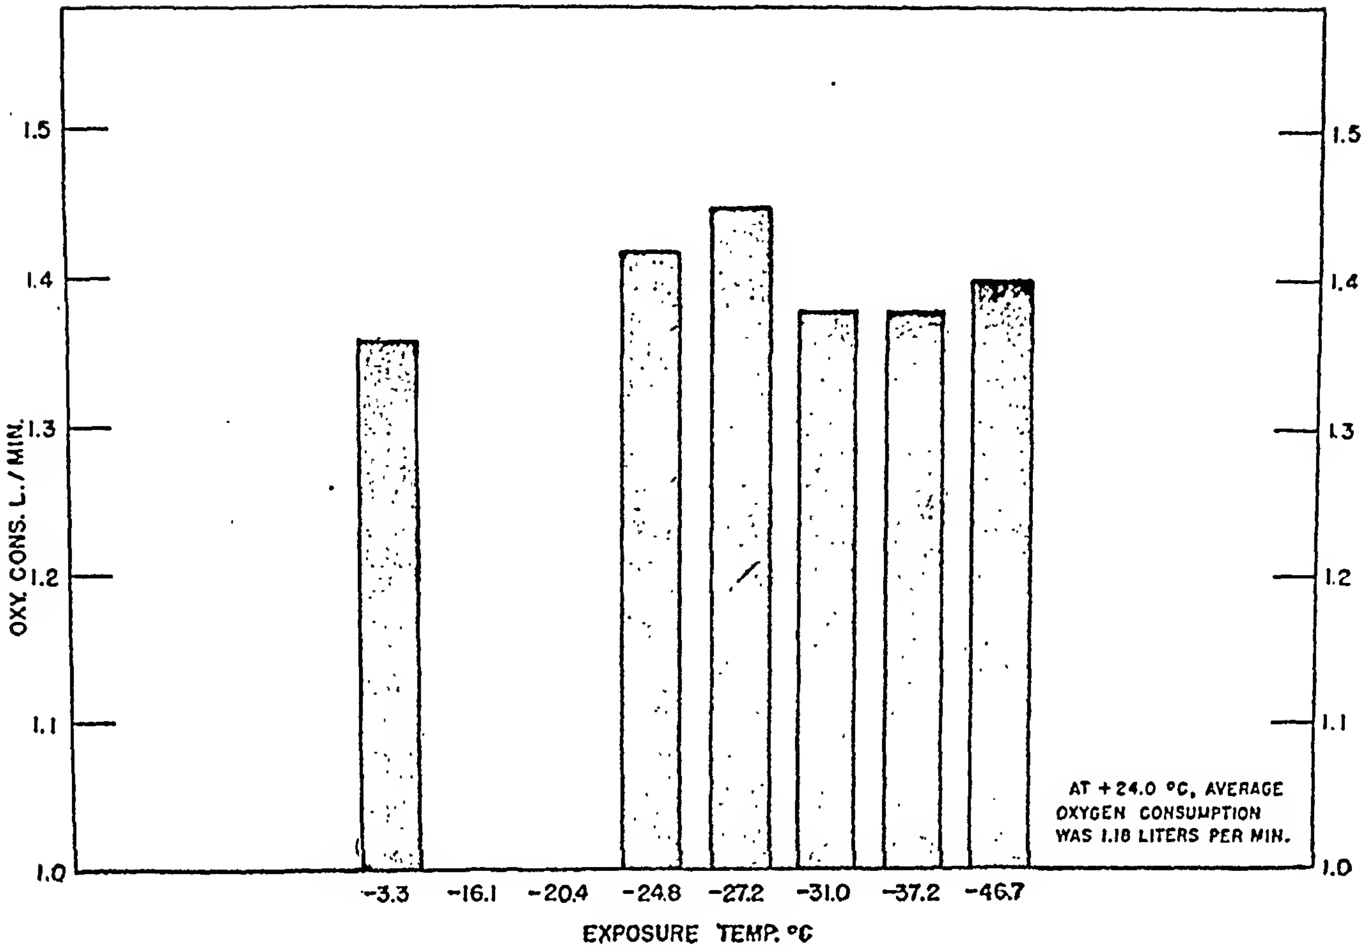

FIG. 2. OXYGEN CONSUMPTION OF ONE SUBJECT (JO.) DRESSED IN ARCTIC CLOTHING AND WALKING ON TREADMILL AT 3.0 M.P.H. AND A 3.3 PER CENT GRADE DURING HIS FIRST HOUR OF EXPOSURE TO THE INDICATED TEMPERATURES

worn completely buttoned during the walk. It was thought that the increased energy expenditure might be due to the weight of this outfit, 10 kilograms, but subsequent experiments with the herringbone twill issue and one experiment on a subject completely nude except for socks and shoes at − 20.4° C. indicated that the higher caloric output was primarily due to the stimulus of the low ambient temperature. Rectal temperatures were elevated to the same degree in normal and very cold environments. Only at − 46.7° C. was the increase significantly higher, 0.4° C. above the control, which was probably related to the greater vasoconstriction occurring at this low ambient temperature. Toe temperatures rose in all cases (Figure 3 and Table III), but the increases were somewhat erratic due to the variations in initial toe temperatures. Again the final level was approximately the same at all environments except at − 47.7° C.—a finding which bears out the suggestion of a more generalized vasoconstriction at this ambient temperature.

The explanation for finding higher final toe temperatures than mean skin temperatures is not available. It may have been due to a vasodilation being present in the extremities or to local friction effects. When subjects walk in hot environments, toe and foot temperatures as high as 3° to 5° C. above mean skin temperatures are frequently observed and could be explained as a consequence of friction.

The initial mean skin temperatures were quite constant. In the two least severe environments, final mean skin temperatures showed an actual increase, but beginning with − 20.4° C. decreases were always observed. The lowest value was found at the lowest ambient temperature. Storage values, calculated according to Burton's (4) formula, followed a pattern similar to the changes in mean skin temperatures primarily because the

rectal temperature exhibited so little change from one environment to another.

Herringbone Twill. This clothing assembly weighs approximately 4 kilograms and has an insulative value between 1 and 2 Clo. There was no change in average calorie output at − 3.3° C. compared to the control environment of 24° C. (Table IV). However, as the environmental temperature decreased the energy expenditure increased, showing a maximum rise of 12 per cent at an ambient of − 46.7° C. The stimulative effect of cold was also reflected in the greater losses of body heat (see Table above). No appreciable debt was incurred at − 3.3° C., but at − 37.2° C., a debt of 100 cal. per M². was noted. There appeared to be a positive correlation between heat debt and ambient temperature at least up to − 37.2° C. These data on storage are reflections of the inability of the subjects to raise their rectal and mean skin temperatures despite the production of almost 400 calories per hour (Table V). The toe temperatures were increased only at − 3.3° C. At all other environments the toe temperatures fell despite the exercise (Figure 3), the final values being lower the colder the environment.

DISCUSSION

There is no evidence that man is seriously handicapped in his ability to work in cold environments. As suggested by the increased energy expenditure for the same work output, the net efficiency for grade walking by these subjects was slightly reduced by the cold. However, additional work loads must be studied before a final statement regarding changes in efficiency of performance can be made. Adolph and Molnar (5) stated that "when the air was too cold, extra heat was produced above that which was a by-product of the work." The caloric output of their subjects at an environmental temperature of 37° to 39° F. was 299 cal. per $M.^2$ per hr. in contrast to 190 at an ambient temperature of 40° to 46° F. Such a degree of stimulation was not observed in our very lightly clothed subjects at environmental temperatures of − 46.7° C. (− 52.1° F.). Their subjects sometimes shivered while working—an observation never noted in this study. The subjects in this study never felt more than slightly chilly and in general were fairly comfortable.

In the group of experiments at − 20.4° and − 37.2° C., during which men walked for periods up to 3 hours, no additional changes were observed above those recorded for the 1-hour tests. Caloric expenditures appeared to decrease slightly, rectal temperatures rose approximately 0.1° C. per hour, and the mean skin temperatures were similar to those obtained at the end of the first hour. A balance in the heat exchange appeared to have been reached.

Heart rates were not significantly different at normally comfortable and extremely cold environments regardless of the amount of clothing worn. Previous reports (5) have suggested some correlation between the pulse rates of working men and lowered environmental temperatures. The differences between the results of this study and that of Adolph and Molnar (5) might be explained on the basis of clothing, since their subjects were nearly nude, but a disparity in clothing insulation of 2 Clo. would not be likely to compensate for a temperature differential of nearly 90° F. However, the effects of cold on sensory phenomena and cold tolerance may be greatly influenced by clothing and so affect the physiological measurements under consideration. Additional studies are clearly needed.

The major differences observed in the responses of the lightly and heavily clothed working subjects were in their rectal and skin temperatures. The rectal temperature rise in the cold was maintained at the same or even slightly higher level in working men wearing arctic suits as in a comfortable environment. Lightly dressed subjects had difficulty in reaching or maintaining this level except in the least cold ambient temperature. The colder the environment, the smaller was the elevation of the rectal temperature. The mean skin temperature exhibited a similar pattern in that large decreases were observed for the lightly clothed individuals with relatively small falls or actual increases for the heavily clothed.

In Figure 4, are plotted the data obtained on the mean skin and toe temperatures of a subject during one of these work periods at three of the lowest environmental temperatures employed. These changes in mean skin temperature with the wearing of the two clothing issues are typical. The major portion of the decrease occurred during the first 10 minutes of work and was maintained at a relatively constant level thereafter. Therefore, the major portion of the heat debt accumulated by the body occurred not only in a short period of time but also relatively early in the exposure. Measurements of the caloric expenditure of the subjects during these first 10 minutes indicated that the rate was the same then as during later portions of the work period. A similar type of response was noted in sitting subjects (1) where the greatest body heat loss also took place in the first phase of the exposure. This initial contribution appeared to be of vital importance in maintaining the working balance of heat exchanges in men exposed to low temperature. The significance of rapid loss of body heat in the regulation of body temperature was not evident from these studies.

The toe temperatures of the same subject (Figure 4) are interesting in that they not only showed the general pattern of response, but they reached the lowest level attained by any of the subjects during work. When the arctic uniform was being worn, an initial fall was noted which in almost every case then proceeded to rise, reaching stable

levels within a half hour after the beginning of the work period. This was not true when the lighter clothing assembly was worn, under which condition the toe temperature continued to go down after an initial fall. The rate of decrease diminished considerably as the experiment continued. The general beneficial effects of greater total insulation are obvious from these data.

The caloric expenditure for a given amount of work was slightly greater in the cold regardless of the degree of insulation provided by the clothing. The difference in the weights of the two

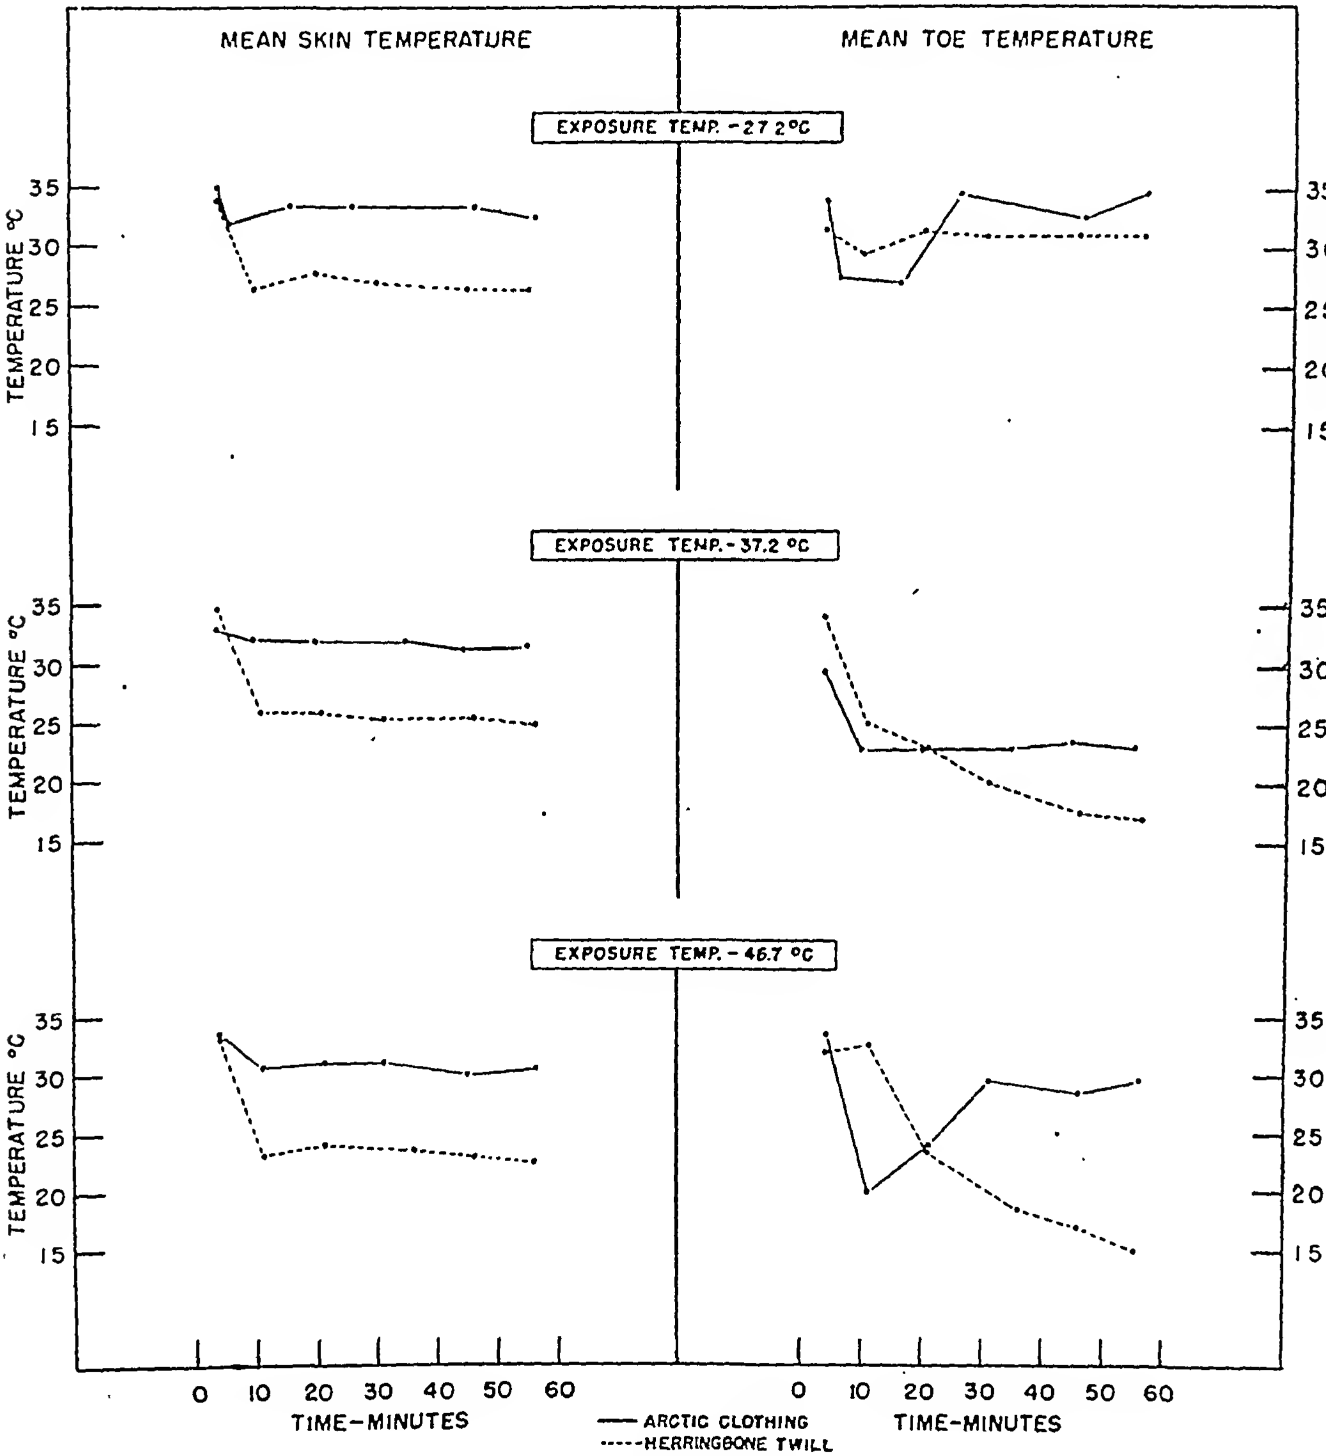

Fig. 4. Comparison of the Rate and Degree of Change of Mean Skin and Toe Temperatures in a Subject During a 1-Hour Walk Dressed in Either a Full Arctic Uniform or a Pair of Herringbone Twill Coveralls

garment assemblies resulted in only minor variations in the extent of the stimulation to metabolic processes. The diminution of mechanical efficiency in these subjects was of small magnitude. It might be explained as being due to the increased cost of respiratory effort, increased viscosity of cold muscles, or any number of small factors that inhibit the development of maximum skill and ease of work performance.

Men dressed in the arctic uniform can strike a balance of heat exchange while working at a caloric expenditure of around 350 calories per hour in ambient temperatures as low as − 46.7° C. However, this is only a partial answer to the adequacy of this type of clothing, since the accumulation of perspiration in the fabrics will alter a man's ability to maintain a balanced heat exchange, especially when he stops work. With very light dress, heat balances are not so readily attained at very low ambient temperatures. The degree of stress may be roughly estimated from the heat debt accrued. Caution in the use of these figures must be exercised, since the calculation of heat debt as presently performed may not be valid in cold environments.

No evidences of acclimatization to cold were found in this study. The intermittent nature of the exposures and the relatively short periods of time spent in the cold probably prevented the development of any such effect.

SUMMARY

1. Five subjects, wearing light and heavy clothing, walked at a standard rate of speed and grade of climb on a motor-driven treadmill in comfortable and very cold environments.

2. The energy expenditure for the standard work was increased by some 10 per cent in the lower ambient temperatures. This stimulation appeared to be independent of the amount of clothing worn. Ability to work was not significantly impaired even at ambient temperatures as low as −46.7° C., although there was a slight diminution of mechanical efficiency at certain of the environments.

3. The loss of body heat was greater with a light weight clothing and the magnitude of the loss appeared to be directly related to the ambient temperature. Heat debts were less but quite variable when heavy clothing was worn. In all cases, the heat debts were accumulated in the early portion of exposure to the cold environment.

ACKNOWLEDGMENT

The authors wish to exress their appreciation of the excellent cooperation of the enlisted men who voluntarily served as subjects and to Mr. James Gregg, M/Sgt. Walter Kupchick, M/Sgt. John Gray, T/Sgt. H. Bloom, T/3 J. Wagar, Mrs. James M. Nelson, and Mrs. Steven M. Horvath, for their assistance in conducting the experiments and the analysis of the data.

CIRCULATORY DYNAMICS IN THE BASAL STATE OBSERVED DURING CONVALESCENCE. CHANGES IN BODY WEIGHT, BLOOD VOLUME, AND VENOUS PRESSURE [1, 2]

By GEORGE R. MENEELY, ALBERT SEGALOFF, and E. B. WELLS

(From the Department of Medicine of Vanderbilt University School of Medicine, Nashville, Tennessee)

(Received for publication May 24, 1946)

Complaints of the circulatory symptoms of palpitation, tachycardia out of proportion to exertion, postural vertigo, and dyspnea are frequent among convalescents as a group. The present study was undertaken to determine if the commonly employed methods of evaluating circulation could be used in the prognostic classification of convalescents, and if such methods would indicate underlying physiological disturbances susceptible to modification with an ultimate shortening of the recovery period.

MATERIAL AND PROCEDURES

The 20 male subjects studied were civilians of military age who had had acute infectious diseases or surgical operations from which recovery was expected within a reasonable period of time. The purpose and general nature of the procedures were explained to the patients who volunteered to cooperate, although some were not too enthusiastic. Studies were begun within a few days of the subsidence of obvious manifestations of illness, such as tachycardia and fever, and at the time when clinical judgment indicated that convalescence had indeed begun. A number of these patients returned for follow up study upon regaining their usual good health. Fourteen of these follow up studies were satisfactory.

Difficulties were encountered in choosing and setting up a series of tests of circulatory function in convalescents. The earlier procedures, requiring several hours for completion, were too rigorous as evidenced by manifestations of severe malaise, nausea, vomiting, diarrhea, or headache. Patients complained bitterly upon their return to the ward and vowed not to participate further in the studies. However, as these individuals had no fever or clinical signs of toxic reaction to the chemicals employed in various techniques, the same materials were used in subsequent and less rigorous schedules of tests. When the procedures were too long or caused discomfort the patients became restless and uncooperative before the end of the period of observation.

Since such stress did not seem advisable in early convalescence, and the results were invalidated by it, the schedule was modified to levels of exertion well tolerated by the patients who then remained cooperative throughout the period of study. The earlier results, obtained when the patients reacted unfavorably during or following the series of tests, were discarded because we are skeptical of the value of such tests under any but basal conditions or those of accurately measured and reproducible stress. Changes in circulation resulting from the rigors of the earlier studies were not further investigated.

The series of observations finally adopted for use required about 1½ hours to complete and included ballistocardiographic records, pulse and respiratory rate, arterial blood pressure, oxygen consumption, blood volume, venous pressure, hematocrit, circulation time, weight, height, electrocardiogram, and a teleroentgengram of the chest.

The general nature of the procedure was explained to the patient, who cooperated purely upon a volunteer basis. Instructions were given to keep the patient in bed on the morning of the test, not to disturb him for routine care, and to delay the morning meal. He was brought to the laboratory upon a rolling stretcher, usually about 6:30 or 7:00 A.M. Here he was transferred to the ballistocardiograph bed (1) and allowed to rest undisturbed for ½ hour. The ballistocardiographic deflections were then photographed. Following this, the pulse and respiration rate were recorded and the arterial blood pressure determined with a mercurial manometer. Then, by using a Benedict-Roth closed breathing circuit, a respiratory tracing over a 7-minute period was obtained in duplicate.

The blood volume was estimated by the method of Gibson and Evans (2). Four samples of blood were delivered into Gibson tubes containing 20 volumes per cent of isotonic potassium oxalate for hematocrit values. Samples of serum were reserved for determination of total protein by the copper sulphate specific gravity method (3). During the blood volume determination, the venous pressure was measured directly with a saline manometer referred to a point 6 cm. below the angle of Louis with the patient supine (4). After completion of the blood volume determination, the blood velocity was

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Vanderbilt University.

[2] This work was done in the Lung Station of the Department of Medicine, a laboratory organized under a grant from the Commonwealth Fund, and some of the equipment used was available through a grant by the Ciba Pharmaceutical Products, Inc.

measured using Macasol [3] by the method of Spier, Wright, and Saylor (5). An electrocardiogram was taken. The patient was then weighed, measured, and transferred by roller stretcher to the X-ray room where a 6-foot film was obtained with the patient erect, either sitting or standing.

The ballistocardiograph employed in this study has been described elsewhere (6) and had physical properties essentially identical with the instrument of Starr and associates (1). The cardiac output was calculated by the area formula (1), modified slightly for the method of standardization employed by the authors. The cardiac output per minute per pound of body weight was compared with Starr's normal standard (7). Starr's normal data were recalculated in terms of cardiac output per calory of predicted basal metabolic rate, with slight improvement in deviations for sex and age, and our findings compared with their recalculated standards.

Heat production was calculated in the usual way from oxygen consumption and compared with predicted values from the Aub-DuBois standard (8). The difference was expressed as a percentage of normal as the usual basal metabolic rate.

Ventilation per minute was determined by integrating the respiratory tracing, and the utilization coefficient of Herbst (9) was derived from this and from the oxygen consumption, expressed as milliliters of oxygen consumed per liter ventilated.

Plasma volumes were calculated from curves of blue dye disappearance, and the total blood volume and cell volume were derived by the use of the hematocrit ratio from antecubital venous blood. Blood volumes were compared with the standards of Gibson and Evans (10) basing the prediction upon the height of the patient.

The transverse diameter of the heart was measured in the teleroentgengram as was the internal diameter of the chest at the level of the fourth costochondral junction. In our experience this latter measure is less subject to irrelevant variation than the usual measure made at a lower level in the rib skirt. The ratio of the heart diameter to the internal diameter of the chest was then calculated.

TABLE I

Mean values of observations of convalescent male civilians of military age and the mean difference upon recovery

	No. of cases	Initial mean and standard deviation	No. of cases	Mean difference upon recovery
Weight, kgm.	20	62.25 ± 9.80	14	+ 3.60*
Respiratory rate per min.	19	16.50 ± 2.80	13	− 1.80

* Changes considered significant.

RESULTS

Data from various tests are given in Table I, including the mean values and standard deviations of the observations made during early convalescence, and the mean differences between these initial values and those following recovery. The mean values of the initial studies do not deviate from commonly accepted normal standards, with the exception of blood velocity. Whether this latter difference is real is discussed below.

There was no uniformity in the changes in systolic and diastolic blood pressure or in the pulse pressure recorded in early convalescence and recovery, since about half of the group showed an increase, the remainder a decrease in pressure.

From Table I, it is apparent that the blood velocity was the same in convalescence and health. The data from arm-to-foot determinations following recovery were too few to be included.

The values for the mean cardiac output per minute per pound of body weight in convalescence compare favorably with Starr's (7) figure of 23 ml. per minute per pound as the normal mean. The mean decrease of 3.5 ml. per minute per pound after recovery was due to the increase in body weight rather than to the small decrease in minute volume.

A correlation of the cardiac output per minute with the predicted and observed basal metabolic rate in the recovery and convalescent states was fruitless. Recalculation of Starr's data for normal subjects showed the mean normal value for cardiac output per minute per calory of the predicted B.M.R. to be 50 ml., with a range of 40 to 60 ml.,

[3] Supplied through the courtesy of the Nepera Chemical Co., Yonkers, New York.

corresponding to Starr's range of 18–29 ml. per minute per pound of body weight.

From the data obtained in these studies it cannot be said that the basal metabolic rate is useful as a criterion for convalescence. In central Tennessee, where all of these studies were made, general experience indicates that a mean basal value of minus 5 per cent by the Aub-DuBois standard may be regarded as normal; farther south, in New Orleans, the figure is minus 10 per cent (11).

As might be inferred from the data on ventilation and the basal metabolic rate, the relation between ventilation and the oxygen consumption expressed by Herbst's coefficient (9) was neither abnormal initially nor was it significantly altered subsequently. The mean coefficient was 39.3 ±

TABLE II

Blood volume studies, blue dye method, of adult males

	No. of cases	Initial observations: mean	Mean difference 1st and 2nd obs.
House officers, normal males (13)	5	5.57 liters	+0.006 liter
Convalescents	20	5.35 liters	+0.461 liter*
Gibson's normal males (10)	49	5.31 liters	

* This represents the mean increase after recovery in the case available for a second observation.

The data on the 5 house officers studied on 2 occasions months apart are included to show that there is little deviation attributable to the method in the study of a group. The mean difference of 0.461 liter between the blood volumes observed in convalescence and in the same cases after recovery is contrasted to the lack of difference in the 5 normal males restudied.

7.6 ml. of oxygen consumed per liter ventilated. After recovery there was a mean increase of 0.31 ml. The normal mean obtained by Hurtado and Boller (12) who used the same procedure was 37.5 ml. oxygen per liter ventilated, with a coefficient of variation of ± 27 per cent. The mean increase of 0.37 cm. in the transverse diameter of the heart cannot be regarded as significant.

From the data it was obvious that weight differences between a patient's reported normal and his observed weight in early convalescence could not be relied upon as a criterion of convalescence. This is illustrated by a discrepancy between the weight loss reported and the weight regained by the individuals followed to recovery. While the patients appeared to have lost an average of 6.11 kgm., to judge from the difference between the patient's estimate of his usual weight and his actual weight during convalescence, yet upon return to usual health, the weight regained averaged only 3.59 kgm. (Table I and Figure 1).

Table II contains data on blood volume obtained from: (a) 5 house officers among whom there was no reason to consider a physical or medical change in status during the 6-month interval elapsing between the 2 determinations (13), (b) our convalescent and recovered groups or subjects, and (c) Gibson's mean of blood volumes in 49 normal males (10). The blue dye method of Gibson (2) was used in all of these studies. Many of the normal values included in Gibson's study were obtained from hospital-bed patients, which might explain the difference between his average total blood volume in males, 5.35 liters, and the aver-

age blood volume, 5.76 liters, in our group of recovered ambulatory subjects.

The increase in total volume of the blood was due to both plasma and cell increases, the latter change predominating in patients frankly anemic in the early convalescent state, the former in those with high hematocrit values in convalescence (Table I and Figure 1).

The venous pressure was significantly increased after recovery in most subjects; it was unchanged in one, and decreased 8 mm. saline in another, the mean increase being 24.6 mm. saline, the greatest, 73 mm. saline, representing a mean increase of 35 per cent (Figure 1 and Table I).

The electrocardiograms were within normal limits in convalescents and following recovery there was no significant change. Plasma total protein and circulating plasma total protein showed no significant change.

DISCUSSION

It is at once evident that the circulation at rest during early convalescence deviates only slightly from normal. The 2 particulars in which deviations were found were blood volume and venous pressure. To these might be added body weight, for some part of the weight deficit appears to be interstitial water (14).

The deficit in blood volume is of the same order of magnitude as that found by Keys and his associates (15) and by Barr and his associates (16) in normal men at bed rest, and by Rutstein (14) in convalescence from pneumonia. Loss of about ½ kgm. of body weight and about 100 grams of protein may be accounted for by the observed deficit in blood volume.

The question arises as to whether these blood volume changes are real. Cruickshank's (17) reiteration of Smith's (18) observation that some unknown fraction of the administered dye is taken up by the reticulo-endothelial system immediately is a valid criticism of the method. The discrepancy between venous and general body hematocrit values (19) is another. Although there is no evidence that errors in the blood volume are consistent on different occasions when the patient is in different clinical states, yet it is to be hoped this is the case so that changes observed in a patient from time to time may be real even though the absolute values are incorrect. The reproducibility of results obtained by the method of Gibson and Evans (2) may be seen in the normal house officers (Table II) who were studied at different times of the year.

The rise in venous pressure upon recovery is not explained. It was not related to changes in cardiac output, to blood volume, nor to any other measurement we made.

It is interesting to compare our findings with those of Lyons and his associates (20) who have recently reported extremely interesting observations on normal individuals who underwent diuresis with ammonium chloride and mercupurin. There was a loss in body weight of a little over 3½ kgm. associated with a fall in plasma volume slightly over 700 ml. Much of the diminution in body weight was aparently due to diminution of interstitial water. His subjects exhibited symptoms "suggestive of an inadequate circulation . . . they complained of weakness, prostration, fatigue, and some felt so faint attempting to stand that they chose to remain in bed." The striking similarity of these symptoms to symptoms experienced by patients during early convalescence is obvious, and possibly the mechanism of production of these manifestations is closely related in the 2 cases.

The values obtained for circulation time seemed long to us. However, as patients returned for follow up without change, we were compelled to reinvestigate the normal standards for this method in our hands. Forty-six normal men in the basal state formed the material for this review and the results are to be published elsewhere (21). Suffice it to say there was no significant difference between the blood velocity in these normals and that found in our early convalescents.

SUMMARY

1. The following measurements were made upon a group of basal convalescent male patients who had undergone infectious disease or surgical operation: height, weight, pulse, respiration, arterial and venous blood pressure, blood velocity from arm to tongue, hand, perineum and feet, cardiac output, cardio-thoracic ratio, oxygen consumption, basal metabolic rate, ventilation, tidal air, utilization coefficient, hematocrit value, total blood volume, plasma volume and cell volume, plasma

total protein, circulating plasma total protein, and an electrocardiogram. None of these observations indicated any characteristic abnormality of the circulation when the results were compared with currently accepted normal standards; so none of these tests is of any use as a routine procedure for the clinical classification of convalescence.

2. Follow up studies revealed small but significant alterations which could be detected only by comparing the individual with himself as a control. These differences were: a deficit in body weight of 3.6 kgm., a deficit during early convalescence of approximately ½ liter of blood volume, and a deficit of 35 per cent of the patient's usual venous pressure.

SULFADIAZINE RESISTANT STREPTOCOCCAL INFECTIONS IN A CIVILIAN COMMUNITY [1, 2]

By ROSWELL D. JOHNSON and THOMAS L. HARTMAN

(From the Mary Imogene Bassett Hospital, Cooperstown, New York and the U. S. Naval Research Unit at the Hospital of The Rockefeller Institute for Medical Research and the Hospital of The Rockefeller Institute for Medical Research)

(Received for publication November 13, 1946)

During a program of mass chemoprophylaxis of streptococcal infections in the Armed Forces (1), it was noted that the effectiveness of such a regimen was lost with the appearance of sulfonamide-resistant strains of hemolytic streptococci. The occurrence and spread of these resistant strains in susceptible populations in the U. S. Army and Navy have been reported (2, 3, 4), and have been the subject of considerable speculation and theoretical implications. To date there have been no reports as to the incidence of streptococcal epidemics in the civilian population due to sulfonamide-resistant strains. It is the purpose of this paper to report the occurrence of such an epidemic in a civilian community due to a sulfadiazine-resistant group A, type 19 hemolytic streptococcus.

METHODS OF STUDY

Early in 1946 a small epidemic of scarlet fever occurred in Cooperstown, New York. Since the first 8 patients with scarlet fever were found to harbor type 19 hemolytic streptococci in their nasopharynges, it was decided to determine whether we were dealing with sulfonamide-resistant strains. All 8 strains of hemolytic streptococci were found to be resistant to the action of sodium sulfadiazine in a concentration of 25 mgm. per cent.

Because of the unique opportunity to study the incidence of sulfonamide-resistant hemolytic streptococci in a small community, it was decided to test the sulfonamide sensitivity of all hemolytic streptococcus cultures sent to the laboratory in this area. Cultures were obtained from patients, living in Cooperstown, New York, and the surrounding area of Otsego County, who were suspected of having streptococcal infections. Records were kept as to the source of the cultures and the clinical diagnosis. No attempt was made to do a widespread survey on a healthy group to determine carrier rates.

All culture swabs were sent to the Otsego County Laboratory at the Mary Imogene Bassett Hospital or to a nearby branch laboratory. The swabs were streaked on 5 per cent rabbit blood agar which was incubated for 24 hours at 37° C. Single colonies of beta hemolytic streptococci were transferred to Avery's media on the following day and incubated for 6 hours. A loopful of this growth was then streaked to a blood agar plate, checked for purity, and the group determined. The group A hemolytic streptococci isolated were grouped and typed at the Rockefeller Institute Hospital by the precipitin technique (5), and the sulfonamide sensitivity was determined by the method of Wilson (6).

EPIDEMIOLOGICAL SITUATION AND RESULTS

From February 15 to May 1, 1946, streptococcal infections were moderately prevalent in Cooperstown, New York. During this period 100 patients with varied group A hemolytic streptococcal in-

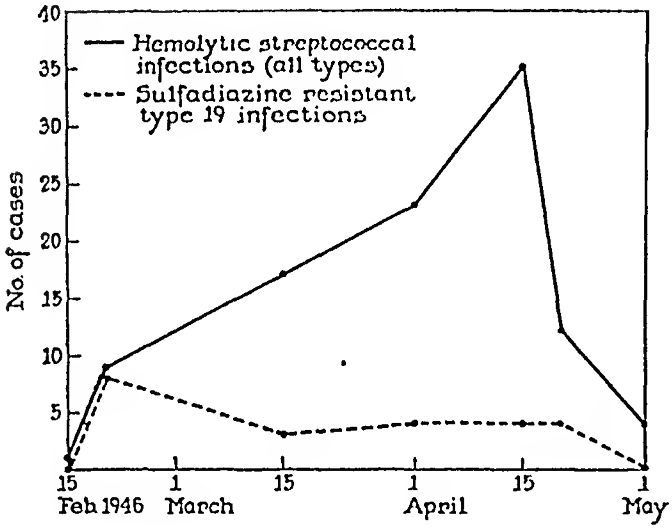

FIG. 1

fections were cultured, with the type distribution indicated in Table I. The cultures were obtained from patients with scarlet fever, pharyngitis, otitis media, wound infections, blood stream infections, and pneumonia. The time incidence of cases during this period is shown in Chart 1. By May 1, 1946, the incidence of streptococcal infections had decreased to the point where it was no longer considered of value to continue the study.

The most common typable streptococcus was type 3, which was responsible for 28 cases of hemolytic streptococcal infections. Type 19 was the cause of 24 cases of disease, with 23 of these strains being resistant to 25 mgm. per cent sodium sulfadiazine and 1 strain non-resistant. Nineteen cases were due to the other types listed in Table I, while 29 were caused by untypable strains. Only type 19 hemolytic streptococci were resistant to the action of sodium sulfadiazine.

Since our main interest in this report is concerned with the occurrence of type 19 sulfonamide-resistant hemolytic streptococci, the epidemiological situation in respect to these infections will be discussed briefly. Of the 23 persons infected with this sulfonamide resistant strain, 14 were under 15 years of age, 10 of public school age, and 4 of pre-school age, 9 cases occurred in adults.

The first case of scarlet fever in this study developed on February 15, 1946, in a 9-year-old boy who attended the public school. Following the onset of this patient's illness, several classmates developed scarlet fever, and from their nasopharynges type 19 sulfadiazine-resistant streptococci were isolated. The next cases developing due to resistant type 19 strains appeared in parents, sibblings, or contacts of the children originally infected in the public school. However, 3 patients were from widely separated communities and had no known contact with any of the previously mentioned cases. None had any known contact with recently discharged or active members of the Armed Forces.

Of these cases of drug-resistant infection, 14 were clinical scarlet fever, and 9 were merely pharyngitis. One case of scarlet fever and one case of pharyngitis were complicated by otitis media and one patient developed rheumatic fever following pharyngitis due to this type 19 sulfadiazine-resistant hemolytic streptococcus. None of these cases presented any special therapeutic problems, nor were they clinically different from infections due to other types of hemolytic streptococci. The incidence of infection with this particular organism was rather evenly distributed throughout the period of this study with the peak occurring early (see Figure 1).

COMMENT

The possibility of a spread of sulfadiazine-resistant hemolytic streptococci to the civilian population has been anticipated ever since their appearance in the Armed Forces (2, 3, 4). The present report indicates that such resistant strains have, indeed, been responsible for infections in at least one civilian community and that similar occurrences may complicate future problems of therapy among civilians.

The mode of development of resistant strains of bacteria is still a matter of discussion. It has been demonstrated that strains of streptococci with low or medium degrees of sulfadiazine resistance appeared in the Army (7) about the time that the program of mass sulfa-prophylaxis had been in progress in the Navy (1) for several months. It had been suggested that these slightly resistant strains were mutants that might possibly have been precursors of the more highly resistant strains later established. The possibility cannot, however, be eliminated that there was a transfer of resistant strains to soldiers from certain Naval personnel, who were subjects of the mass prophylaxis program, and hence possible carriers of highly resistant streptococci. It is noteworthy that no evidence of sulfonamide resistance was

found in any strains of hemolytic streptococci prior to the institution of the mass chemoprophylaxis programs (2, 8).

The possibility that sulfonamide-resistant hemolytic streptococci could arise in the civilian population must be considered. The evidence to date, however, would seem to indicate that all strains of hemolytic streptococci which were present in the civilian population prior to the time of mass chemoprophylaxis in the Armed Forces were susceptible to the action of the sulfonamides. Evidence (8) has also been presented to show that the usual therapeutic doses of sulfonamides, such as might be prescribed in a civilian population, did not cause the development of resistant organisms.

Since the sulfadiazine-resistant hemolytic streptococcal infections reported in this study were caused by a type 19 strain, which was known to be a prominent resistant strain in the Armed Forces, it seems probable that this strain was introduced into this civilian community by military personnel even though a history of recent contact with sick soldiers and sailors could not be elicited. Contact of civilians with discharged veterans, some of whom might have been healthy carriers of these resistant strains, could hardly have been avoided. The fact that most cases of sulfonamide-resistant infections here reported occurred among school children is noteworthy, since all previous reports of sulfonamide-resistant infections occurred in adults.

Although the cases mentioned in this report did not offer any problems as to therapy, one cannot overlook the importance of determining whether one is dealing with an organism sensitive to the chemotherapeutic agent being administered. Since the clinical picture of infections caused by resistant strains of hemolytic streptococci is no different than those caused by non-resistant strains, one can only determine this property by isolation and testing of the organism causing the infection. From an epidemiological and clinical point of view, the determination of the presence of resistant strains would be of definite value if the prevention and treatment of resistant-strain complications is to be effectively accomplished.

The appearance of increasing numbers of bacteria which are resistant to various chemotherapeutic agents, formerly effective against them, suggests the desirability of a careful bacteriological diagnosis of infectious agents prior to treatment with specific antibacterial drugs, especially when there is an obvious failure of clinical response to the chemotherapeutic agent under consideration.

SUMMARY

Twenty-three cases of type 19 sulfadiazine-resistant hemolytic streptococcus infections occurred in a civilian community. None of the cases presented any problem as to treatment nor were there any serious complications. Attention is directed to the importance of determining the sensitivity of infecting bacteria to chemotherapeutic agents prior to the start of treatment with specific agents.

The authors wish to thank Dr. Ann Kuttner and Dr. Homer F. Swift for their interest and criticism during this study.

Dr. Walter Eells, Walton, New York, and Dr. George Rosenthal, Cherry Valley, New York, were instrumental in obtaining many of the streptococcal cultures used in this study. Valuable technical assistance was rendered by Mrs. Winifred Cary, Cooperstown, New York, and Miss Jeanne Epstein of The Rockefeller Institute Hospital, New York, New York.

STUDIES ON THE RELATIONSHIP OF THE HEPATITIS VIRUS TO PERSISTENT SYMPTOMS, DISABILITY, AND HEPATIC DISTURBANCE ("CHRONIC HEPATITIS SYNDROME") FOLLOWING ACUTE INFECTIOUS HEPATITIS [1]

By JOHN R. NEEFE,[2] JOSEPH STOKES, JR., ROBERT S. GARBER, and SYDNEY S. GELLIS

(From the Nutritional Service of the Department of Pediatrics (Medical School) and of the Gastrointestinal Section (Medical Clinic of the Hospital), University of Pennsylvania)

The term "chronic hepatitis" has been suggested by Barker, Capps, and Allen (1) for reference to those patients with infectious hepatitis who fail to recover within 4 months of the onset of the disease. This term also appears to be applicable to those patients with homologous serum hepatitis who fail to recover within 4 months. As used here the word "chronic" refers only to "duration without implication concerning the nature of the pathologic process or the eventual prognosis."

The frequency with which "virus hepatitis"[3] becomes chronic is not known and probably varies with the patient's age, general condition (nutritional and otherwise), management, and possibly with the strain of virus concerned. However, in a series of 431 unselected cases diagnosed as "infectious hepatitis" in the Mediterranean Theater (1), 18 per cent were classified as chronic on the basis of the above definition. Furthermore, under the favorable conditions associated with the study of induced infectious hepatitis in one group of healthy, well-nourished, adequately treated volunteers between the ages of 18 and 32, approximately 15 per cent failed to recover completely within 4 months, although all achieved complete clinical recovery within one year (2, 3). On the basis of these data and the high incidence of acute virus hepatitis during recent years, the occurrence of a relatively large number of such chronic cases (as defined above) might be expected.

Chronic hepatitis presents a number of important medical problems. Recognition frequently may be difficult, particularly in the non-icteric cases, and a lack of knowledge of the factors leading to chronicity has prevented a fundamental approach to its prevention and treatment. Furthermore, the chronic form of the disease may be of importance in the epidemiology of virus hepatitis, particularly when unrecognized.

The relationship of the hepatitis virus to the chronic stage of the disease unfortunately is obscure. A knowledge of this relationship obviously is essential for the clarification of some of the problems mentioned. For this reason, it was considered desirable to attempt to isolate the hepatitis virus from patients with a chronic form of the disease. Suitable materials for study were available from three volunteers with chronic active non-icteric hepatitis observed among a group of volunteers in whom acute infectious hepatitis had been induced under experimental conditions by the oral administration of feces known to contain the virus of infectious hepatitis (virus IH) described in previous reports (4, 5). It is the purpose of this preliminary report to describe the results of attempts to demonstrate the hepatitis virus in serum, feces, and liver tissue obtained from these three chronic cases.

MATERIALS AND METHODS

Source and materials. The histories of the three volunteers with chronic active non-icteric hepatitis have been described elsewhere (3) and do not warrant repetition here. The diagnosis appeared to be unequivocal and was based on the history, symptoms, laboratory evidence of hepatic disturbance, and, in two of the cases, on the histologic findings in liver biopsy specimens obtained 6 and 9 months respectively after the onset of acute hepatitis. The same strain of virus had been used for the induction of acute infectious hepatitis in all three cases. Specimens of feces and serum were collected at intervals through-

---

[1] This investigation was made possible by a grant from the Donner Foundation, Inc., Philadelphia, Pa., and also was aided in part by the Commission on Measles and Mumps, Army Epidemiological Board, Preventive Medicine Service, Office of the Surgeon General, U. S. Army, Washington, D. C.

[2] National Research Council Senior Fellow in the Medical Sciences.

[3] The term "virus hepatitis" is used to include both infectious hepatitis and homologous serum hepatitis.

out the course of the disease. The times of collection of the individual serum and feces specimens included in the pools used in the present study are shown in Figures 1, 2, and 3 in which the results of serial hepatic tests roughly reflect the course of the disease in the three cases. The liver tissue tested for the presence of virus was part of a biopsy specimen obtained surgically from Case 2 (HPZ) at the time indicated in Figure 2 (approximately 6 months after the onset of hepatitis). Serum and feces specimens were frozen within 1 hour after collection. They were stored at $-10°$ to $-20°$ C. until the time of administration to volunteers, with the exception of a few hours

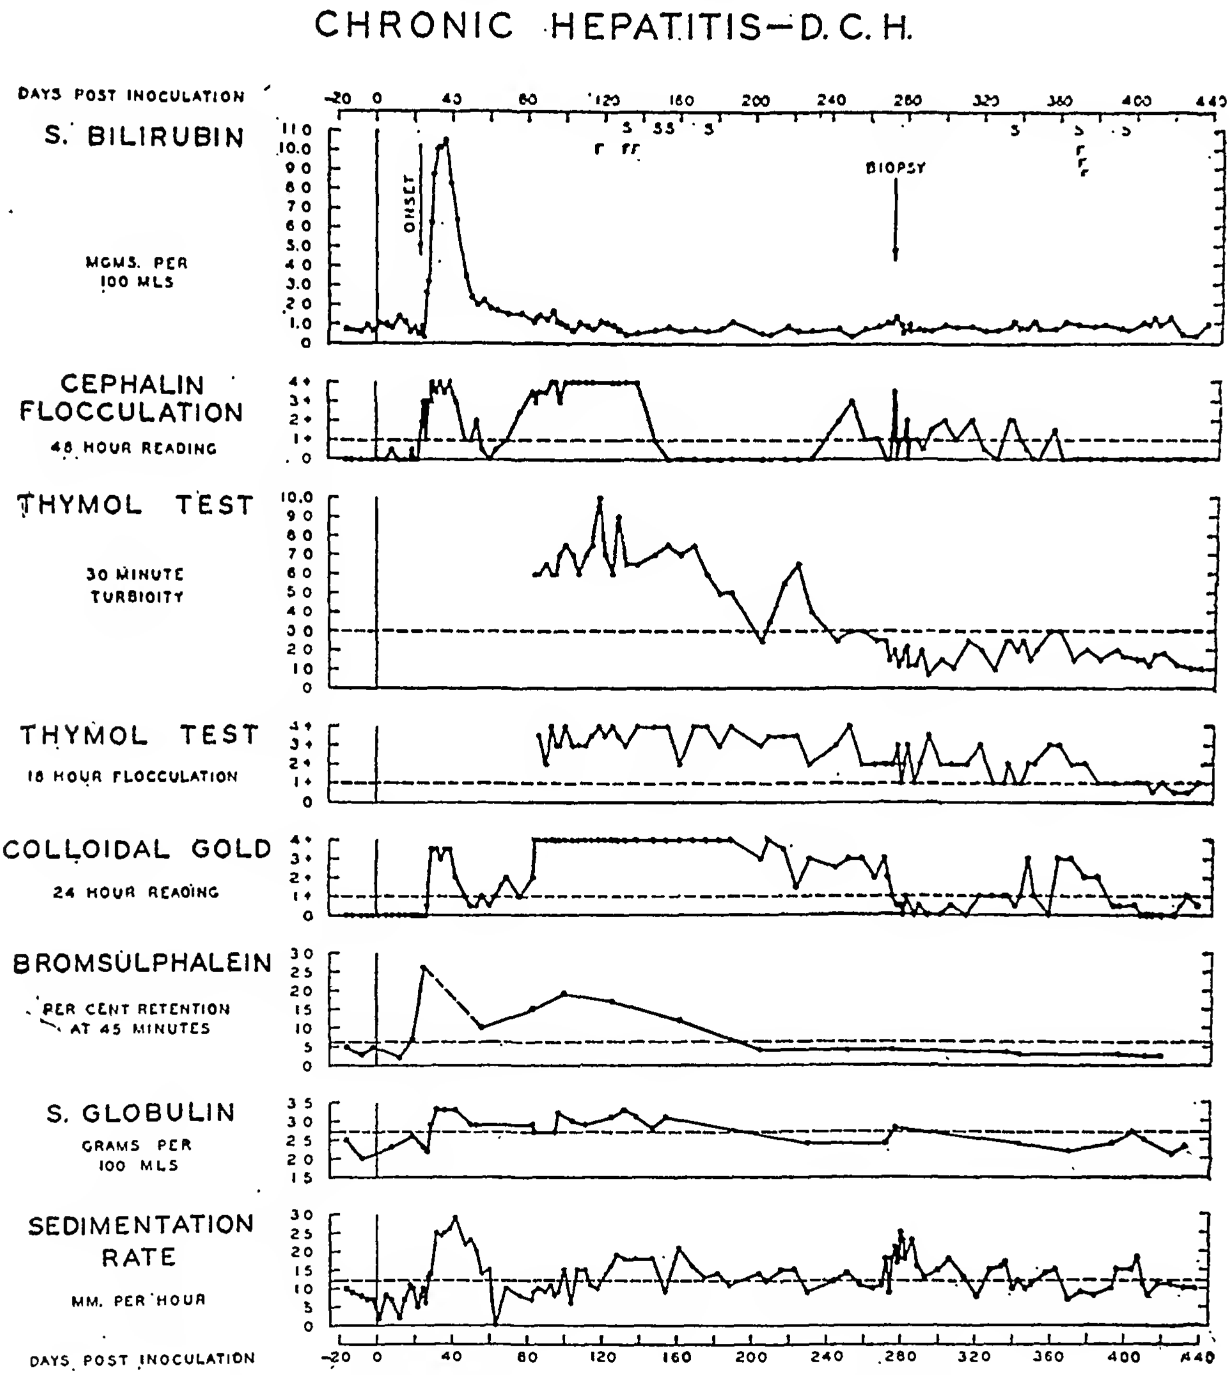

Fig. 1. Results of Serial Hepatic Tests in Volunteer D. C. H.

The "S" and "F" located beneath the time scale at the top of the figure indicate the times when serum (S) and feces (F) specimens were collected. Acute hepatitis had been induced in this subject by the oral administration of a feces preparation known to contain a representative strain (virus IH, Pa.) of infectious hepatitis virus. For approximately one year after the disappearance of jaundice associated with the acute hepatitis, he had persistent symptoms resulting in partial incapacitation. A microscopic examination of the liver biopsy, obtained at the indicated time, revealed the stroma of many of the portal triads to be infiltrated with excessive lymphocytes, plasma cells, and histiocytes.

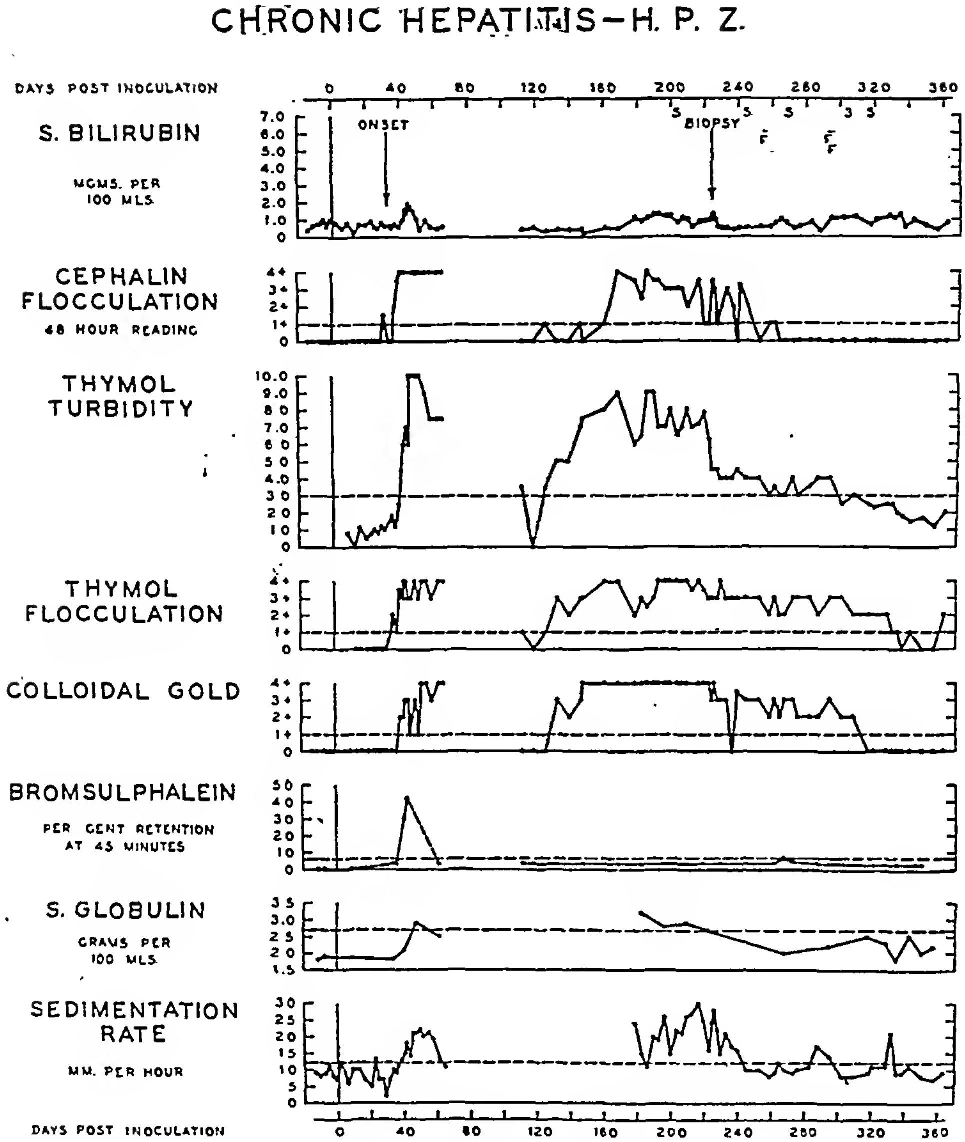

FIG. 2. RESULTS OF SERIAL HEPATIC TESTS IN VOLUNTEER H. P. Z.

Acute hepatitis was induced as described in the legend of Figure 1. For other data referable to the figure, see legend of Figure 1. A part of the liver biopsy obtained at the time indicated was used in the present studies (see text). This volunteer continued to have symptoms and partial disability for approximately 10 months after the onset of the acute attack.

on one day when they were thawed simultaneously, the pools prepared, and then refrozen. The liver tissue was placed in a dry bottle and was frozen within 15 minutes after its surgical removal. It also was stored at $-10°$ to $-20°$ C. until used.

Preparation of materials: Feces pool 13-14-15 FIH. The feces specimens from the individual cases were thawed and a portion of each was pooled with the others from the same case, yielding pools 13, 14, and 15 respectively. Sufficient distilled water was added to each of these pools to produce, after mixing, the consistency of a thick paste. Additional distilled water then was added and a heavy homogeneous suspension was obtained by thorough mixing in a Waring Blendor. This then was strained through gauze to remove any remaining large particles. Each of the 3 pools (13, 14, 15) then was cultured (no commonly pathogenic intestinal bacteria were isolated), and, after the culture reports were available, equal portions from each were pooled and mixed to yield *feces pool 13-14-15 FIH.* The final pool thus included a total of 23 feces specimens obtained 92 to 342 days after the initial onset of hepatitis (Figures 1, 2, and 3.).

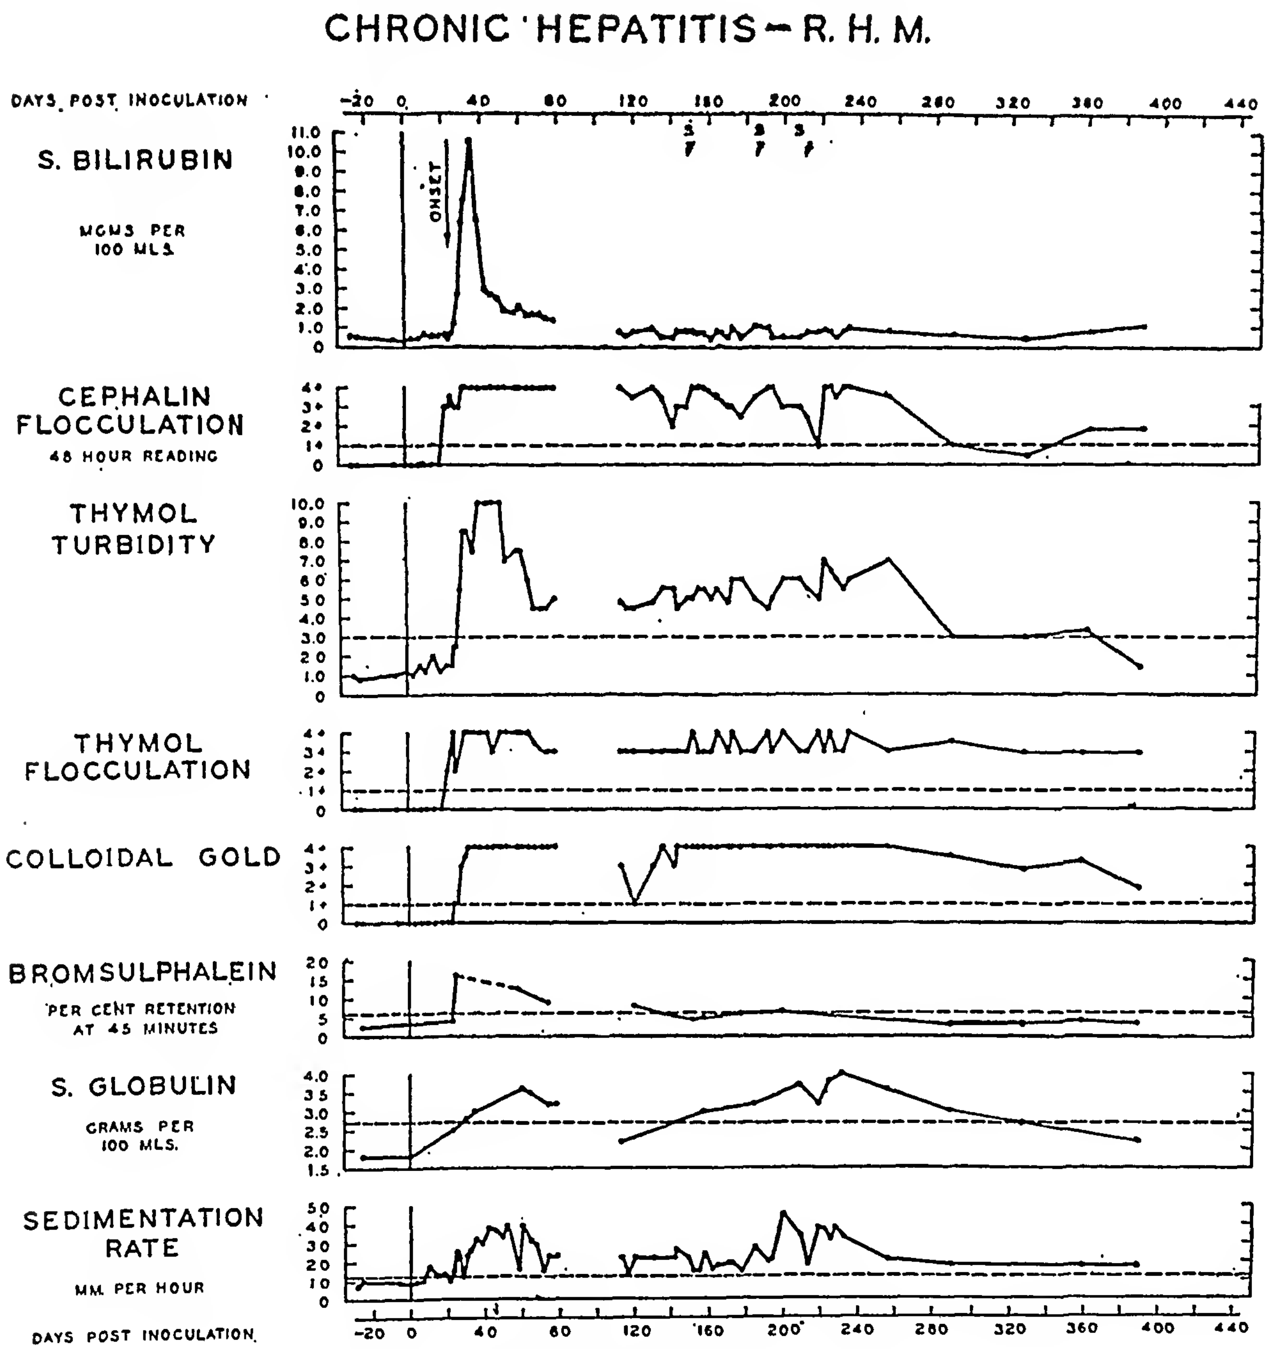

FIG. 3. RESULTS OF SERIAL HEPATIC TESTS IN VOLUNTEER R. H. M.

See legend Figure 1 for the other data referable to this figure. This subject continued to have persistent symptoms and partial disability for approximately 10 months after the onset of acute hepatitis.

Serum pool 1-CSIH. Approximately 2 ml. of each serum specimen obtained from 106 to 367 days after the onset of hepatitis were mixed together to form this pool which included a total of 15 serum specimens (Figures 1, 2, and 3).

Liver suspension 1-CLIH. The biopsy specimen of the liver tissue, estimated to weight between 100 and 200 mgm., was thawed and promptly was ground with sterile alundum. The ground liver tissue then was suspended in approximately 12 ml. of sterile beef heart infusion broth. The suspension was centrifuged for 10 minutes at 2,000 r.p.m. The supernatant then was removed and stored at − 10° C.

Just prior to its oral administration to the volunteers, the supernatant was thawed and diluted to approximately 100 ml. with sterile physiological saline solution and this (liver suspension 1-CLIH) was divided into equal portions (20 ml.) which were ingested by each of the 5 subjects.

The report of Colonel Balduin Lucké, of the Army Institute of Pathology, Washington, D. C., on the microscopic appearance of this liver tissue was as follows:

"The hepatic structure is preserved but allowance must be made for variations in lobular configuration that are normal at the surface of the liver. The stroma of most portal triads contains a moderate excess of cells, mostly lymphocytes and histiocytes; some triads, however, are entirely normal. No connective tissue proliferation is evident. Occasionally minute foci of cell reaction similar to those of the triads are met within the interior of some lobules. Many liver cells are swollen and appear to be laden with glycogen; these cells are often binucleated. It is probable that they represent regenerated cells. About half of the liver cells seem to have a low glycogen content, suggesting that storage of this material has varied in different parts of the tissue."

Volunteers. All of the men who volunteered as subjects for the study were male inmates of the New Jersey State Prison, Trenton, N. J. Because of statistically significant evidence (2) indicating that susceptibility to the virus of infectious hepatitis used in this study decreased after the age of 26, and decreased rapidly after the age of 30, an effort was made to obtain volunteers under 30 years of age. Unfortunately, only a few of the volunteers within this age range could be made available at the time. It was necessary, therefore, to use a number of men who were not within the age range of greatest susceptibility (up to 26 years of age) to this strain of virus. The ages of the 5 men who were inoculated with the feces pool were 23, 27, 31, 32, and 33 respectively. Those inoculated with the serum pool were 20, 29, 31, 32, and 39 respectively. Those who received the liver suspension were 21, 28, 29, 34, and 34 respectively. All were considered to be in good health. None had a history of previous jaundice or presented clinical evidence of hepatic disease prior to inoculation. All of the men were isolated as a group in a special ward provided by the New Jersey State Hospital, Trenton, N. J. The period of isolation began 1 month prior to inoculation and continued for 2 months after inoculation. During this period, the only contacts were with the nurses, the special guards assigned by the prison, the technicians, and the supervising physicians. None of these contacts reported any illness during the period of experiment. Although personal contact between the volunteers was not preventable at meal and recreation times, they were quartered in individual rooms with individual toilet facilities and individual eating utensils were used. Registered nurses were in constant attendance during the isolation period. Following their release from the isolation ward at the New Jersey State Hospital, the men were returned to the New Jersey State Prison where they were followed for an additional 3-month period.

Studies on volunteers. The hepatic studies described in previous reports (3, 6, 7) were conducted on each subject at frequent intervals both before and after inoculation. Total and prompt direct-reacting (1') serum bilirubin determinations, urine bilirubin and urobilinogen tests, and the cephalin-cholesterol flocculation, colloidal gold, and thymol tests were conducted at least twice weekly during the period of observation. Bromsulphalein tests were done once weekly. Serum total protein, albumin, and globulin were determined at less frequent intervals. Oral temperatures were recorded at least twice daily. With the appearance of any symptoms or laboratory abnormalities, the studies were repeated with greater frequency. After release from the isolation ward, the hepatic tests were continued at 1- to 3-week intervals.

Inoculation of volunteers. On each of 4 successive days, 5 ml. of feces pool 13-14-15 FIH was administered orally in chocolate milk to each of 5 volunteers. Each of 5 other volunteers ingested 3 ml. (1 man) to 5 ml. (4 men)

TABLE I

Results in volunteers after ingestion of feces pool 13–14–15 FIH

Subjects	Age	Illness (– to ++++)	D. A. I.	Remarks
J. D.	31	+	20 to 28	Symptoms only
		+++	127 to 137	Symptoms, liver tenderness, mild hepatic dysfunction
R. A.	32	+	18 to 41	Intermittent symptoms
G. S.	23	+	20 to 35	Symptoms only
E. S.	27	–	–	–
A. M.	33	–	–	–

Illnesses graded from – (no illness) to ++++ on the basis of the relative severity of symptoms and signs as observed in these subjects. D.A.I. indicates the number of days after inoculation when symptoms were present.

TABLE II

Results in volunteers after ingestion of liver suspension 1–CLIH

Subjects	Age	Illness (– to ++++)	D. A. I.	Remarks
E. Mc.	29	+	22 to 29	Symptoms
		++++	36 to 50	Symptoms, plus hepatic enlargement and tenderness; no significant hepatic dysfunction detected
T. K.	21	+	26 to 30	Symptoms and laboratory evidence suggestive of mild hepatic dysfunction
M. P.	28	+	28 to 51	Intermittent symptoms only
P. S.	34	+	15 to 60	Intermittent symptoms only
J. M.	34	–	–	–

See legend of Table I for other data referable to interpretation of table.

TABLE III

Results in volunteers after ingestion of serum pool 1-CSIH

Subjects	Age	Illness (− to ++++)	D. A. I.	Remarks
V. P.	39	±	10 to 15	Very mild symptoms only

See legend of Table I for other data referable to interpretation of table.

of the undiluted serum pool 1-CSIH, the material being administered in milk. The 5 men of the third group each ingested (in milk) 20 ml. of liver suspension 1-CLIH.

Previous experience with the strain of infectious hepatitis virus (virus IH) that was used for induction of hepatitis in the three volunteers from which the present materials were obtained had shown it to be highly effective in inducing the apparent disease when administered orally but much less effective when administred parenterally. For this reason, and because of the limited number of volunteers available for these preliminary studies, only the oral route of inoculation was used.

RESULTS

The results obtained from the oral administration of the feces, liver, and serum preparations are summarized in Tables I, II, and III and are described in detail below.

Feces pool 13–14–15 FIH

J. D. (AGE 32). Eleven days after inoculation he complained of cramps in the abdomen. On the 16th day, he noted a "slight rash" associated with pruritis. As this was transient, it was not observed by a physician and a reliable description is not available. From the 20th to 28th days inclusive, he complained of nausea, headache, and general malaise. No significant physical findings were recorded during this period, and no definite evidence of hepatic disturbance was revealed by the various hepatic tests. After the 28th day, he apparently was well until the 127th day. He had been released from the isolation ward and returned to the New Jersey State Prison on the 70th day. On approximately the 122nd day, he was released from the prison and went to his home. From the 122nd to 127th days, he had little sleep and ingested moderate quantities of alcoholic beverages. On the 127th day, he noted extreme malaise. This was associated with chilly sensations and his temperature was found to be 102.8° F. (oral). He was admitted the next day (128th) to the Hospital of the University of Pennsylvania. At that time, he complained chiefly of weakness, headache, aching of the eyes on movement, anorexia, and pain in the right costovertebral angle. Examination revealed an oral temperature of 102° F., slight enlargement of the inguinal, axillary, and cervical lymph nodes, and pronounced tenderness in the right upper quadrant and right costovertebral angle. The liver and spleen were not palpable. The symptoms and findings persisted until the 132nd day after which they gradually subsided. By the 137th day, he was asymptomatic and physical examination was negative. The oral temperature varied between 99° and 101° F. on the 129th and 130th days, from normal to 100.4° F. on the 131st and 132nd days, and thereafter was normal. He was discharged from the hospital on the 137th day.

The results of the laboratory studies made during this period were as follows: The blood hemoglobin varied between 90 and 95 per cent; the total leukocyte count was 5,000 on the 128th day and 5,000 on the 131st day. The differential leukocyte count on the 131st day revealed: neutrophiles—59 per cent, lymphocytes—40 per cent, monocytes—1 per cent. Routine urinalysis consistently revealed no abnormal findings. The *hepatic* tests gave the following results suggesting the existence of mild hepatic disturbance: The Harrison spot test for urine bilirubin was constantly positive between the 128th and 139th days, the response varying from 1 to 3 +. Urine urobilinogen was somewhat increased, the maximum recorded value being 2.0 Ehrlich units in a morning 2–hour specimen. Bromsulphalein tests on the 128th, 129th, 130th and 137th days gave 30- and 45-minute values (30 minute per cent retention —45 minute per cent retention) of 7/4, 12/11, 7/4, and 4/3 respectively. The results of the total and prompt direct reacting serum bilirubin determinations, the cephalin-cholesterol flocculation, collodial gold and thymol, and the serum pro-

tein and cholesterol studies showed no significant variations from the normal.

Typhoid H and O, paratyphoid A and B, and brucella abortus agglutinations on the 126th day were negative. A heterophile antibody test (Paul-Bunnell) on the 137th day (maximal response graded 4 +) gave 2 +, 1 +, and negative reactions in the 1:32, 1:64, and higher dilutions respectively.

Although very cooperative, this subject was anxious to leave the hospital as soon as possible due to the fact that he had been released from prison just prior to onset of this illness. As he felt perfectly well by the 137th day, it was not possible to detain him for further studies after that time. Two months later, he returned for follow-up studies, having been entirely well during the interval. All hepatic tests were normal and the heterophile antibody test gave a 1 + reaction in the 1: 64 dilution, the reaction being negative in the higher dilutions.

R. A. (AGE 32). Eighteen days after inoculation, this subject complained of general malaise and moderate pain in the lumbar area of the back. Between the 19th and 22nd days, he voluntarily remained in bed and complained of malaise, backache, and anorexia. On the 23rd day, he had intermittent chilly sensations during the evening. These continued during the 24th and 25th days and were associated with nausea and one episode of vomiting. Although he then felt relatively normal until the 39th day, his oral temperature varied from 99.8° to 100.8° F. between the 34th and 37th days. From the 39th to the 41st day, he complained of persistent headache and intermittent nausea. After the 41st day, he remained asymptomatic. No significant physical findings, other than the slight elevation of temperature, were recorded. The hepatic studies revealed no definite evidence of hepatic disturbance. However, the thymol test, which had not given 30-minute turbidity readings greater than 1.5 units or 18-hour flocculation reactions greater than 1 + with numerous serum specimens obtained during the month prior to inoculation, gave turbidity readings up to 3.0 units and 2 + flocculation reactions during the period of symptoms.

G. S. (AGE 23). On the 11th day, the subject complained of slight nausea, headache, and abdominal cramps that persisted for only 24 hours. From the 20th to the 35th days, he had frequent headaches, intermittent lumbar backache, and mild to moderate anorexia and nausea. On the 25th and 30th days, he vomited several times. The only laboratory abnormality was the finding of an increased excretion of urine urobilinogen (2.0 E. U.) on the 34th day. He remained well after the 35th day.

SUBJECTS E. S. (AGE 27) AND A. M. (AGE 33). The remaining two volunteers who ingested feces pool 13-14-15 FIH experienced no significant symptoms, and no evidence of hepatic disturbance was revealed by hepatic tests during the period of observation.

Liver suspension (1–CLIH)

E. MC. (AGE 29). This subject was well until the 22nd day when, for a period of 24 hours, he reported general malaise, anorexia, nausea, and one episode of vomiting. Although he was relatively asymptomatic between the 23rd and 26th days, symptoms recurred on the 26th day, and persisted till the 29th day. During this period he complained of weakness, general malaise, anorexia, nausea, and pain in the region of the right costovertebral angle. He was relatively free from symptoms between the 29th and 36th days. However, from the 36th to the 50th day, he experienced rather severe symptoms. They included: (1) marked malaise of sufficient intensity to keep him in bed; (2) complete anorexia, severe nausea, and vomiting one or more times daily for a period of approximately 10 days; any attempt to eat solid food was followed by vomiting; (3) headache with considerable orbital pain on movement of the eyes; (4) pain in the right upper quadrant that at times was of sufficient severity to require morphine. He was given daily intravenous infusions of glucose and saline during this period. No significant temperature elevations were recorded until the 48th day when the oral temperature was 100° F. It fluctuated between 98° and 100° F. on the 48th and 49th days. About 2 hours after a plasma transfusion on the 50th day, he had a chill and, during the next few hours, his temperature gradually rose to a maximum of 107° F. (rectal). The significance of the fever noted on the 48th and 49th days is uncertain as he had received glucose and saline infusions on these days. That of the 50th day appeared to be the result of

a plasma reaction. With the subsidence of this reaction, all of his symptoms diminished rapidly and he felt relatively normal by the 65th day.

Physical examination throughout the period of severe symptoms (36th to 50th days) revealed marked tenderness in the right upper quadrant. The liver was enlarged and quite tender. With inspiration, the edge of the liver was easily palpable 3 to 4 cm. below the costal margin. After subsidence of the symptoms, the size of the liver decreased. The spleen was not palpable. No other significant physical abnormalities were detected.

The several blood counts (hemoglobin, total and differential leukocyte counts) made during the period of acute symptoms revealed no significant abnormalities. Hepatic tests revealed no significant abnormalities until the 49th day when the urine gave a positive reaction for urobilinogen in a dilution of 1 to 30 and bromsulphalein retention was 10 per cent at 30 minutes and 3 per cent at 45 minutes.[4] The following day the 30- and 45-minute retentions were 40 and 30 per cent respectively. The urine was positive for urobilinogen in dilutions of 1 to 100 and 1 to 150 on the 50th and 51st days. On the 55th day, difficulty was encountered in obtaining a 30-minute blood specimen for the bromsulphalein test. A specimen obtained at 41 minutes revealed 8 per cent retention. The other hepatic tests revealed no significant abnormalities and thereafter all results were within normal limits. The abnormalities mentioned are of doubtful significance in respect to his illness because of their relationship to the reactions from the intravenous infusions. Roentgenological examination of the gastrointestinal tract on the 57th day revealed no abnormal findings.

T. K. (AGE 21). Between the 26th and 30th days after inoculation, he complained of malaise, mild anorexia, nausea, one episode of vomiting, and headache. These subsided by the 30th day and he remained well thereafter. There were no abnormal temperature elevations.

The hepatic tests during this period revealed a maximum total serum bilirubin of 1.7 mgm. per 100 ml. (pre-inoculation maximum 1.2 mgm.), a delayed direct qualitative van den Bergh reaction, a maximum thymol turbidity of 4.0 units (maximum pre-inoculation reading—2.5 units), and a maximum 2-hour urine urobilinogen concentration of 6.0 Ehrlich units (maximum pre-inoculation 1.6) with a positive reaction also being obtained in a urine dilution of 1 to 200.

J. M. (AGE 34). This subject had no significant symptoms or laboratory manifestations of hepatic disturbance following inoculation.

M. P. (AGE 28). Between the 28th and 51st days following inoculation, he complained of malaise and intermittent rather severe headaches. No other significant symptoms or laboratory manifestations suggestive of hepatic disturbance were present.

P. S. (AGE 34). Fifteen days after inoculation a pruritic rash, slight headache, and an elevation of oral temperature to 100° F. were experienced. No adequate description of the rash is available as it was observed only by the attending nurse and disappeared in 24 hours before he was seen by a physician. From the 21st to 26th days he was nauseated intermittently, vomited on two occasions, and his appetite was moderately diminished. He then was relatively asymptomatic until the 39th day when anorexia, abdominal cramps, and headache were present and persisted for approximately 2 days. He again was free from symptoms until the 59th day when, for a 24-hour period, he had anorexia, nausea, and one episode of vomiting. Thereafter he remained well. No significant laboratory evidences suggestive of hepatic disturbance were detected at any time.

Serum pool (1–CSIH)

None of the 5 men who ingested this serum (V. R., age 39; E. S., 31; W. H., 32; L. S., 29; A. W., 20) developed significant laboratory evidence suggestive of hepatic disturbance following their inoculation. One (V. P.) complained of slight nausea and mild headache between the 10th and 15th days. Another (E. S.) between the 14th and 26th days, had malaise, and intermittent mild nausea and headache. The symptoms in both were not sufficient to interfere with their voluntary continuance of their usual activities.

[4] With 7 previous bromsulphalein tests performed during the preceding 2 months, retention at 30 and 45 minutes was never greater than trace and O respectively.

DISCUSSION

The results of the present studies permit no definite conclusions concerning the presence of a hepatitis virus in the serum, feces, and liver preparations. Nevertheless, four of the five men who ingested the liver suspension and three of the five who ingested the feces preparation developed illnesses, of mild to moderate severity, after intervals corresponding to the usual incubation period of infectious hepatitis. The symptoms of subject E. McE. (liver suspension) were typical of infectious hepatitis of moderate severity and were associated with enlargement and tenderness of the liver. The only definite laboratory evidence of hepatic disturbance in this subject was observed late in the course of the illness. This was quite transient and could be explained entirely on the basis of febrile reactions that followed intravenous glucose, saline, and plasma. Except for the lack of laboratory evidence of hepatic disturbance, his illness clinically was typical of infectious hepatitis without jaundice.

The symptoms and physical findings in volunteer J. D. (feces preparation) beginning 127 days after inoculation also were typical of mild infectious hepatitis without jaundice. Liver tenderness and laboratory evidence of mild hepatic disturbance were present. This illness began after a period of unaccustomed physical activity, inadequate rest, and ingestion of considerable amounts of alcohol, all following his release after a number of years in prison. Although the possibility that this illness was coincidental and unrelated to the experiment obviously cannot be excluded, it also is quite possible that his symptoms beginning on the 20th day were the result of the hepatitis virus and that his resistance was sufficient to protect him until it was lowered by the activities following his release from the prison. Such activities have been related to an increased incidence of relapse in infectious hepatitis.

The illnesses of the other men were mild. The symptoms and the interval between inoculation and their onset were similar to the symptoms and incubation period of infectious hepatitis. However, evidences of hepatic disturbance either were absent or minimal. In other volunteers with symptoms of comparable and even less severity due to hepatitis resulting from inoculation with this strain of virus, as obtained from acute cases, the illness usually has been associated with fever, and hepatic tests consistently have revealed evidence of marked hepatic disturbance. If these illnesses are considered to be due to a hepatitis virus in the materials obtained from the volunteers with chronic hepatitis, the difference in the manifestations observed in these volunteers from those observed in others inoculated with materials from acute cases must be explained. Some change in the virus itself, a difference in the resistance of the volunteers used, or both possibly could account for the difference. Unfortunately, the volunteers available at the time of the present experiment did not include persons in the age groups most susceptible to the strain of virus concerned. Previous studies (2) have shown that the age range of greatest susceptibility to this strain of virus was from 6 to 25, the incidence in exposed persons over this age being much lower. Furthermore, with the more marked decrease in incidence observed after the age of 30, the incidence of hepatitis without jaundice in those over this age who acquired the disease increased from 26 per cent in the 10 to 30 age group to 66 per cent of those over 30. Of the 15 volunteers available for the present study, only 3 (1 in each group of five) were under 25, 4 were between 25 and 30, and 8 were over 30 years of age. It is possible, therefore that the illness observed in these volunteers represented the response of relatively resistant hosts to the hepatitis virus. On the other hand, it also is possible that, in the volunteers with chronic non-icteric hepatitis, some modification of the virus had occurred. However, lacking any specific serological or other test for the hepatitis virus, conclusions regarding the significance of the present results must be deferred. It is hoped that additional volunteers will become available for further tests of the materials used in the present study and of materials obtained from the present subjects during their etiologically obscure illnesses. In addition to the possible influence of factors mentioned above, the failure of serum pool 1-CSIH to produce any significant manifestations suggesting the presence of the hepatitis virus also could have been due either to the absence of the virus in the pool or to the presence, in some of the specimens, of neutralizing substances which inactivated the virus. Thus, the

negative results with this serum pool do not necessarily indicate that the virus was absent from all of the individual specimens.

SUMMARY AND CONCLUSIONS

Serum and feces specimens and liver tissue (biopsy) were obtained from 3 subjects who had persistent symptoms and other evidence of continued hepatic disturbance (chronic nonicteric hepatitis) following acute hepatitis that had been induced by oral inoculation with a known strain of "infectious hepatitis" virus. In an attempt to clarify the relationship of the hepatitis virus to the persistent symptoms and continued hepatic disturbance, volunteers were inoculated orally with materials collected from 3 to 12 months after the onset of the disease. Following ingestion of the feces preparation, 3 of the 5 volunteers developed mild illnesses after 18 to 20 days. Likewise, 4 of the 5 volunteers developed illnesses of mild to moderate severity 15 to 36 days after ingestion of a suspension of the liver tissue. None of the 5 volunteers who ingested the serum pool developed significant illness during a 5-month period of observation. The symptoms and manifestations of those who became ill included two or more of the following: malaise, headache, anorexia, nausea, vomiting, abdominal cramps, and pain in the right upper quadrant. Two presented tenderness in the liver area and, in one of these, the liver became moderately enlarged.

In spite of moderately severe symptoms in two of the cases, laboratory evidences of hepatic disturbance in all cases either were absent or minimal. None developed overt jaundice. The intervals between inoculation and onset and the clinical manifestations were compatible with mild infectious hepatitis without jaundice, particularly in two of the cases. The laboratory evidences of hepatic disturbance usually associated with mild hepatitis, however, were not present. Although no other explanation for the illnesses is apparent, their exact nature and their relationship to the materials used for inoculation are uncertain. Factors of possible importance in interpretation of the results are discussed.

ACKNOWLEDGMENT

The authors wish to express their appreciation and gratitude for the contribution of those inmates of the New Jersey State Prison, Trenton, N. J., who volunteered as subjects for the investigation. The assistance and cooperation of the administrative staffs of the Department of Institutions and Agencies, State of New Jersey, the New Jersey State Prison, and the New Jersey State Hospital, Trenton, N. J., also are gratefully acknowledged as is the technical assistance of Mr. and Mrs. Charles Ming and Mr. Ewing Joiner in the conduct of the laboratory studies.

BLOOD LACTATE RESPONSE DURING MODERATE EXERCISE IN NEUROCIRCULATORY ASTHENIA, ANXIETY NEUROSIS, OR EFFORT SYNDROME [1]

By MANDEL E. COHEN, FRANK CONSOLAZIO, AND ROBERT E. JOHNSON

(From the Medical and Psychiatric Clinics and Cardiac Research Laboratory of the Massachusetts General Hospital; the Departments of Medicine and Diseases of the Nervous System, Harvard Medical School; and the Fatigue Laboratory, Harvard Graduate School of Business Administration)

(Received for publication November 23, 1946)

INTRODUCTION

It has been amply demonstrated that the concentration of blood lactate rises during moderate exercises (1). It was therefore of interest to study the response of blood lactate in men with neurocirculatory asthenia (N.C.A.), anxiety neurosis, or effort syndrome to a standard amount of moderate exercise. Studies have been made on blood lactate response in patients with effort syndrome (2). In those studies, however, the patients exercised a lesser amount than did the control subjects, thereby rendering the blood lactate results difficult of interpretation. Two types of work experiments must be differentiated. The first is that in which the patient is asked to perform until exhaustion. In this type of experiment, it is of interest that one subject may perform longer than another. Physiologic data from this type of study are difficult to compare with those of control subjects since time of exercise is not comparable (3, 4). This type of experiment is subject to considerations of the subjects' willingness to perform, "true ability" to perform, persistence, and similar factors which are as yet difficult to quantitate.

Another type of work experiment is the moderate exercise test. The task is set at a level where the work can be finished both by the patient and the control subject. This study reports tests of this second kind. By using a standard amount of work which both the patient and control subject finish it is possible to compare response of one group of patients with a control group.

[1] The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts General Hospital. Responsible Investigators: Paul D. White and Stanley Cobb.

METHOD

Patients selected were men in the armed forces in whom a diagnosis of neurocirculatory asthenia had been made (5). Forty-two patients with chronic neurocirculatory asthenia and 19 patients with acute neurocirculatory asthenia were studied, along with 41 healthy control subjects. On grounds of history alone, two groups of patients were differentiated. Those who had a lifelong course of the condition or who could never do hard work or athletics were designated "chronic neurocirculatory asthenia," while those who gave convincing evidence of good health, ability to do muscular work or athletics, and nervous stability previous to the onset of the illness were designated "acute neurocirculatory asthenia." The control subjects were soldiers who had been through basic training and were in a good state of health. These studies were done as part of a general study of work in neurocirculatory asthenia. A half-hour rest period is followed by a 15-minute walk on a treadmill, which is set at 3.5 miles per hour, and 8.9 per cent grade. The work output in this test is 1.17 large calories per kilo and hour (81.90 large calories per hour for a 70-kilo man). Specimens of finger blood are collected during the ninth minute of the walk, blood being taken from the finger of the dependent hand into a heparinized watch glass. Care is taken to avoid contaminating the blood with alcohol or any other substance which might interfere with the accurate estimation of blood lactate. The determinations were done in duplicate for lactate concentration by the method of Edwards (6). The values recorded here are the mean for duplicate determinations which checked within 3 milligrams. In some cases respiratory studies (ventilation and O_2 consumption) were done from the ninth to the fourteenth minute of the walk. The walk is concluded at the end of 15 minutes. Patient is given a short rest and then allowed to run on the treadmill to exhaustion. The results of the run will not be reported on or discussed in detail in this paper (7).

RESULTS

All patients reported here finished the full walk. Results of blood lactate concentration determinations in the patients are presented in Figure 1 which shows that patients' average is higher than

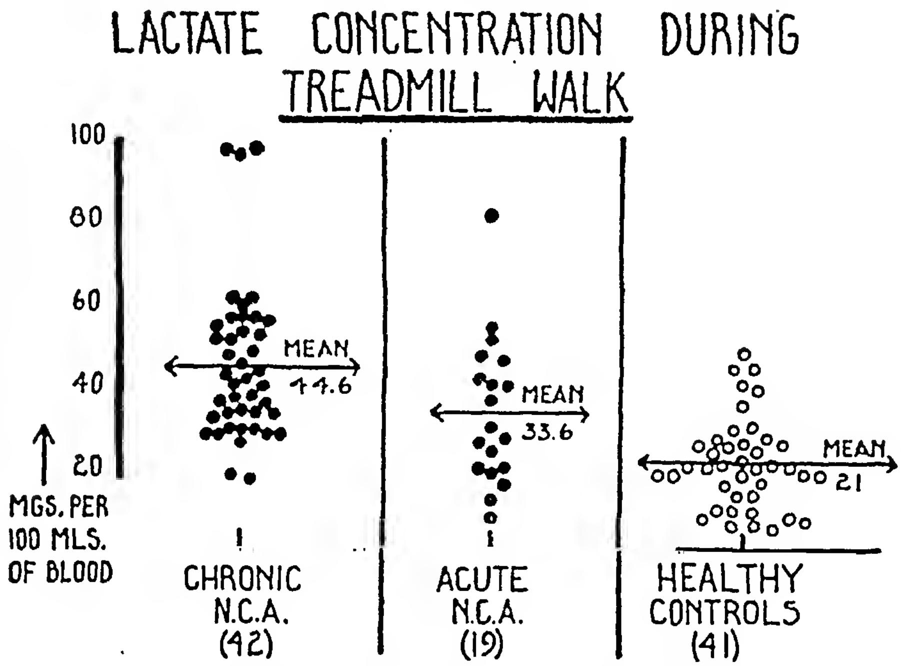

FIG. 1. DATA FOR BLOOD LACTATE CONCENTRATION DURING TREADMILL WALK

Each dot or circle represents average of duplicate determinations from first test in each subject. The patients show significantly higher blood lactate concentration as compared with controls. The chronic N.C.A. patients show significantly higher levels of blood lactate concentration as compared with acute N.C.A.

that of healthy control subjects. The men with acute neurocirculatory asthenia do not average so high as do the men with chronic neurocirculatory asthenia. The differences between these groups are statistically significant as is shown in Table I. The mean blood lactate concentration for all 61 N.C.A. patients is 41.2 mgm. per 100 ml. of blood. This differs markedly from the controls with a significance ratio of the difference being 7.02.

TABLE I

Summary of averages, statistical calculations, and significances of differences in lactate results in walking

	Healthy control subjects	Acute N.C.A.	Chronic N.C.A.
Number of cases	41	19	42
Mean	21.3	33.6	44.6
Coefficient of variation	.51	.53	.42
Standard deviation	10.86	17.86	18.52
Standard error	1.70	4.10	2.86
Standard error of the difference between means:			
Healthy		4.44	3.32
Acutes	4.44		5.00
Chronics	3.32	5.00	
Significance ratio: Difference of means/standard error of the difference between means:			
Healthy		2.79	7.02
Acutes	2.79		2.20
Chronics	7.02	2.20	

Odds against the occurrence of a deviation as great or greater than the designated number of Standard Errors:
Healthy to acutes—180 to 1. Acutes to chronics—35 to 1. Chronics to healthy—400,000,000,000 to 1.

Table II shows the resting blood lactate values along with the values obtained during walking for each subject. The resting values for the controls and the patients are the same despite the fact that the walking values are higher for the patients.

There is no correlation in individual cases between resting and walking values of blood lactate concentration in N.C.A. or controls (Correlation Coefficients, chronic N.C.A., .25; healthy, .18).

Table III shows that replicate determinations, from successive walk studies in patients with N.C.A., give consistent results, the difference in means of the two groups being less than one mgm. per 100 ml. of blood.

DISCUSSION AND SPECULATION

These data show that during standard moderate exercise blood lactate concentration in patients is greater than that of healthy control soldiers. Similarly, poorly trained subjects (8), normal women (9), and elderly men (1) show high blood lactate concentration during treadmill walking. These patients had spent some time in the hospital and were not in active training. Most of them had been through basic training in service. Whether these results merely reflect poor state of training cannot be ascertained from these data.

TABLE III

Blood lactate during successive walks on different days in patients with neurocirculatory asthenia

Case	First walk	Second walk	Difference

No.	13	13	13
Mean	39.2	38.6	− 0.9

An attempt to train some of these men was unsuccessful as the men did not train properly (4). This left open the question as to whether training would bring this abnormality in blood lactate concentration to normal levels. Methyl testosterone, administered because of similarities in some aspects of the physiology of N.C.A. with that of women and older men, did not increase physical fitness test scores in N.C.A., nor did intravenous administration of cytochrome C change the blood lactate concentration during walk significantly (7). These data do not tell whether the high blood lactate in N.C.A. during walking is due to increased formation, increased blood concentration, abnormal rate of destruction, or removal from blood.

The abnormality in blood lactate concentration during moderate work shows a clear cut difference betwen N.C.A. and healthy control subjects. It suggests that N.C.A. patients have special difficulties in doing muscular work and fits well with patients' constantly reiterated statements that they are unable to keep up in muscular work with other men.

In discussing their lactic studies, Jones and Scarisbrick (10) concluded that the patients "show very poor response to exercise as judged by the amount of work done." At the same time, however, there is no major biochemical abnormality in their response. The pH and lactate were in keeping with the amount of work done, though we have ocasionally seen a case where the rise of

lactate and pH shift is excessive for a small output of work." This inspired a medical editorial which stated (11), "The patients' bodily response to exercise does not differ in any discoverable respect from that of other subjects of their own age. . . . The level of lactic acid reached in these experiments lent no support to the view that patients with effort syndrome behave otherwise in physiologic respects to other people."

Our data are in direct contradiction to these statements. It is true, to be sure, that if N.C.A. patients perform for a shorter time than do controls their blood lactate concentration may be lower. This was true in our studies of severe work where patient's ran for a shorter time (4). However, for the same duration and amount of muscular work, whether moderate or severe (4, 7, 12), blood lactate concentration is high in N.C.A. The lower level at "exhaustion" and the higher levels for the same amount and duration of muscular work confuse some readers and may seemingly offer a contradiction. The seeming contradiction is due to the fact that in severe muscular work N.C.A. patients reach the stopping point earlier than do controls; but, for the same amount and duration of effort, blood lactate concentration is higher in N.C.A. This demonstrates that, if the patients' difficulty is, as was stated (10), simply a matter of lack of "persistence," this lack of persistence is usually associated with a chemical abnormality—that is, increased blood lactate concentration.

The exact explanation for this is not at hand. Taken with our evidence of low oxygen consumption in N.C.A. during running (7, 12), it suggests deficient aerobic metabolism and excessive oxygen debt. It is noteworthy that cytochrome C did not correct the high blood lactate during walking in N.C.A. We have no data which explain completely the exact mechanism of this abnormality in neurocirculatory asthenia.

CONCLUSIONS

1. Blood lactate concentration is significantly higher in neurocirculatory asthenia during moderate exercise than in controls.

2. The abnormality is greater in chronic N.C.A. than in acute N.C.A.

3. It cannot be stated whether state of training or other factors account for the difference.

4. A chemical abnormality has been demonstrated in neurocirculatory asthenia which fits well with patients' statements that they cannot keep up with other men in muscular work.

WATER STORAGE AND THE MOVEMENTS OF BODY FLUIDS AND CHLORIDES DURING ACUTE LIVER DISEASE

By DANIEL H. LABBY, AND CHARLES L. HOAGLAND[1]

(*From the Hospital of The Rockefeller Institute for Medical Research*)

(Received for publication December 9, 1946)

The role of the liver in directing fluid shifts in the body has never been accurately defined. The effect of hepatic disease on the water balance of the body, however, has been appreciated for many years. In evidence of this is the fact that a patient with liver disease experiences greater delay in diuresis than does a normal person after drinking large amounts of water (1). The suppression of urine that may accompany acute liver disease as well as the oliguria of cirrhosis are old clinical observations (1, 2, 3, 4, 5). The phenomenon of water storage during acute hepatic disease was suggested by Jones and Eaton (6) who pointed out that the convalescent phase of acute hepatitis was frequently initiated by diuresis which they assumed was a result of the mobilization of previously stored water. Since reasonably reliable methods exist for the measurement of individual body fluid spaces and have been applied with success to the study of other infections (7), it was thought that a systematic study of the distribution of body water during the course of acute infectious hepatitis would reveal the presence of water storage and would further serve to identify the individual fluid compartments participating. In addition, periodic measurements of separate fluid shifts during the course of the disease would give quantitative expression to the relative role played by each fluid compartment while operating under hepatic control.

In a previous communication (8) data from one typical case were presented. However, in observing the fluid alterations in a group of 14 patients with acute infectious hepatitis, the movements of body water in each case were found to follow a pattern of great similarity. It was, therefore, thought that a presentation of consolidated data from the entire study would serve to emphasize the uniformity of these phenomena.

The present study was concerned with 14 young adult males who were part of a large group of Navy personnel with acute infectious hepatitis observed at the Hospital of The Rockefeller Institute for Medical Research (9). Each patient had been previously healthy and had developed hepatitis during active naval service. Only those cases in the early acute phase of hepatitis were included in the present study. Since water and electrolyte measurements were of primary interest, it was thought advisable to study only those patients who had been able to maintain a fluid intake approximating normal and in whom diarrhea, vomiting, severe fever, and dehydration were not complicating features of the acute phase of illness. The course of disease was comparable in each patient, being of moderate severity and proceeding in each instance through uncomplicated convalescence to complete clinical healing (10).

METHODS

On admission to the hospital, each patient was placed at bed rest in the Metabolic Ward where the entire study was conducted. The diagnosis of acute infectious hepatitis was readily established after a careful medical history and physical examination, and tests of liver function served to confirm the presence of acute liver disease in each instance. A urine examination done on admission and repeated frequently during the hospital course ruled out underlying renal disease in each case. Strict control of water balance was established by measurements of fluid intake and urine output and daily determinations of body weight. No patient received additional fluid by clysis. The entire group received a diet composed of 150 grams of protein, 50 grams of fat, and sufficient carbohydrate to maintain the daily food intake between 3,000 and 3,500 calories. The total daily salt intake including the calculated intrinsic food salt was kept constantly between 9 and 10 grams.

The initial measurements of plasma volume, blood volume, and "extravascular thiocyanate space" were begun under basal conditions on the day following admission to the hospital and repeated at least every 7 days, occasionally as often as every 4 days. The simultaneous method of Gregersen and Stewart (11), based upon the plasma dilution of the dye T-1824 and the "extravascular space" dilution of sodium thiocyanate, was adapted to the Coleman Jr. spectrophotometer. The selectivity of this instrument minimized the theoretical effect of the inter-

[1] Dr. Hoagland died August 2, 1946.

ference of bilirubin and hemolysis (12) on the determination of T–1824. Dye-free samples of serum obtained before injection of T–1824 were used for control readings. Many preliminary tests on other patients with hepatitis indicated that 15 minutes was an appropriate interval for the "mixing time" of the dye in each case (13). All blood samples were obtained without the use of a tourniquet.

In the present study the "extravascular thiocyanate space" was derived by subtracting the plasma volume from the total thiocyanate space. So little change was encountered in the total red blood cell volume as expressed by the venous hematocrit (14) that small variations in the amount of red cell water were not considered of importance for these calculations (11). The total blood volume was calculated from simultaneous determinations of the plasma volume and venous hematocrit according to the formula (15):

$$\frac{\text{Plasma volume}}{(100-\text{hematocrit})}\times 100=\text{Blood volume.}$$

The measurements of all body fluid compartments were finally expressed on a per kilogram of body weight basis according to previously described standards (16). No measurements of the intracellular fluid phase were undertaken.

It had been previously determined (9) that the most reliable index of liver function during the course of acute infectious hepatitis is a combination of measurements of the total serum proteins with estimations of the albumin and globulin fractions, the plasma bilirubin level, the bromsulfalein exerction test (5 mgm. per kgm.—45-

* 5 mgm. per kgm. of body weight; 45-minute interval.
† Urine volume excreted during 4-hour period following ingestion of 1,500 ml. of water under basal conditions.

minute specimen), and the thymol turbidity reaction of the serum. These measurements and tests were performed each week and correlated with the above described body fluid measurements (Table I and Figure 3). The total plasma protein and albumin and globulin fractions were determined by a salting out procedure in which micro-digestion and Nesslerization were used (17). The plasma bilirubin method of Malloy and Evelyn (18) was adapted to the Coleman Jr. spectrophotometer, as was the bromsulfalein test (19) and the thymol turbidity reaction of the serum (20, 21). Blood chlorides were measured according to the methods of Wilson and Ball (22) on blood samples collected under oil. The same method was also applied to urine and all values were expressed as milliequivalents of chloride per liter.

In an attempt to reveal water storage and to give quantitative expression to the tendency for fluid retention, the patients under study were periodically "challenged" with a water tolerance test (23). Under basal conditions the patients drank 1,500 ml. of tap water in a 20-minute period or less and the volume of urine excreted every half hour for the first hour and every hour thereafter for a total period of 4 hours was recorded. These tests were not undertaken on the days that the body fluid compartments were measured.

RESULTS

In Table I are shown the correlated data obtained in each case during simultaneous observations on body fluids, water tolerance, tests of liver function and measurements of the hematocrit, plasma proteins, and chlorides at periodic intervals in the course of acute hepatitis.

It is apparent that all patients exhibited greater thiocyanate spaces during the acute phase of hepatitis than later in the course of convalescence. The absolute and percentile increase in each case may

be seen by reference to Table II. Although great individual variation is evident in the degree of change seen, the average expansion of this compartment over the lowest convalescent level was 24.5 ml. per kgm. of body weight which represents a 13.5 per cent increase. With the exception of case 3, the plasma and blood volumes were also expanded during this period, less in absolute amount than the thiocyanate space, but greater when considered in terms of per cent of the lowest convalescent values. Although the average increase in plasma volume was 9.3 ml. per kgm. of body weight, and the same value for blood volume was 18.9 ml. per kgm., the per cent increase in these two compartments was 23.4 per cent and 27.1 per cent, respectively. Since these two figures indicate relatively identical percentage enlargements, it is evident that expansion of both the plasma and blood volumes during the acute phase of hepatitis occurs in a symmetrical manner. The increase in total circulating red cell volume, therefore, must keep pace with the swelling plasma volume, resulting in minimal alterations in the venous hematocrit throughout the course of illness. The acute phase of infectious hepatitis in comparison to convalescence is, therefore, characterized by an increase in both total red cell volume and plasma volume [polycythemic hypervolemia (38)].

TABLE II

Tabular listing of 14 cases of acute infectious hepatitis to illustrate the absolute and percentile expansion of the thiocyanate space, plasma volume, and blood volume during the acute phase, with the lowest convalescent values as a base line

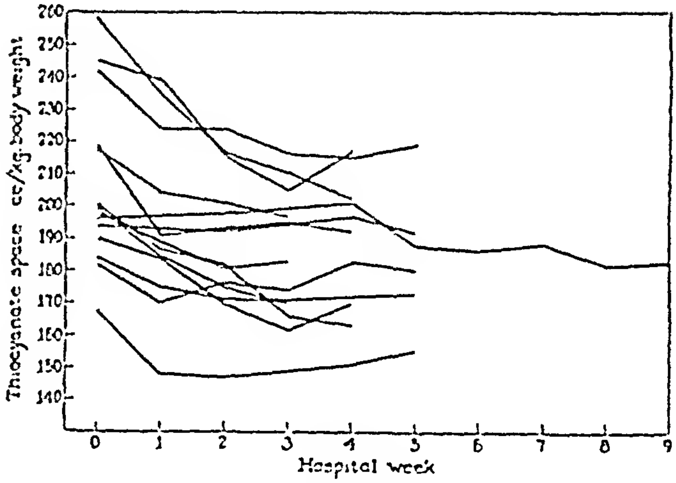

FIG. 1. ALTERATIONS IN THIOCYANATE SPACE IN 14 PATIENTS DURING THE COURSE OF ACUTE INFECTIOUS HEPATITIS

The rate of fall in the individual fluid compartments with recovery may be seen by reference to the individual columns in Table I. The composite values for the thiocyanate space throughout the course of illness are graphically represented in Figure 1. The rate of fall in this compartment was greatest during the first week of hospitalization and was usually detectable by a loss in body weight quite comparable to the amount of fluid lost by reduction in the size of this compartment. When mobilization of this fluid space occurred rapidly, a detectable diuresis appeared (Figure 3). Despite the demonstration of an expanded thiocyanate compartment in every case studied, edema and ascites were never clinically apparent.

The variable urine volume following ingested water during these periods was of particular interest. The water tolerance test previously described yielded progressively larger excretory volumes during the course of convalescence. The greatest increase in the output of urine following the 1,500 ml. drink of water occurred when the thiocyanate space was maximally contracting and was thought to indicate a decreasing tendency to retain water. The excretion patterns obtained at different periods of illness were quite distinct. An example of delayed urine output following the test dose of water given during the most acute phase of illness is illustrated in the slowly rising pattern of Figure 2A (case 10). In this instance

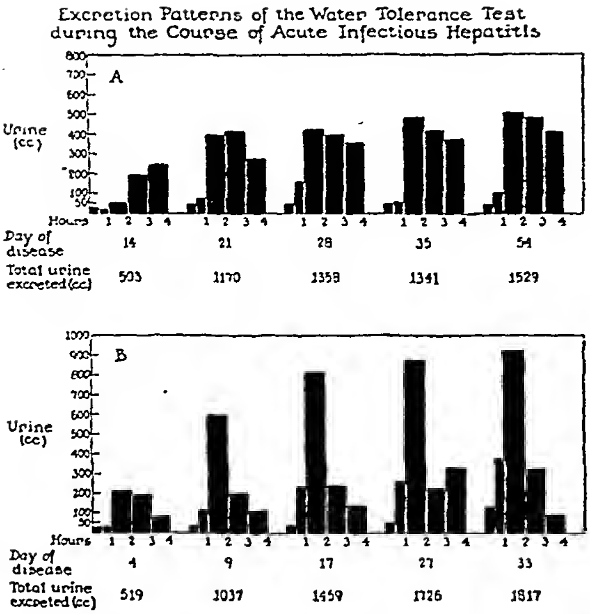

FIG. 2. EXCRETION PATTERNS OF THE WATER TOLERANCE TEST DURING THE COURSE OF ACUTE INFECTIOUS HEPATITIS

there was a step-wise increase in urine volume over the 4-hour period of observation. Later in convalescence larger amounts of urine were excreted in the earlier time periods of the test and a "shift to the left" occurred in the pattern (23). The total urine volume of the test period likewise increased with convalescence. The peak of excretion during the recovery period was usually reached in the second hour of the test. In many cases these peaks were conspicuous (Figure 2B, Case 3) and increased in size as the patient recovered. With the adjustment of the thiocyanate space to base line convalescent levels, little tendency to retain ingested water was noted as measured by the water tolerance test and almost the entire volume of ingested water was excreted within the 4-hour period and often surpassed.

Tests of liver function applied during the observations of fluid shift indicated progressive restoration of function. The extent of hepatic control over the dynamics of this shifting fluid pattern may be appreciated from the fact that the largest movements in body fluid occurred during those periods of greatest improvement in hepatic function and were most apparent during the first two weeks of hospitalization. Following this period, both hepatic function and fluid shift moved less rapidly towards stabilization.

A slight depression of plasma protein concentration was observed during the acute phase of illness that was undoubtedly due in part to the hypervolemia and in part to nutritional factors. These changes were of too little magnitude to have been influential in affecting the fluid movements described above. However, a secondary rise in plasma volume was noted in cases 2, 3, 7, 12, 13 and 14 during the second week of recovery which often approached the level of the plasma volume obtained during the early acute phase of the disease. This may have been due to the slight but inconstant rise in the total circulating albumin which occurred at this time, possibly on the basis of enhanced nutrition and improvement in albumin synthesis by the liver.

The behavior of the plasma and urine chlorides during the course of acute hepatitis was thought to be of importance because of the previous demonstration of chloride retention in cirrhosis and liver atrophy (24, 25), sodium retention in "catarrhal" jaundice (26), and disturbance in the metabolism of inorganic salts of the blood and tissue in various hepatic diseases (27). In addition, it had been shown that depressed plasma and urine chloride levels develop in animals following acute liver injury by arsphenamine (28).

On admission, the majority of patients revealed low plasma chlorides varying from 90 to 98 meq. per liter. The urine chloride concentration and total 24-hour urine chloride excretion were similarly depressed at this early period. With recovery and mobilization of the expanded thiocyanate space, the plasma chlorides rose and increasing amounts of chloride appeared in the urine. This rise could not be explained wholly by the chloride intake of the patient which was kept constantly between 9 and 10 grams daily, because it often occurred several days after the beginning of the constant salt intake. More often these adjustments awaited the contraction of the thiocyanate fluid compartment. In the presence of an increased thiocyanate compartment, as well as an increased plasma and blood volume, it was difficult to attribute the low urine volume, depressed urine chlorides, and tendency for water storage to simple dehydration (29). It was believed on the basis of these observations, therefore, that increased amounts of chloride were held in the expanded thiocyanate compartment during the acute stage of

hepatitis, in compliance with the laws of diffusion equilibria, and that with contraction of this compartment during recovery, increased quantities of chloride were mobilized and appeared in greater amounts in both plasma and urine.

Presentation of data from case 10 (Figure 3) with a description of the course of the disease will serve to correlate more clearly the movements of body fluids, the tendency to store fluid, the alterations in blood constituents, and the state of liver function during the course of acute infectious hepatitis.

F. J. E., a 34-year-old naval lieutenant commander, was admitted to the Hospital of The Rockefeller Institute on March 24, 1946, complaining of jaundice. Twelve days before admission he had developed a mild headache followed by anorexia, malaise, generalized muscular aches, and lassitude. He went to bed and felt slightly better after 3 days of rest, fluids, and a moderate food intake. During this time light tan stools were passed and 2 days later darkening of the urine appeared. By March 22, ic-

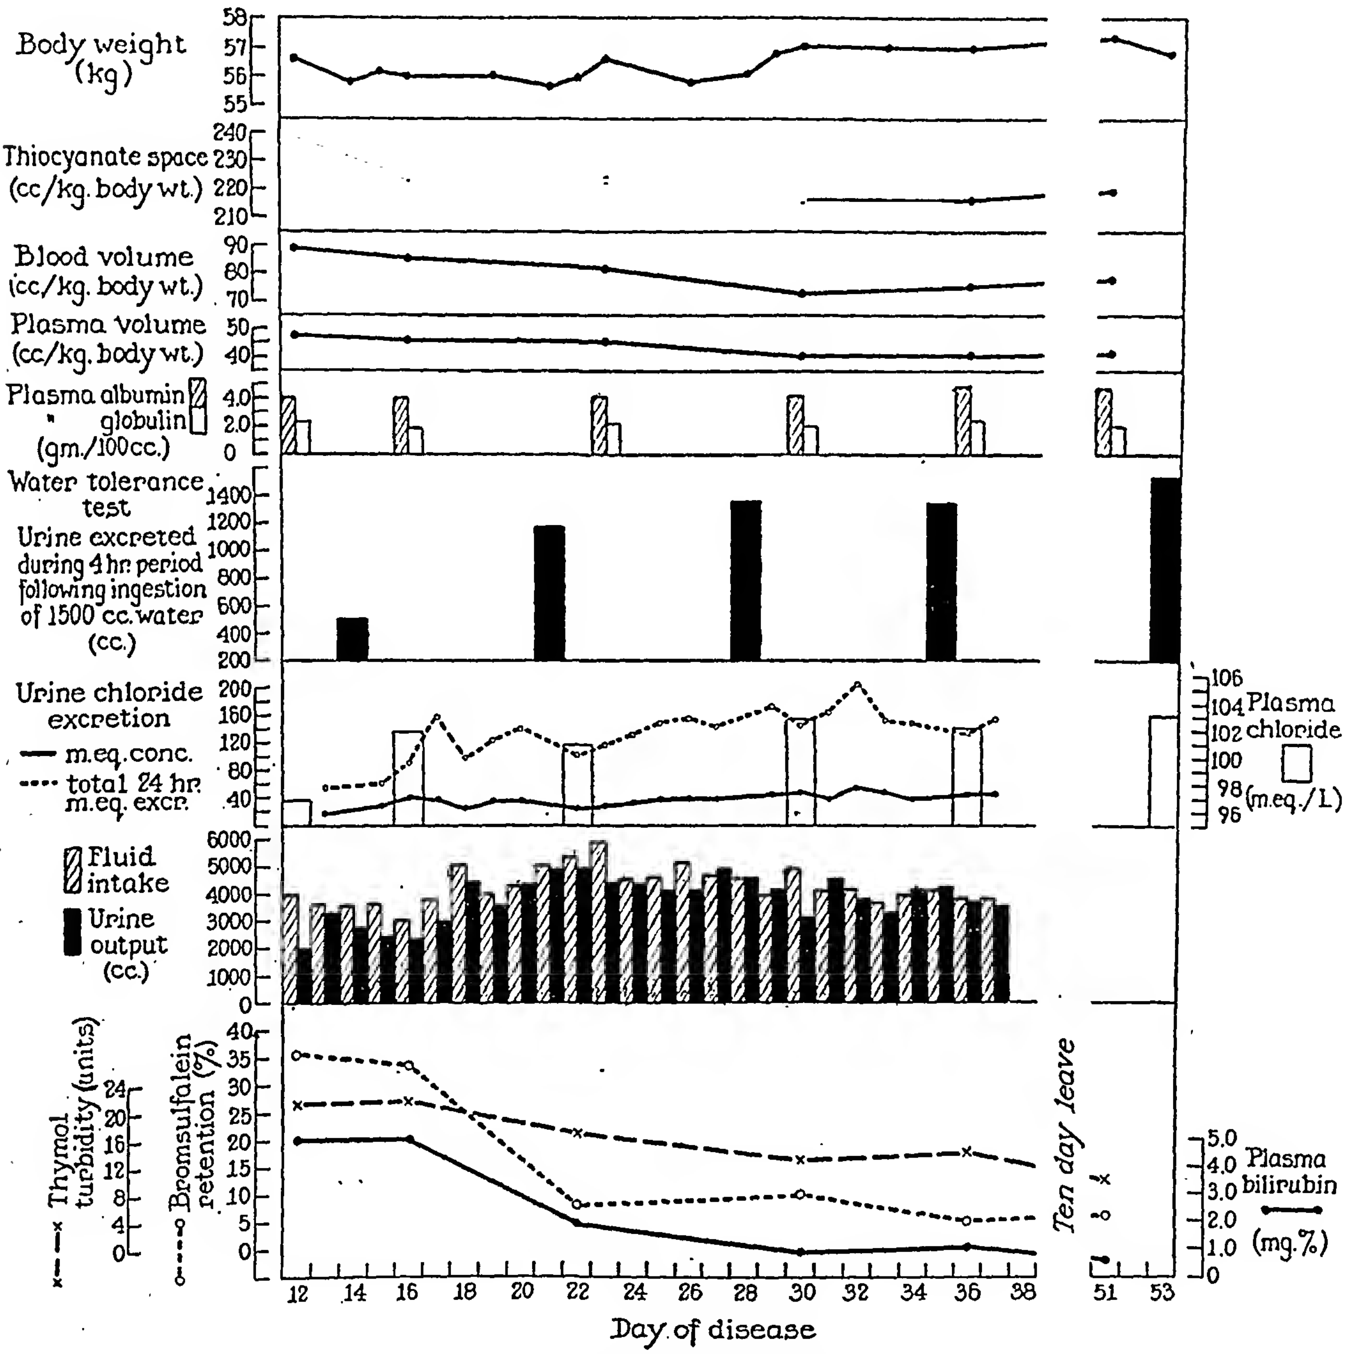

FIG. 3. THE DATA FROM CASE 10 CORRELATING THE ALTERATIONS OF THE BODY FLUID COMPARTMENTS, WATER TOLERANCE, BLOOD CONSTITUENTS, CHLORIDES AND WATER BALANCE WITH RECOVERY OF LIVER FUNCTION DURING THE COURSE OF ACUTE INFECTIOUS HEPATITIS

terus of the sclerae was noted but he was better able to eat and maintain his fluid intake. There was no history of previous illness, transfusions, inoculations or exposure to toxic chemical agents. One month before onset, however, the patient's fiancée had developed acute infectious hepatitis and was moderately ill for a period of 10 days. Physical examination of the patient on admission revealed a lean, muscular, adult male with a rectal temperature of 99.2° F.; he appeared to be moderately ill. There was marked icterus of the skin and sclerae. No rash or spider angiomata was discernible. The edge of the liver was felt 1.0 cm. below the costal margin and was tender; the tip of the spleen descended one finger's breadth below the left costal margin. There was no apparent edema or ascites. The remainder of the physical examination was negative.

Laboratory data on admission revealed a hematocrit of 46, normal blood counts, a negative urine examination, urine specific gravity 1.010, serum bilirubin of 5 mgm. per cent, bromsulfalein retention of 35.5 per cent, and a thymol turbidity reaction of 21.3 units. The total plasma proteins were 6.25 grams per cent, albumin 3.97 grams per cent and globulin 2.28 grams per cent with an A/G ratio of 1.7.

The patient was given the diet and salt intake previously prescribed for this group and careful measurements of fluid intake and urine output were begun.

The patient was completely afebrile while in the hospital. Following the institution of bed rest and adequate nutrition, recovery proceeded without complication. The urine became lighter, increased color appeared in the stool, icterus diminished and disappeared. The liver and spleen receded in size, finally becoming impalpable.

The initial measurements of the body fluid compartments were undertaken the day following admission. The first 2 hospital days were marked by a fall in body weight amounting to 0.8 kilogram. Parallel with this, the thiocyanate space contracted from 237 ml. per kgm. of body weight to 223 ml. per kgm. of body weight. This represented a contraction of 14 ml. per kgm. of body weight or a total of 784 ml. which could quite accurately account for the drop in body weight described above if this fluid volume was simultaneously excreted. A slight decline in blood and plasma volume accompanied these changes. During convalescence there was marked improvement in the tests of liver function and the final value for the thiocyanate space was 215 ml. per kgm. after recovery was complete.

In spite of a fluid intake of 3,000 ml. to 4,000 ml. from the time of admission, the urine volume remained small. In addition, the plasma and urine chloride concentrations remained low. The water tolerance test, performed on the third hospital day, yielded only 503 ml. of urine following the ingestion of 1,500 ml. of tap water. By the 17th day of illness, when marked improvement in liver function was evident, there appeared an increase in urine output which approximated 85 per cent to 90 per cent of the fluid intake for any given day. Although the salt intake had been maintained between 9 and 10 grams since admission, chlorides did not appear in the urine in increased amounts until this period of diuresis. On the 21st day of illness, 1,170 ml., or more than double the previous urine volume, was excreted during the water tolerance test. Subsequent tests showed slight increase over this value (Figure 2A). For the remainder of the period of study the daily urine volume remained at normal levels. A weight gain appeared in the mid-period of recovery which was probably a result of improvement in nutrition and liver function. By the time of discharge from the hospital the gain in body weight had been held, liver function had been adequately restored, and recovery was considered complete. In addition, a 10-day leave period had been tolerated without difficulty. The minimal fluctuations in plasma protein concentration noted during the course of illness bore no constant relation to the alterations of body fluids described above. Throughout the period of hospitalization, dehydration, edema, and ascites had never become clinically evident.

DISCUSSION

The expanded thiocyanate compartments and the relatively poor water tolerance of patients during the acute phase of infectious hepatitis substantiate the concept of Jones and Eaton (6) that increased water storage occurs during this period of the disease. It was also their suggestion that the diuresis of convalescence resulted from improved hepatic efficiency, and that this resulted in a "shift of fluid from the tissues or serous cavities to the blood stream with the ultimate establishment of diuresis." In keeping with these suggestions, the shifts of body fluid, as demonstrated by the present study with methods that offer quantitation of individual fluid compartments, reveal shrinkage of the thiocyanate compartment during recovery with an accompanying rise in urine output. The tendency to retain water during acute hepatic in-

sufficiency, as expressed by the water tolerance test, has been noted to occur in infectious hepatitis (23) as well as in acute liver injury produced by chemical substances (28, 30). In the partially hepatectomized dog, hydrothorax may develop within a few days of operation, often of sufficient amount to drown the animal (31). Ascites may also appear despite the presence of an Eck fistula. In addition, total extirpation of the liver in frogs has been shown to result in tremendous edema (32) and decreased water tolerance (33). The oliguria and anuria of yellow fever are reported to be most severe in those cases in which there is a correspondingly great amount of hepatic necrosis (34). It has been suggested that the increased retention of water resulting in hyperhydration of the body because of damage to organs such as the liver might serve a useful purpose in diluting and overcoming the harmful effects of too great a concentration of injurious substances formed during infection (35). Similar water retention phenomena have been produced by dietary liver injury as demonstrated by the experiment in which rats kept on a high fat diet when dehydrated retained more from a given quantity of water than did normally fed animals under the same conditions (36).

The expansion of the thiocyanate space during the acute phase of hepatitis, together with the enlarged plasma volume, signifies a general distension of all the extravascular spaces. The minimal change in the venous hematocrit noted throughout the course of hepatitis, despite the increased plasma volume, must indicate a symmetrical enlargement of the total red cell volume. However, the slight reticulocytosis during this period of the disease could not account for the increase in the red blood cell volume on the basis of the formation of new red cells, although extramedullary hematopoiesis has been reported in fatal cases of acute liver disease (37). A partial explanation may reside in the fact that the acutely inflamed liver fails to store blood efficiently with the result that more blood remains in the general circulation (38, 39). During the acute stage of hepatitis, wide-spread edema and necrosis occupy much of the liver substance (40, 41) which, under these circumstances, probably contains relatively less blood. In addition, sinusoidal congestion is more evident during the healing phase of hepatis. Although there is no information available relating to the hepatic blood flow and total blood contained within the liver during acute infectious hepatitis, it is not unreasonable to consider that acute inflammatory disease of the liver might shunt large amounts of blood to the general circulation. Simple hypervolemia has been reported in cirrhosis of the liver (42, 43).

A partial explanation for the maintenance of the hematocrit in the face of an expanded plasma volume might be found in the slight macrocytosis of acute hepatitis. Variations in the Mean Corpuscular Volume of from 95 cu. μ to 120 cu. μ and in the Mean Corpuscular Hemoglobin Concentration of from 28 per cent to 35 per cent, have been encountered in hepatitis (44, 45), suggesting that the red cells may be swollen during the acute phase of jaundice but gradually return to normal size with recovery of the patient.

The results of the investigations cited above have served to indicate in outline the conditions under which water retention may occur in the presence of diminished liver function, and have pointed out the possible factors believed to be responsible for the expansion of the plasma and blood volumes during acute hepatitis. There remain to be defined the forces underlying this shifting fluid pattern.

The exact role of the kidney in relation to these movements of fluid in liver disease has never been established. While the "hepato-renal" syndrome clinically suggests that disastrous disturbances in water balance may occur under combined hepatic and renal control, biochemical and metabolic studies of this state have failed to disclose what fundamental mechanisms are aberrant (46, 47).

The fluid content of the tissues has been considered to be under hepatic control by virtue of metabolic (48) and hormonal regulation (49, 50, 51). Relevant to this concept are the unconfirmed data indicating that the acute phase of hepatitis is accompanied by an increase in the urinary excretion of biologically active estrogen (52). The water-storing influence of active estrogen is well recognized and is commonly encountered in the premenstrual state when there may occur edema, swelling of the breasts, and a gain in body weight (53).

A recent report (54) indicated that the urine of patients with cirrhosis and ascites, when injected into hydrated rats, delayed the excretion of urine.

When the urine of cirrhotic patients in whom ascites had been controlled was injected, it was found to have antidiuretic activity greater than normal urine but less than urine from ascitic patients. In 6 patients with cirrhosis, re-accumulation of ascitic fluid ceased with dietary therapy and intravenous liver extract before demonstrable increase in the plasma albumin levels. This experience has been confirmed (55) and emphasizes the importance of factors other than the serum proteins that may have influence over water storage during liver disease. This has been a matter of comment in reference to the general problem of edema for many years (56).

The serum protein concentration and total circulating protein exhibited little alteration during the course of acute hepatitis in the 14 patients in the present study and bore no constant relation to the changes in plasma volume. The quantitative changes in the plasma proteins that may occur independent of alterations in the plasma volume have been reported experimentally and are to be found especially where nutritional features are of great importance (57). The results of the present work, therefore, suggest that factors other than the simple effect of the serum proteins account for water storage and decreased water tolerance during the acute phase of jaundice and the movement of water from the interstitial fluid spaces with recovery. Reference to the antidiuretic principle, therefore, seems to be pertinent. The pituitary origin of this substance has been suggested (58, 59) but requires further elucidation. Heller and Urban (60) have demonstrated that normal liver *in vitro* possesses great capacity to adsorb (inactivate) the antidiuretic principle of the posterior lobe of the pituitary when compared with blood, muscle, brain and kidney. Boiled liver tissue, however, was completely ineffective. In addition, following the intravenous injection of large doses of pituitrin, there was rapid disappearance of antidiuretic activity from the circulating blood. These experimental data suggest that the normal liver inactivates the antidiuretic principle and thereby maintains normal diuresis and body water content. In acute hepatitis it is conceivable, therefore, that with diffuse hepatic damage and depression of liver function, this inactivation is incompletely performed and water retention results. With recovery and improvement in hepatic efficiency, inactivation of the antidiuretic principle is resumed, resulting in diuresis and shrinkage of the thiocyanate space to a normal volume. Bioassays of the antidiuretic substance in the urines of patients with acute infectious hepatitis are now under way in this laboratory.

SUMMARY

1. Periodic observations of the thiocyanate space, total blood and plasma volumes were undertaken during the hospital course of 14 patients with acute infectious hepatitis under conditions of rigid water balance and correlated with measurements of plasma and urine chlorides, the tendency to retain ingested water as measured by a water tolerance test, and tests of liver function.

2. During the acute phase of hepatitis, the thiocyanate compartment and blood and plasma volumes were found to be expanded. Depressed plasma and urinary chlorides as well as an increased tendency to retain ingested water accompanied these changes.

3. With convalescence and improving liver function, shrinkage of the thiocyanate compartment and a decrease in the total blood and plasma volumes occurred. A diuresis and decreased tendency to retain ingested water were noted at this time and a rise in plasma and urinary chloride levels followed.

4. The slight alterations in total circulating protein were thought to be attributable to nutritional factors and to decreased protein synthesis during hepatitis and were not considered to be of major importance in determining these fluid shifts.

5. It is suggested that these movements in body fluids during acute infectious hepatitis may be directed by endocrine factors and related to incomplete inactivation of the antidiuretic principle by a damaged liver.[2]

[2] Recent studies by Shorr, Zweifach and Furchgott (Science, 1945, 102, 489) have indicated that a vasodepressor substance of hepatic origin (VDM) is associated with the opening up of the capillary bed during the decompensatory stage of experimental shock. More recently, in studies with Furth and Sobol, they have also been able to detect VDM in the blood of mice with granulosa cell tumors, concurrent with the development of hypervolemia in these animals (Science, 1947, 105, 41). VDM was also shown by them to appear in the blood of human beings with liver cirrhosis during periods of hepatic decompensation and in the blood and liver mash of rats with experimental hepatic cirrhosis. Finally, a

highly purified VDM concentrate, prepared from beef liver by Mazur in their laboratory, was found to exert a profound anti-diuretic effect in the normal dog on intravenous administration. These observations have led these investigators to suggest the causal relation between the hepatic vaso-depressor, VDM, and the increased blood volume and the anti-diuresis of hepatic cirrhosis and infectious hepatitis. THE DISTRIBUTION OF ASCORBIC ACID IN THE BLOOD

By JOSEPH H. ROE, CARL A. KUETHER, and RUTH G. ZIMLER

(From the Department of Biochemistry, School of Medicine, George Washington University, Washington, D. C.)

(Received for publication April 29, 1946)

In this paper we are reporting the results of a study of the distribution of ascorbic acid in the blood in human subjects and in guinea pigs.

EXPERIMENTAL

Fifty healthy medical students (47 males and 3 females) on self-selected diets and 50 patients (41 males and 9 females) in a municipal hospital were studied. Oxalated blood samples were collected under fasting conditions about 15 hours post-prandial. The ascorbic acid content of the whole blood and the plasma was determined by the method of Roe and Kuether (1). The concentration of ascorbic acid in oxalated whole blood and plasma was also determined by the same method in guinea pigs upon an apparently adequate diet (2) made up to contain different levels of ascorbic acid.

RESULTS

The results of our studies with healthy human subjects are shown graphically in Figure 1. Since all bloods were collected approximately 15 hours after food intake, the values may be considered as representing equilibrium conditions. The distribution ratio of ascorbic acid in the plasma to that in the whole blood follows a characteristic pattern. At whole blood levels below 0.6 mgm. per 100 ml., the plasma concentration was lower than the whole blood concentration in all cases. At whole blood levels ranging from 0.6 to 0.9 mgm. per 100 ml., the plasma concentration was either equal to, or slightly greater or less than, the whole blood concentration; in other words, at these levels, the plasma and whole blood concentrations approached each other very closely. At whole blood levels above 0.9 mgm. per 100 ml., the plasma concentration was higher than the whole blood concentration in all instances, except one.

The results shown in Figure 2 with 50 hospitalized patients suffering serious illness are in striking contrast to those obtained with healthy human subjects. In these patients, the ascorbic acid of the plasma was lower than that in the whole blood in all cases. The clinical diagnoses made in this group of patients were as follows: Pulmonary tuberculosis, hyperthyroidism, syphilis, glomerulonephritis, portal cirrhosis, hepatitis, diabetes mellitus, carcinoma, pernicious anemia with cellulitis, cystitis, pyelonephritis, duodenal ulcer, Addison's disease, rheumatoid arthritis, and cardiovascular heart disease.

In Figure 3 is shown the relation of the level of ascorbic acid in the plasma to that in the whole blood in 52 guinea pigs fed an apparently adequate diet containing different levels of ascorbic acid. The same pattern of distribution ratio of ascorbic acid in the plasma to that in the whole blood was observed in the guinea pigs as in our healthy human subjects. The results are not so clear-cut, however. We think this was due to the fact that smaller samples of blood were collected from the guinea pigs than from the human subjects, especially the scorbutic pigs, which probably influenced the precision of the analytical data obtained.

DISCUSSION

Pijoan and Eddy (3) found the ascorbic acid content of the plasma higher than that in the whole blood in 12 normal subjects with high ascorbic acid blood levels. Heinemann reported that the concentration of ascorbic acid is consistently higher in whole blood than in plasma or serum (4, 5), in fasting subjects. Stephens and Hawley (6) observed that the concentration of ascorbic acid was higher in the plasma than in the whole blood in 12 of 19 normal subjects. With 10 normal subjects having whole blood concentrations above 0.8 mgm. per 100 ml., Butler and Cushman (7) found the concentration of ascorbic acid in the plasma higher than in the whole blood in 3 subjects, lower in 4 subjects, and the same as in the whole blood in 3 subjects. With 8 subjects having whole blood concentrations lower than 0.23 mgm. per 100 ml., Kyhos, Sevringhaus, and Hagedorn (8) found the plasma level lower than the whole blood level in all cases; and, with 9 subjects having whole blood levels above 1.17 mgm. per 100 ml., there

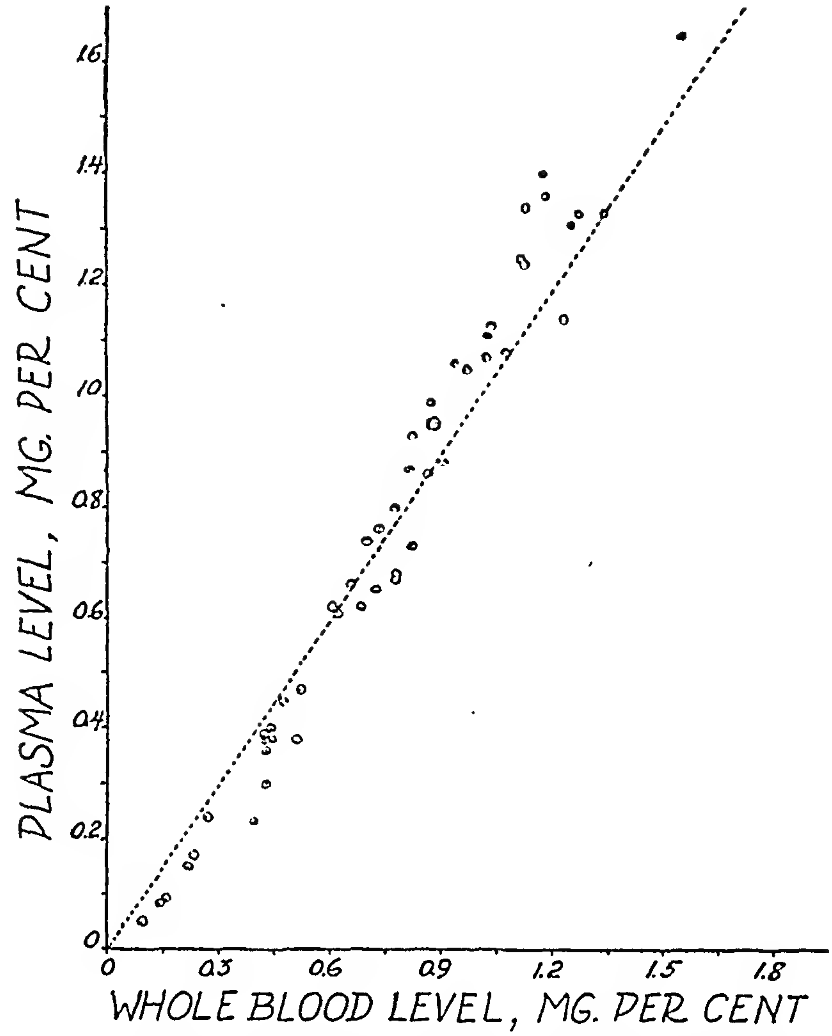

FIG. 1. THE RELATION OF THE LEVEL OF ASCORBIC ACID IN THE WHOLE BLOOD TO THAT IN THE PLASMA IN 50 HEALTHY HUMAN SUBJECTS

authors found the plasma content higher than the whole blood content in 2 instances and lower in 7 instances. Lubschez (9) made a study of whole blood and plasma concentrations of ascorbic acid in 63 subjects. She found that the majority of whole blood values were higher than the plasma values and that the relation between plasma and whole blood concentrations did not show any trend at different levels.

Our data upon subjects having high blood levels of ascorbic acid are in agreement with the work of Pijoan and Eddy (3); and our results with subjects having low blood levels agree with those data in the report of Kyhos, Sevringhaus, and Hagedorn (8) dealing with low blood levels. We are unable to explain the disagreement of our data with Heinemann's results, unless it is due to the different methods of analysis used. It is suggested that some of the opposite results in the literature may be reconciled by a recognition of the effect of the concentration of ascorbic acid in the blood upon its distribution between plasma and whole blood. It also appears desirable for data to be classified on the basis of whether the subjects are healthy or are suffering from some underlying disease that may alter the metabolism of vitamin C.

In our normal subjects the data show that the distribution of ascorbic acid between the plasma and the whole blood is related to the level of ascorbic acid in the blood. At high blood levels the plasma concentration is higher than the whole blood concentration; at intermediate blood levels the plasma and whole blood concentrations are approximately the same; and at low blood levels the plasma concentration is considerably lower than the whole blood concentration.

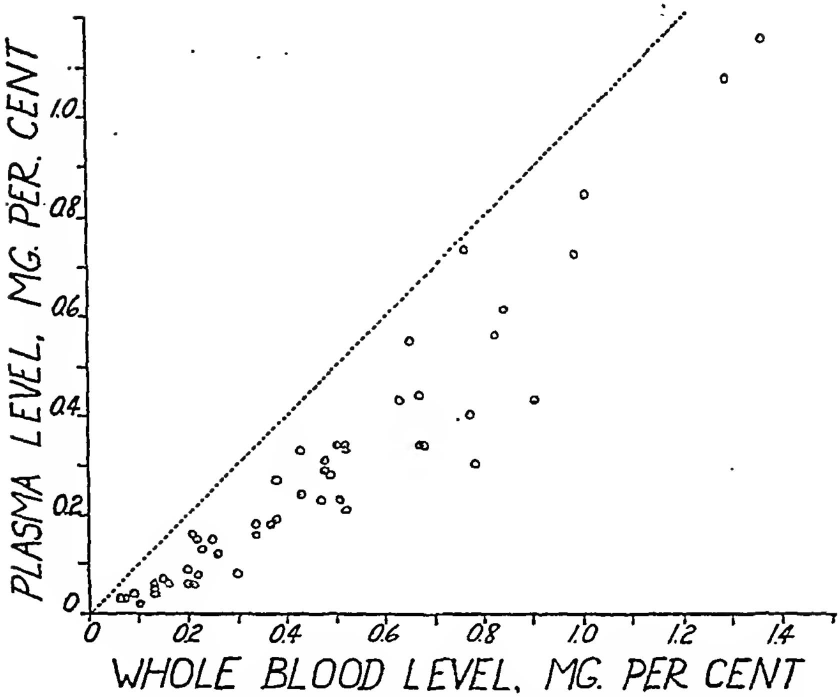

FIG. 2. THE RELATION OF THE LEVEL OF ASCORBIC ACID IN THE WHOLE BLOOD TO THAT IN THE PLASMA IN 50 PATIENTS

In guinea pigs upon the levels of ascorbic acid fed in our studies it has been observed that the concentration of ascorbic acid in the blood varies directly with the intake of this vitamin as shown in Figure 3 (2). In normal human subjects it is well-accepted that the blood level of ascorbic acid parallels the dietary intake of the vitamin up to a point where massive doses are administered (10 to 14). The unexplained effect of massive doses of ascorbic acid, observed by Wilson and Lubschez (14), was not present in our normal human subjects. In view of the evidence upon the relation of intake to the blood level of ascorbic acid and our observations upon the effect of blood level upon the distribution of ascorbic acid in blood, it is suggested that the change in the ratio of the concentration of ascorbic acid in the plasma to that in the whole blood in our normal subjects (Figures 1 and 3) was due to a parallel variation in the intake of ascorbic acid.

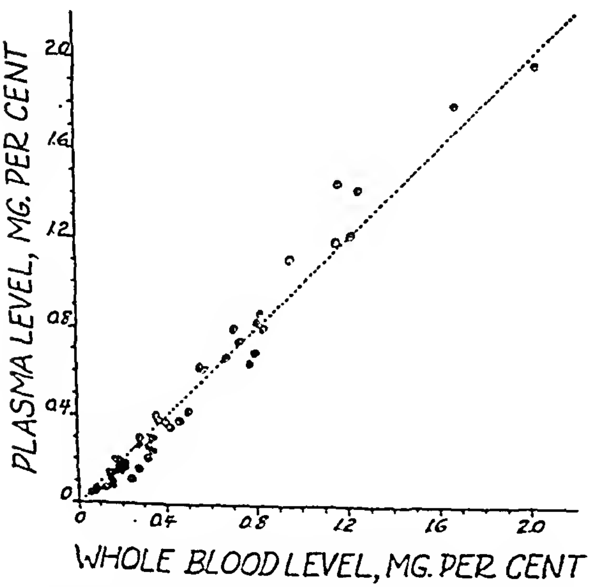

FIG. 3. THE RELATION OF THE LEVEL OF ASCORBIC ACID IN THE WHOLE BLOOD TO THAT IN THE PLASMA IN 52 GUINEA PIGS

The results of our studies with 50 patients, showing that the concentration of ascorbic acid in the plasma was lower than that in the whole blood in all instances, are of considerable interest. The concentration of the ascorbic acid in the plasma would be expected to be lower than that in the whole blood in patients with whole blood levels below 0.6 mgm. per 100 ml., since this distribution was observed in normal subjects with similar blood levels. However, the plasma con-

tent was lower than the whole blood content in 15 subjects with blood levels above 0.6 mgm. per 100 ml. Furthermore, comparison of Figure 2 with Figure 1 clearly shows that, at the same whole blood levels, the ratio of the plasma concentration to the whole blood concentration is considerably lower in the patients than in the healthy subjects. Therefore, in the patients, other factors, not in operation in the healthy subjects, contributed to the production of a concentration of ascorbic acid relatively lower in the plasma than in the whole blood. The most probable explanation of this finding is that in patients with serious illnesses there is a greater need for ascorbic acid because of the underlying pathologic processes, and this need is supplied by a more rapid withdrawal of the vitamin from the plasma than occurs in healthy subjects.

SUMMARY AND CONCLUSIONS

1. A study of the distribution of ascorbic acid in the blood in human subjects and in guinea pigs has been made.

2. In 50 fasting healthy human subjects, the following was observed: At whole blood levels of ascorbic acid below 0.6 mgm. per 100 ml., the plasma content was lower than the whole blood content; at whole blood levels about 0.6 to 0.9 mgm. per 100 ml., the concentration in the plasma was approximately the same as in the whole blood; at whole blood levels above 0.9 mgm. per 100 ml., the plasma content was higher than the whole blood content.

3. In 52 non-fasted guinea pigs the distribution of ascorbic acid between the plasma and the whole blood followed the same pattern as observed in healthy human subjects.

4. In 50 hospitalized fasting patients with various diseases, the concentration of ascorbic acid in the plasma was lower than that in the whole blood in all instances.

5. It is suggested that in normal subjects the change in the ratio of the ascorbic acid in the plasma to that in the whole blood is due to a parallel variation in the intake of ascorbic acid and that in patients both dietary intake and underlying pathologic processes operate to produce the resulting pattern of distribution of ascorbic acid in the blood.

We wish to express our thanks to Dr. S. Loube, of the Staff of the Gallinger Municipal Hospital, for selecting the clinical cases studied, and to R. W. Prichard, W. R. Strong, O. H. Christofferson, and N. Goldstein, of the George Washington University Medical School, for collecting the blood samples and laboratory data of the patients.

FACTORS CONCERNED IN THE CIRCULATORY FAILURE OF ADRENAL INSUFFICIENCY

By A. P. W. CLARKE, R. A. CLEGHORN, J. K. W. FERGUSON, and J. L. A. FOWLER

(*From the Departments of Medicine and Pharmacology, University of Toronto*)

(Received for publication July 5, 1946)

An increase in the packed cell volume of the blood is a typical finding in the crisis of adrenal insufficiency. Swingle, Vars and Parkins (1), by direct and indirect (dye method) measurements of blood and plasma volumes, demonstrated that a reduced plasma volume was the main cause of the increase in the relative volume of red cells. In a series of papers, Swingle and his coworkers (2, 3, 4, 5) postulated the importance of impairment of capillary tone and consequent increase in capillary permeability to protein as an independent factor in the causation of reduced plasma volume and of circulatory failure in crisis.

On the other hand, Loeb (6, 7) and Harrop (8, 9) focused their attention on the changes in the elimination of sodium and potassium by the kidneys and on the changes in electrolyte content of the blood and their logical consequences upon the body fluids. A net loss of sodium could cause a depletion of the plasma volume either by carrying away an equivalent volume of extracellular fluid or simultaneously causing a shift of water from the extracellular to the intracellular compartment because of the reduction in effective osmotic pressure of the extracellular fluid. A net retention of potassium might be expected to have a similar net effect, namely, a shift of fluid from the extracellular to the intracellular compartments. According to Harrison and Darrow (10), "Shifts in body fluids do not play a deciding role in the genesis of symptoms following adrenalectomy in the rat." Others, however, have found that slight hydration of muscle does occur in the rat (10) and in the dog (11, 12, 13) in adrenal insufficiency, being more pronounced in the latter animal.

If the plasma volume were diminished as a result of any or all of these aberrations in the regulation of electrolytes, it should be accompanied by a decrease in the interstitial fluid (extracellular tissue fluid). And, indeed, since interstitial fluid is considered to be a labile reservoir for the plasma volume, one might even expect a greater relative change in the interstitial volume than in the plasma volume. On the other hand, if decreased capillary tone and increased capillary permeability to protein were the only important factors in the reduction of plasma volume, the volume of interstitial fluid should show a concomitant increase. If both electrolytes and capillary factors were important and independent consequences of adrenal insufficiency, the changes in interstitial fluid might well be very variable. The interstitial fluid volume might sometimes increase and sometimes decrease. If the permeability of capillaries to protein increased as a result of changes in electrolytes, *e.g.* a change in ratio of sodium to potassium, a decrease in the interstitial fluid volume should be the rule, but it might be very variable in extent. A study of interstitial fluid volumes in adrenal insufficiency produced under different circumstances might thus throw some light on the relative importance of the various factors which have been postulated. So far, the only study of the interstitial fluid of the body as a whole in adrenal insufficiency is that of Harrop (9) on one adrenalectomized dog, which showed a striking decrease, supporting the importance of the electrolyte changes in the production of crisis.

In the present study, we have measured the plasma volume by the blue dye T 1824 and the interstitial fluid by sulfocyanate in adrenalectomized dogs during adequate maintenance with hormone and during crisis after deprivation of hormone. We have also watched for evidence of still another factor in the circulatory failure of crisis, namely, impairment of the function of the heart. Cleghorn and his coworkers have stressed the importance of cardiac failure in adrenal insufficiency in cats, in dogs, and in patients with Addison's disease (14, 15). It may occur in the absence of hemoconcentration or changes in the electrolyte pattern of the blood and quite apart from

over-treatment with desoxycorticosterone, as reported by Ferrebee *et al.* (16). Loeb (17), too, has reported cardiac failure in patients apparently not over-treated and McGavack (18) has drawn attention to the small size of the heart in Addision's disease.

A preliminary account of these experiments has been reported previously in abstract form (19).

METHODS

The following series of experiments were conducted:

Series 1. Seven adrenalectomized dogs were studied while adequately maintained with cortin (1 ml. twice daily) on a diet containing approximately 2.0 per cent NaCl. The studies were repeated on the same dogs during crisis after deprivation of cortin.

Series 2. Three of these dogs, after recovery from the experiments of Series 1, were maintained on a low salt diet (about 1.0 per cent NaCl) and larger amounts of cortical extract (4 ml. twice daily) and the studies repeated and again repeated during crisis after deprivation of hormone.

Series 3. Two dogs were maintained on cortin (2 ml. twice daily) and desoxycorticosterone acetate (1.25 mgm. once daily) with low salt diet and the same studies repeated before and during crisis after deprivation of both substances.

Plasma volumes and available fluid volumes were measured by the method of Gregersen and Stewart (20), modified for use with the Evelyn photoelectric colorimeter. Available fluid volume is defined as the volume in which sulfocyanate would be dissolved in the same concentration as in the plasma. Available fluid $(A) = Q/S$, where $Q =$ quantity of sulfocyanate injected and S its concentration in serum. This volume includes plasma volume and approximately half the red cell volume, in addition to some volume corresponding roughly to the volume of extracellular tissue fluids. The latter hypothetical entity we have called the Interstitial Volume (I.V.). It is calculated by the formula I.V. $= 0.95(A-P-.5C)$, where $P =$ plasma volume and $C =$ erythrocyte volume. No particular significance is attached in this paper to the absolute value of the Interstitial Volume as defined above. In spite of some disagreement (21, 22) as to the meaning of the apparent volume of distribution of sulfocyanate in the body, it is generally conceded that changes in its magnitude represent changes in a fluid compartment of the body in which many electrolytes diffuse rather freely. Determinations were done during the period of maintenance and after the development of severe adrenal insufficiency when loss of appetite, vomiting, weakness, or bradycardia had developed. All animals were restored by energetic therapy after the determinations in insufficiency and were used again. Blood was drawn from the jugular vein in an oiled syringe and delivered under oil. Urine was analyzed for chloride in daily specimens, for sodium in 2-day samples. The analytical methods were: sodium [Butler and Tuthill (23)], potassium [Shohl and Bennett (24)], chloride [modified Volhard Harvey (25)], non-protein nitrogen [Folin and Dennis (26)]. Packed cell volume determinations were made on heparinized blood spun to a constant volume at 3,000 r.p.m. No calculation was made for plasma trapped between the cells.

RESULTS

The observations on all 3 series of experiments are shown in Table I. Table II gives the averages of the principal findings in each series. The average plasma volume in Series I during maintenance agrees well with the average value for normal dogs (48 ml. per kgm.) (27).

In Series II the average plasma volume during

A—Control. B—Crisis.

Zn Metobolism Studied by Means of the Radioactive Isotope $_{30}Zn^{65}$. BERT L. VALLEE and REX G. FLUHARITY, Boston, Mass. (Introduced by John G. Gibson, 2nd).

External scanning with a gamma ray Geiger-Müller counter has shown that, following i.v. administration, $_{30}Zn^{65}$ becomes widely distributed throughout the entire body of the normal dog. The normal range of zinc content of organs has been determined in normal dogs by an improved dithizone method. The ranges, in completely perfused organs, in gamma per gram (wet weight), are: heart and great vessels 15–20; respiratory organs 10–20; digestive organs 10–60; genito-urinary tract 20–50; muscle 40–50; cortical bone 40–50; C.N.S. (brain) 10–15; endocrines 20–100; lymph glands 15–100; liver 50–60; spleen 10–20; marrow 60–80; plasma 2–4 (per cc.); whole blood 7–9. Simultaneous measurements of Zn^{65} and total zinc content have not shown selective localization of the element in any of the above organs.

The complete separation of white cells from blood can be effected by floatation of heparinized whole blood on an isosmotic solution of bovine serum albumin of specific gravity of approximately 1.079. The normal zinc content of white cells is 1×10^{-2} gamma and of red cells 1×10^{-4} gamma per million cells, respectively. Following the intravenous injection of Zn^{65} the isotope becomes concentrated within the circulating white cells in amounts sufficient for accurate x-ray detection in the leucocyte mass separated from 15 cc. of whole blood (1.0 to 2.0×10^{9} w.b.c.).

Blood, white cells and tissue samples are dry ashed, and the zinc extracted with dithizone for colorimetry. The zinc is removed from the dithizonate with sulfuric acid and electroplated from an alkaline solution with added carrier zinc on a copper disk. The x-ray counting procedures are similar to those used to measure Fe^{55}.

These procedures have opened the way to a study of overall zinc metabolism in addition to the physiology of leucocytes.

Late Manifestations of Epidemic Infectious Hepatitis. WADE VOLWILER and JOSEPH A. ELLIOT Boston, Mass. (Introduced by Chester M. Jones).

Accurate and complete observations on the late manifestations of epidemic infectious hepatitis are relatively rare. Needle liver biopsy and multiple laboratory tests were carried out on twelve army and civilian patients having symptoms of this disease four months to twenty-one years after the initial illness. A small group with continued mild jaundice showed normal liver histology and normal liver function tests with no evidence of a hemolytic process. Of the remaining eight, all showed definite histologic evidence of a persisting inflammatory process associated with clinical symptoms of varying severity. Abnormal physical signs and symptoms did not correlate well with the degree of observed histologic damage. Bromsulfalein excretion was the only consistently abnormal hepatic function test in this group. The sedimentation rate was usually elevated, in contrast to the normal values commonly seen in the acute phase of the disease. Flocculation tests and quantitative 24-hour urine urobilinogen determinations frequently did not reflect the histologic abnormalities. Two patients with severe laboratory hepatic functional impairment were found to have developed fibrosis in association with still active inflammation. Colored photomicrographs of biopsy specimens will be shown.

The Hemodynamics of Rapid Changes in Cardiac Output in Man. JAMES V. WARREN, New Haven, Conn., and (by invitation) EMMETT S. BRANNON and FREDERICK W. COOPER, JR., Atlanta, Ga.

Patients with large arteriovenous fistulas offer an unusual opportunity to study the hemodynamic alterations associated with rapid changes in cardiac output. Ballistocardiographic studies on fifty such patients during the recent war indicated that the resting cardiac output was often abnormally high, and on occlusion of the fistula fell to a normal value. Further observations on the nature of these circulatory alterations have been made in 14 patients utilizing the technique of right heart catheterization.

The present observations confirmed the ballistocardiographic findings. In the patients with a large stroke volume, the arteriovenous oxygen difference (determined from right heart blood) was found to be low, with blood draining the area of the fistula giving evidence of an even lower arteriovenous oxygen difference.

Although the venous pressure near the fistula and distal to it was elevated in some instances, the right atrial pressure was normal in all patients where it was studied. Although compression of the fistula produced a striking fall in cardiac output in some patients, there was no change in atrial pressure. Experimental lowering of the atrial pressure failed to produce significant change in cardiac output, thus indicating that minor undetectable changes in atrial pressure were not responsible for the changes in cardiac output.

The right ventricular and pulmonary arterial pressure were recorded in four patients during opening and closing of the fistula. Despite considerable change in cardiac output, only minimal change in pressure and pulse contour occurred.

These observations give further support to the belief that wide variations in cardiac output may occur in the absence of significant change in atrial pressure. The constancy of pulmonary arterial pressure indicates a rapid, presumably reflex, alteration in pulmonary vascular resistance associated with changes in cardiac output.

Kidney Function Studies in Adrenal Insufficiency. CHRISTINE WATERHOUSE and E. HENRY KEUTMANN, Rochester, N. Y. (introduced by William S. McCann).

The glomerular filtration rate (mannitol), renal plasma flow (PAH), and maximum tubular excretory capacity (PAH) were studied in six male and six female patients with adrenal insufficiency. Nine had Addison's Disease and three had pan-hypo-pituitarism. All were in good clinical condition at the time of study.

All female patients had markedly reduced maximum tubular excretory capacity. This function was normal in all males except two patients who had hypertension. These results suggest that maintenance of approximately

normal amounts of functioning tubular tissue occurs only in males.

The reduced tubular function in females was not corrected by desoxycorticosterone acetate, testosterone propionate, thyroid, aqueous adrenal cortex extract in large doses or pork adrenal cortex extract in oil.

The renal plasma flow was normal in two men but in all other patients it was below normal. Neither clinical nor laboratory data clarified this difference entirely but the patients with Addison's Disease receiving desoxycorticosterone acetate had a greater decrease of renal plasma flow than reduction in the ability of the tubules to excrete PAH (low ratio R.P.F/Tm). This suggests that the post glomerular arterioles are constricted by the hormone.

All patients had reduced glomerular filtration rates at all times. While this defect may be exaggerated in crisis and improvement is caused with restoration of electrolyte deficit by administration of salt, adrenal cortex extract or desoxycorticosterone, normal values are not attained.

Correlation between the Effect of Quinidine Sulfate on the Rate of the Circus Movement in Auricular Fibrillation and its Concentration in the Blood Plasma. René Wégria, New York, N. Y. (Introduced by Alexander B. Gutman).

Patients with auricular fibrillation were given orally single and repeated doses of quinidine sulfate. The concentration of the drug in the plasma and the intensity of its effect on the rate of the circus were followed.

In 7 studies in which one single dose (0.4 gm. to 0.8 gm.) of quinidine was given, the intensity of the cardiac effect of the drug and its plasma concentration were found to be grossly parallel but not parallel in a strictly quantitative manner. Indeed, discrepancies between intensity of cardiac effect and plasma concentration were found, the plasma level of the drug decreasing faster than the intensity of its cardiac effect. In 3 studies in which repeated doses (0.4 gm. every 2 hours for 3 or 4 doses) were given, there was a less marked discrepancy between plasma concentration and intensity of cardiac effect. Several possible explanations which may account for the discrepancies between the plasma level of the drug and the intensity of its cardiac effect, were investigated.

Observations on a Perfusion Method for Reducing Azotaemia in Temporary Renal Failure. Donald M. Whitlaw, Toronto, Canada (Introduced by W. Hurst Brown).

Perfusion of the peritoneum was carried out for six days in a patient with extreme oliguria of five days duration due to sulfathiazole nephrosis. Perfusion fluid was solution "A" of Abbott and Shea with added heparin, penicillin and streptomycin. Perfusion rate was 1.5 liters per hour for two days and 0.4 liters an hour for the four subsequent days. Nonprotein nitrogen was reduced from 145 mg per cent to 82 mg per cent in the first two days and maintained at that level. Carbon dioxide combining power was maintained between 18 and 21 mEq. per liter. Edema was at first reduced but later reappeared due to loss of protein in the perfusate. A total of 71.35 liters of perfusate was recovered which contained 46.4 gm. of nonprotein nitrogen and 178 gm. of protein. Concentration of nonprotein nitrogen in the perfusate averaged 70 mg. per cent and varied directly with the length of time that the fluid remained in the peritoneal cavity. Diuresis began on the second day of perfusion and reached 5.5 liters on the last day. Twenty-five days later urine output was normal. Urinary specific gravity remained fixed between 1.010 and 1.012. Urea clearance was 25 cc., nonprotein nitrogen was 42 mg per cent. No peritoneal infection occurred.

The Effects of Splanchnicectomy upon Hepatic Function and Blood Flow in Hypertensive Patients. Robert W. Wilkins, (by invitation) James W. Culbertson and Franz J. Ingelfinger, Boston, Mass.

Hepatic function and blood flow were estimated in hypertensive patients before, and again early after sympathectomy (Smithwick) by the method of Bradley *et al.* Briefly this involves the measurement of BSP concentration in serial pairs of samples of peripheral and hepatic (catheter method) venous blood, during a constant intravenous infusion of the dye. In the presence of a constant, or constantly changing, peripheral blood level of BSP calculations of total removal rate may be made. The hepatic extraction of BSP is represented by the peripheral-hepatic venous difference. Hepatic blood flow is estimated by dividing the total removal rate by the extraction.

Preoperative values for total BSP removal rate and estimated hepatic blood flow fell within the normal range. Postoperative measurements revealed a marked decrease in total removal rate of BSP, usually associated with a marked decrease in hepatic extraction. The data indicated that hepatic blood flow was markedly increased when resting blood pressure was unchanged after splanchnicectomy, whereas it was increased only slightly or not at all when blood pressure was lowered. These results suggest that sympathectomy markedly decreases the resistance to blood flow through sizable portions of the splanchnic beds draining through the liver.

The cause of the decrease in total BSP removal rate after sympathectomy is not clear, but probably is not a non-specific postoperative debility, since no decrease occurred after other major surgical procedures. Perhaps it is related to the increase in hepatic blood flow.

How Should Thyrotoxicosis Be Treated? Robert H. Williams and (by invitation) Samuel P. Asper, Jr., Walter F. Rogers, Jr., William H. Daughaday and Beverly T. Towery, Boston, Mass.

The increased availability of many effective and relatively safe antithyroid drugs and of radioactive iodine has made it necessary, in choosing the best treatment in thyrotoxicosis, to give individual consideration to the problems of each patient. As a result of treating 320 thyrotoxic patients with from 1 to 16 thiourea or aminobenzene derivatives, of following 28 individuals treated with radioactive iodine, of observing 155 patients subjected to thyroidectomy, and on the basis of the experiences reported by others, it has been possible to draw

tentative conclusions regarding the choice of therapy in this disease.

The antithyroid drugs are desirable in a large proportion of individuals because of the simplicity of administration, availability, inexpensiveness, regulability, safety, relative lack of physical or mental discomfort, and lack of damage to the thyroid gland and surrounding structures. The compounds tested clinically in this clinic are: tetramethylthiourea, diethylthiourea, thiourea, 2-thiobenzimiazoldine, aminothiazol, thiothymine, thiobarbital, thiouracil and 6-methyl-, 6-propyl-, 6-cyclopropyl-, 6-butyl-, 6-isobutyl-, thiouracil. p-Aminobenzoic acid and its 3,5-diiodo derivative, as well as 3,5-diiodo-o-aminobenzoic acid have also been used. Of these compounds, 6-propyl-, 6-cyclopropyl-, and 6-butyl- thiouracil are the ones of choice. They have a high degree of effectiveness and the complications from their use are very infrequent. The pharmacology of the derivatives of thiouracil was found to be similar to that of thiouracil, but they tend to be broken down more slowly and are concentrated more in the thyroid gland, in rats. Substituents in the 6-position of thiouracil bearing an odd number of carbon atoms (methyl, propyl and amyl derivatives) persist in the carcass in greater concentration and in the thyroid gland in less concentration than was found with ones containing an even number of carbon atoms (ethyl and butyl). The antithyroid activity of thiouracil and propylthiouracil is enhanced by the simultaneous administration of bromide, fluoride and chloride, presumably due to competitive reactions of these halides with iodine.

Radioactive iodine is quite useful in thyrotoxic patients who have large goiters, individuals who cannot or will not take prolonged therapy, and ones who have not responded satisfactorily to antithyroid drugs or to thyroidectomy. It is also useful in certain patients with carcinoma of the thyroid gland which has metastasized.

It is not necessary for a large proportion of patients to be subjected to thyroidectomy, but this procedure is desirable in certain individuals with a large thyroid gland, in ones who may likely have carcinoma of the thyroid and in the small number of subjects who cannot be satisfactorily treated otherwise.

Sustained Contraction of the Diaphragm, the Mechanism of a Common Type of Dyspnea and Precordial Pain. STEWART WOLF, New York, N. Y.

Complaints of respiratory distress characterized by inability to get a full breath were found to occur commonly among anxious individuals and among those who did not obviously display anxiety. By discussion of situational conflicts, attacks were induced in 17 subjects during flouroscopic observation. In each instance a characteristic disorder of diaphragmatic function was observed. Inspiration became jerky and the excursion of the diaphragm exceeded that in expiration. The diaphragm thus assumed a progressively lower position. When its contractile state was such that an adequate inspiratory excursion was no longer possible, dyspnea occurred with a feeling of inability to take a breath. Frequently pain in the precordium, elsewhere in the chest, and in the shoulder accompanied such sustained diaphragmatic contraction.

Three subjects had attacks accompanied by pallor, sweating, fall in blood pressure and angor animi, simulating superficially the syndrome of coronary occlusion.

In seven of the subjects occlusion of the cardiac end of the esophagus during diaphragmatic spasm was demonstrated with barium. Occasionally esophageal occlusion occurred when the increase in contractile state of the diaphragm was insufficient to impair ventilation of the lungs and cause dyspnea. Such patients also complained of difficulty in swallowing.

TABLE II

Averages

	Plasma volumes		Interstitial volumes		Decrease in absolute volumes	
	Control	Crisis	Control	Crisis	P.V.	I.V.
	ml. per kgm.	*ml. per kgm.*	*ml. per kgm.*	*ml. per kgm.*	*per cent*	
Series I	48.3	35.3	227	218	30.9	9.0
Series II	46.1	37.9	211	202	22.8	7.2
Series III	63.0	37.8	253	200	43.5	21.8

maintenance was slightly lower, while in Series III it was distinctly higher than the average for normal dogs. In crisis the plasma volume was invariably reduced. Expressed as ml. per kgm. of body weight in crisis, the average plasma volume in all 3 series is strikingly similar.

Interstitial fluid volumes (I.V.) in Series I and II were within normal limits during maintenance but higher than average for the 2 dogs receiving desoxycorticosterone (Series III). In all cases the interstitial volume was reduced in crisis but much less in relation to its original value than was the plasma volume. In some cases there was no reduction in the I.V. relative to body weight, although a small absolute decrease had occurred.

In all but 3 experiments, bradycardia developed during crisis.

In the dogs on the high salt diet, crisis occurred 11 to 13 days after stopping cortin. The dogs on low salt diets went into crisis on the third to the fifth day after stopping cortin.

Sodium and potassium levels in the serum showed the usual alterations. The total urinary excretion of electrolytes and water was followed in several animals, but control of total intake and output was hardly rigorous enough to allow us to draw definite conclusions as to the relative importance of electrolyte and water loss versus fluid redistribution within the body as contributory factors to the reduction of extracellular fluid. In the animals maintained without added salt, the increased excretion of sodium chloride and water was sufficiently great to account for most of the reduction in extracellular fluid.

In the dogs on the diet with extra sodium chloride a net loss of sodium and chloride was not obvious from the primary findings but might have occurred. On these animals, however, one striking observation was made which appears to have escaped notice heretofore. After deprivation of cortin, the intake of water and output of urine increased markedly, as if in the absence of cortin there was some hindrance to the excretion of urine with a high concentration of salt.

TABLE III

Water intake and urinary volumes and electrolytes on constant diet

A. 2.0 per cent NaCl diet—Average daily amounts for 7 days before, and 7 days after withdrawal of cortin.

DISCUSSION

The observation that interstitial fluid volumes are reduced in crisis, together with the well known fact which has been confirmed in these experiments that a high salt diet delays the onset of crisis, may be taken as evidence of the importance of electrolyte disturbances as a contributory factor in the production of crisis. Since, however, changes in the interstitial volume are variable and often slight, our results must be regarded as giving some support to Swingle's hypothesis of increased capillary permeability to protein.

In another communication we plan to present data which show that there is a considerable loss of protein, especially albumin, from the circulating plasma during the development of adrenal insufficiency. This loss must have been slow, for the concentration-time curves of the blue dye used in the determinations of blood volume did not de-

cline more rapidly in crisis than in control experiments. Our experiments contribute no evidence on the question of whether the capillary changes may be due to changes in the ratio of sodium and potassium in the plasma or are a manifestation of some effect of cortin quite independent of actions on sodium and potassium, either as to their renal excretion or distribution between intracellular or extracellular fluids.

If the average decrease in plasma volume in crisis is only about 30 per cent and the decrease in total blood volume much less (17 per cent according to our calculations), then we are forced to the conclusion that the circulatory failure of crisis must be due to something more than diminished blood volume. The extra factor may well be cardiac damage, as evidenced by the frequent occurrence of bradycardia. Dogs with intact adrenals will stand bleeding which reduces their blood volume by 45 per cent (28, 30). More recently blood volume measurements have been made by the dye method on humans in shock from burns and hemorrhage (29, 31). The reductions in blood volume compatible with recovery seem to be considerably greater than we have found in dogs in crisis. Cardiac failure would be a factor which would enhance the gravity of a modest decline in blood volume.

Evidence regarding the shift of fluid from extracellular to intracellular spaces is provided in these experiments only by changes in body weight of the animals. The loss in body weight in the 12 experiments averaged 500 grams. The estimated loss of plasma and interstitial fluid averaged 440 grams. In the 12 hours prior to crisis the animals usually ate and drank nothing. During that time the net loss of weight in the form of exhaled H_2O and CO_2 (less O_2 retained) might have amounted to 200 grams. If the decrease in extracellular fluid all represented urinary (and fecal) loss, the total weight loss should have been 640 grams. It seems permissible to postulate an average shift of about 140 grams of extracellular fluid into the intracellular space.

CONCLUSIONS

Our data on the whole support the hypothesis that in the crisis of adrenal insufficiency, loss of interstitial fluid contributes significantly to a decrease in plasma volume but does not account for all of it. Loss of protein from the plasma may also be a factor in reducing the plasma volume.

The reduction in circulating plasma volume seems insufficient to account for the circulatory failure in crisis. Cardiac failure and possibly loss of capillary tonus may contribute to the circulatory failure.

The loss of interstitial fluid seems to be mostly by renal excretion but some shift to intracellular spaces may also occur.

SUMMARY

1. In 12 experiments on 8 dogs, plasma volumes measured by the dye method in the crisis of adrenal insufficiency were about 30 per cent below normal on the average, while the total blood volume calculated from the plasma volume was only about 17 per cent below normal.

2. Interstitial fluid volumes measured by the sulfocyanate method in crisis were always reduced, but relatively much less than the plasma volumes, *viz.* about 5 per cent on the average with much variation.

3. The decrease in plasma volume may be attributed to at least 2 factors: (*a*) loss of total extracellular fluid as a result of loss of sodium and retention of potassium; (*b*) reduction in plasma proteins and consequent loss of plasma to the extravascular spaces.

4. Cardiac failure as evidenced by a high incidence of bradycardia is a more important factor in crisis than is usually recognized. It may be responsible, together with decreased capillary tone, for the severe circulatory failure associated with the apparently moderate decrease in blood volume.

5. In those experiments in which crisis after deprivation of cortin was delayed by a high salt diet, there was evidence suggesting inability of the kidneys to produce urine of high salt content.

EFFECT OF BLOOD PROTEASE AND TRYPSIN INHIBITOR ON THE CLOTTING MECHANISM [1]

By ANTHONY J. GLAZKO

(*From the Department of Biochemistry, Emory University, Georgia*)

(Received for publication August 17, 1946)

The influence of proteolytic enzymes on blood coagulation has attracted considerable attention in recent years because of the possibility of their involvement in the normal clotting process. Eagle and Harris (1) showed that certain proteolytic enzymes such as trypsin could activate prothrombin; while other enzymes such as papain could clot fibrinogen directly. Schmitz (2, 3, 4) claimed that he isolated both trypsin and a specific trypsin-inhibitor from plasma. However, more recent work indicates that the protease is not identical with trypsin, although it is quite similar in many respects (5, 6).

It has long been known that proteolytic activity appears in blood following treatment with chloroform, acetone, or certain other denaturing agents. Tagnon and others (7, 8, 9) used this technic to activate blood protease and described many of its properties. Holmberg (10) and Christensen (11) independently demonstrated that streptokinase,[2] which is itself devoid of proteolytic activity, could activate the protease in blood and thus produce digestion. Christensen also showed that the blood protease activated by streptokinase was identical with chloroform-activated serum protease (6). The inactive enzyme is located principally in globulin fraction III–2, along with considerable amounts of prothrombin (12, 13). Active protease is present in globulin fraction III–3, which is actually a sub-fraction of III–2. Fraction III–3 was used in the present experiments as a convenient source of blood protease.

A definite coagulation-inhibiting effect of crystalline pancreatic trypsin-inhibitor was demonstrated by Ferguson (14), supporting his thesis that a protease is involved in the activation of prothrombin (15). Similar results were obtained by Grob (16), who also found that serum anti-protease prepared by the method of Schmitz (4) delayed coagulation. Tagnon and Soulier (17) showed that trypsin-inhibitor isolated from soy bean flour could also inhibit coagulation. Their work has been confirmed and extended by the observations described in this paper.

METHODS AND MATERIALS

Most of the experiments described here involve changes in thrombin concentration which can be measured indirectly by means of the clotting time (18). In all cases, solutions were maintained at 38° C., and the pH was kept in the range of 7.2 to 7.6 as measured with a glass electrode. A small amount of phenyl mercuric borate was added to the reagents to prevent bacterial growth. Tests for thrombic activity were carried out by pipetting 0.5 ml. of thrombin into 1 ml. of fibrinogen solution, using 10 mm. × 75 mm. serological tubes. Clot formation was timed from the moment of addition of thrombin or, in the case of plasma, from the moment of recalcification, and the tubes were tilted once each second until the first signs of clotting were observed.

Plasma: Whole blood was collected from dogs under nembutal anaesthesia into paraffined bottles containing 1/10 volume of 3.8 per cent sodium citrate solution. The blood was centrifuged at 1,800 r.p.m. for 30 minutes, and the plasma was siphoned off and re-centrifuged in a high speed angle centrifuge. The plasma was then filtered through a sintered glass disc and kept refrigerated until used.

Buffered saline: M/100 phosphate at pH 7.4 was made up in 0.5 per cent saline.

Fibrinogen: Fibrinogen was prepared by several precipitations with quarter-saturated ammonium sulfate, the final precipitate being dried under vacuum over P_2O_5; 0.15 per cent solutions were made up in buffered saline as needed. The dry powder was stable for over 3 months when kept in the ice box. All fibrinogen solutions were routinely tested for absence of prothrombin by the addition of calcium chloride and thromboplastin.

Calcium chloride: A 1M stock solution of $CaCl_2$ was diluted to M/10 each day as required.

Thromboplastin: Dog brain washed free of blood was macerated in saline, and the extract was preserved by freezing storage. Tests were made for prothrombin by

[1] This work was supported in part by grants from the Life Insurance Medical Research Fund and the University Center in Georgia.

[2] Following the suggestion of Christensen (11), it was decided to adopt the term "streptokinase" for use throughout this paper. The earlier designation "streptococcal fibrinolysin" was based on the erroneous assumption that the fibrinolytic enzyme itself was produced in the bacterial culture.

the addition of calcium chloride; they were found to be negative.

Prothrombin: The prothrombin was prepared by the acetone precipitation method of Howell (19).

Thrombin: Unless otherwise specified, Lederle's Hemostatic Clotting Globulin diluted 1:10 with buffered saline was used as the source of thrombin.

Soy trypsin-inhibitor: A crystalline preparation of soy trypsin-inhibitor[3] was dissolved in buffered saline to give a solution containing 1 mgm. per ml. This was diluted as required.

Globulin fraction III–3: This alcohol-precipitated fraction[4] contains a protease which is unstable in aqueous solution. Therefore, the dry material was weighed out on an analytical balance and dissolved in saline just before use.

RESULTS

A. *Effect of soy trypsin-inhibitor on the clotting time of recalcified plasma*

The relation of clotting time to concentration of inhibitor was studied by recalcifying citrated plasma in the presence of excess thromboplastin and different quantities of crystalline soy trypsin-inhibitor. One milliliter dilutions of inhibitor in saline were added to 1-ml. portions of plasma, followed by the addition of 0.5 ml. thromboplastin and 0.5 ml. of M/10 calcium chloride. The results presented in Figure 1 show that the increase in clotting time is directly proportional to the concentration of inhibitor in plasma over the range of concentrations used. We have adopted this technic for the rapid assay of inhibitor in various stages of purification by comparing the effect on clotting time with that produced by standard crystalline inhibitor preparations.

B. *Absence of effect of inhibitor on the second phase of coagulation*

Various concentrations of inhibitor were made up by serial dilution in saline and added in 0.5-ml. quantities to 0.5-ml. portions of plasma and fibrinogen solutions. These mixtures were warmed to 38° C. and clotted by the addition of 0.5-ml. thrombin. The clotting times presented in Table I show no inhibitory effect whatsoever, confirming

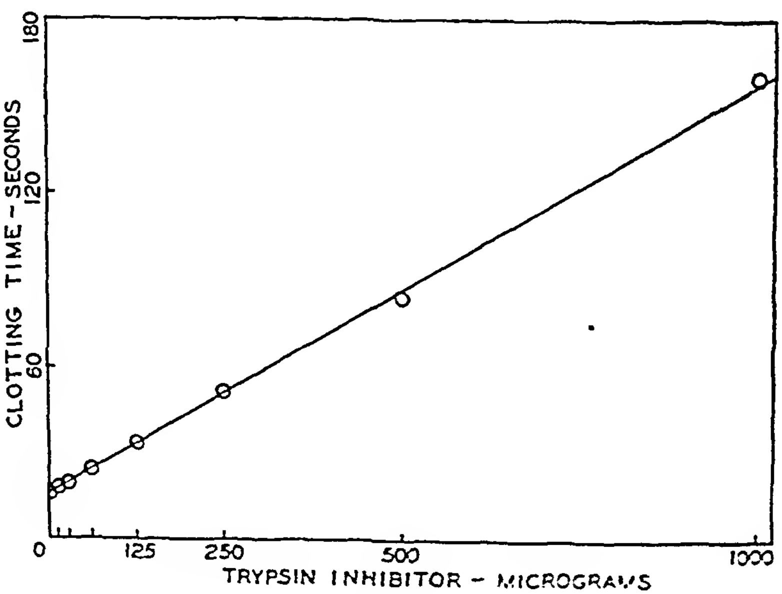

FIG. 1.

the observations of Tagnon and Soulier (17). The absence of inhibition in plasma minimizes the possibility that an albumin co-factor is required for the second-phase action of trypsin-inhibitor (14).

C. *Effect of inhibitor on the activation of prothrombin*

Our attention was next directed to the first phase of coagulation, which normally results in the formation of thrombin. Serial dilutions of inhibitor were made in 1-ml. volumes of buffered saline, and 3 ml. of prothrombin solution was added to each. The mixtures were warmed to 38° C. and activated by the addition of 0.5-ml. quantities of thromboplastin and calcium chloride solutions. After standing for different periods of time, the mixtures were tested for thrombic activity by the addition of 0.5-ml. portions to 1 ml. of fibrinogen solution. The clotting times are presented in Figure 2, from which the following observations are made:

(*a*) The minimum clotting times, indicating maximum concentrations of thrombin, were fairly uniform with low concentrations of inhibitor but showed a marked increase at higher concentrations. The activation time required for maximum thrombin formation was also greater with higher concentrations of inhibitor.

(*b*) The rate of thrombin disappearance increased markedly with higher concentrations of inhibitor. This does not necessarily mean an increased *rate* of thrombinolysis, since Glazko and Ferguson (18) demonstated that a constant rate of thrombin inactivation produced an increase in clotting time which varied inversely with thrombin concentration. The implication is that the rapid increase in clotting time is apparent only because of the small amount of thrombin formed in the presence of inhibitor. An experiment in which 200 µg. of soy inhibitor was added to 1 ml. of thrombin produced no significant changes in thrombic activity over a period of 18 hours at 38° C., showing that the presence of inhibitor *per se* had no influence on the rate of thrombin disappearance.

D. *The effect of the concentration of prothrombin and thromboplastin on the action of inhibitor*

An attempt was made to determine whether the action of trypsin-inhibitor was influenced by variations in the concentration of prothrombin and thromboplastin. Since it has been reported (7) that blood protease is inhibited by prothrombin, especially in the presence of thromboplastin, it was thought that changes in the concentration of these

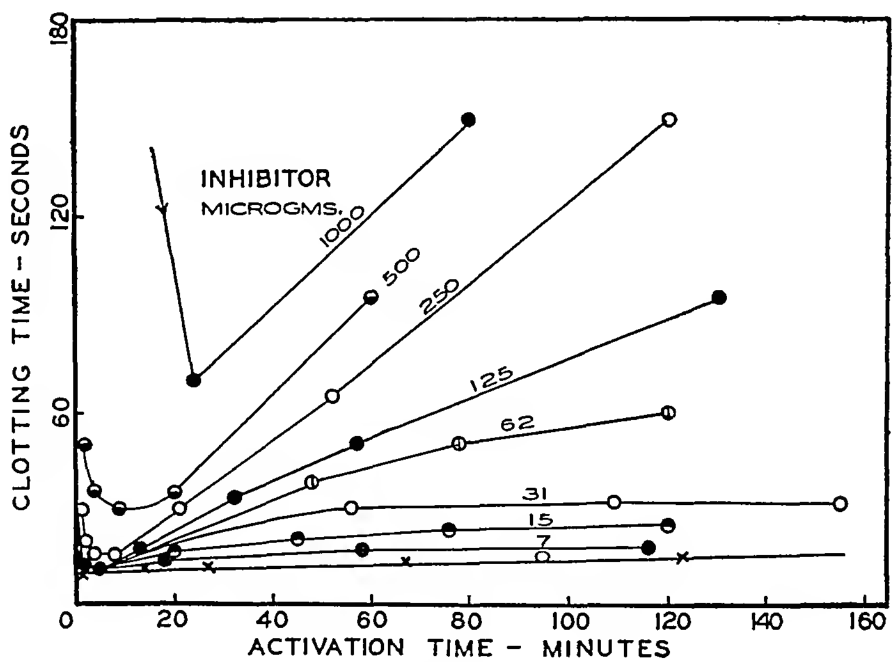

FIG. 2.

factors might produce an exaggerated effect in the presence of trypsin-inhibitor.

The clotting time of recalcified plasma was measured at 38° C. in the presence of soy inhibitor and different concentrations of thromboplastin, as shown in Table II. The range of thromboplastin

concentration extended from that of the stock preparation to a dilution of 1 in 10,000. In all cases, the presence of soy inhibitor produced about the same proportional inhibition with low concentrations as with larger amounts. The results presented in Table III show that sufficient thrombin was produced for reliable clotting tests in a maximum prothrombin dilution of only 1 : 80, under the particular experimental conditions used. The clotting times given are the minimum values observed during the activation process. Here again, the decreased concentration of prothrombin did not appear to enhance the inhibitory effect of trypsin-inhibitor.

E. *Effect of inhibitor on blood protease*

The effect of trypsin-inhibitor on blood protease was demonstrated by following the rate of casein digestion in the presence of various concentrations of inhibitor. Globulin fraction III–3 was added to 1 per cent casein (at pH 7.4) containing 0, 100, 200 and 400 μg. of soy trypsin-inhibitor. The mixtures were incubated at 38° C. and 1-ml. samples were taken at intervals for determination of acid-soluble phenols, using 6 per cent trichloracetic acid for precipitation of protein and the Heidelberger modification (20) of the Folin-Ciocalteu reaction for color development. From the results presented in Table IV it is evident that the degree of inhibition was proportional to the concentration of soy trypsin-inhibitor in the digestion mixtures. This is in agreement with the results observed with trypsin-inhibitor obtained from pancreas and from serum (4, 6, 16).

Digestion mixture: 10 ml. 1 per cent casein +4 ml. inhibitor dilution +1 ml. (=10 mgm.) globulin III–3 solution.

F. *Thrombin activity of globulin fraction III–3*

Thrombic activity was found to appear in aqueous solutions of globulin fraction III–3 in the absence of any added calcium or thromboplastin, as shown by the data in Table V. This experiment was performed in the presence of sufficient citrate to eliminate the effect of the small amount of calcium present, which was found to be about 2.5 μg. per mgm. of globulin.

It was first thought that the results were due to the direct activation of prothrombin in the globulin fraction by the protease, but similar results were also obtained in the presence of sufficient trypsin-inhibitor to stop the action of the

TABLE V

Thrombin formation by globulin fraction III-3

10 mgm. globulin was dissolved in 5 ml. saline containing 0.38 per cent sodium citrate. Thrombic activity was measured after different periods of incubation at 38° C. by the addition of 0.5 ml. to 1.0 ml. fibrinogen.

protease. Therefore, it seems likely that the appearance of thrombin in the solution was not due to the activation of prothrombin, but to some other mechanism involving the presence of pre-formed thrombin.

DISCUSSION

The experiments presented here show that crystalline soy trypsin-inhibitor interferes with the activity of the protease in globulin fraction III–3 and also inhibits the activation of prothrombin. There is a good possibility that these observations are dependent on the same process, namely inhibition of proteolytic activity. The activation of prothrombin may be dependent on the presence of active protease, although we have no proof for this as yet. There is good evidence that the protease in blood is not pancreatic trypsin (5, 6), although it is similar in many respects. Tagnon (7) has already indicated that the blood protease can activate prothrombin in the absence of calcium, but his observations have not been confirmed.

Ionic calcium and thromboplastin are unquestionably involved in the normal activation of prothrombin, but their precise functions are still unknown. It is suggested that calcium may be necessary for the activation of blood protease, just as it produces an increased yield of trypsin in the autocatalytic activation of trypsinogen (21). The protease might then function in the activation of prothrombin.

Blood protease and prothrombin are closely associated in many respects. Prothrombin has been reported to inhibit the proteolytic action of chloroform-treated plasma (7). Both prothrombin and inactive protease are present in globulin fraction III–2 (12, 13), while active thrombin and active protease are present in globulin fraction III–3 (see sections E and F). These relations are so striking that they merit further investigation. Some evidence indicates that thrombin itself is proteolytic (22), but the best preparations of thrombin made to date have no demonstrable fibrinolytic activity (23). The ultimate solution of this problem seems to depend on the preparation of pure crystalline thrombin and blood protease.

SUMMARY

1. The anticoagulant action of crystalline soy trypsin-inhibitor is due to interference with the thrombin-forming mechanism. No effects were observed on the second phase of coagulation.

2. The rate of thrombin formation and also the maximum amount of thrombin produced were diminished in the presence of inhibitor.

3. The increase in clotting time of recalcified plasma was found to be directly proportional to the concentration of inhibitor.

A STUDY OF THE DISTRIBUTION AND FATE OF ANTIMONY WHEN USED AS TARTAR EMETIC AND FUADIN IN THE TREATMENT OF AMERICAN SOLDIERS WITH SCHISTOSOMIASIS JAPONICA

By STUART W. LIPPINCOTT,[1] LESTER D. ELLERBROOK,[2] MARK RHEES,[3] AND PORTER MASON [4]

(From the Department of Pathology, University of Washington School of Medicine, Seattle)

(Received for publication August 27, 1946)

During the Leyte campaign in the Philippines a number of American soldiers were infected by the cercariae of *Schistosoma japonicum.* While under observation at Harmon General Hospital, 138 out of 495 such previously treated patients were found to be passing eggs in their stools and were, therefore, treated again either with tartar emetic or fuadin. The purpose of this report is to present data on the concentrations of antimony attained in body fluids under given dosages of these drugs, together with the amount and rate of excretion in urine and stool. Reference is also made to the therapeutic efficiency of the chemical regimes employed.

MATERIAL AND METHODS

1. *Treatment*

Patients found to have the eggs of *Schistosoma japonicum* in their stools were given in rotation, and without regard to previous treatment overseas, equivalent amounts of antimony (0.566–0.576 gram) in the form of fuadin or tartar emetic (freshly prepared or commercially prepared). One ml. of the fuadin solution contained 0.0087 gram antimony and 1 ml. of tartar emetic solution 0.0018 gram antimony. Fuadin was given by the intramuscular injection of a 6.3 per cent solution, beginning with daily doses of 1.5, 3.5, and 5.0 ml. and continuing with 5.0 ml. doses on alternate days until a total of 65 ml. had been given over a period of 25 days (33 patients). Tartar emetic was given by the intravenous injection of a 0.5 per cent solution on alternate days, beginning with doses of 8, 12, 16, and 24 ml. and continuing with 24-ml. doses until a total of 320 ml. had been given in 29 days (77 patients). Subsequently 15 patients were treated with a course of 105 ml. of fuadin (0.914 gram antimony) and 31 patients with 416 ml. of tartar emetic (0.748 gram antimony). The total number of courses of treatment was 156, but this included some patients with 2 courses of treatment. The times at which various specimens were taken are shown in appropriate tables and figures.

2. *Method of analysis*

The method of Maren (1) has been slightly modified in order to make it more sensitive and specific, and the modified method has been applied to the determination of microgram quantities of antimony in body fluids. Maren states that the blank is of the order of 0.4 microgram and that the iron in blood interferes by giving still larger blanks. The limit of the method in the absence of iron is stated to be 0.5 microgram. When 5-gram specimens of blood are analyzed, he substracts 1 microgram from the final value to compensate for the iron blank. Such a procedure seems inadvisable, especially when the quantity of antimony in the specimen being examined is itself often considerably less than the 1 microgram value being subtracted.

It has been found that the blank may be reduced by the use of chemicals of the proper degree of purity, and it may be eliminated by reading the optical density of the unknown against reagent blanks instead of against benzene. The blank produced by iron has been eliminated by precipitating the iron as ferric-ferrocyanide during the color development. The precision of the method has been further improved by developing the color rapidly at a nearly constant low temperature, by minimizing the fading of the developed color caused by sunlight, and by including specimens of known antimony content along with each lot of unknowns and calculating the unknown values accordingly.

3. *Reagents*

The reagents used were those given by Maren with the following exceptions:

a. Mallinckrodt phosphoric acid was the only one of several brands found to give low consistent blanks.

b. Potassium ferrocyanide 2 grams in 100 ml. of 0.02 per cent Rhodamine B solution.

c. Hydrochloric acid 6 N containing 1 mgm. of ferric iron per ml.

4. *Digestion*

a. Ten ml. or smaller specimens of blood, plasma, urine, or bile are digested according to Maren's directions.

[1] Lt. Colonel, MC.
[2] Major, SnC.
[3] First Lieut., SnC.
[4] Lt. Colonel, MC.

b. Stool: To 5 grams of stool are added 6 ml. of sulfuric acid and 10 ml. of nitric acid. Digestion with nitric acid is carried out in the usual way. Remove the solution from the hot plate, add 2 drops of perchloric acid and immediately put back on the hot plate, in order to eliminate spattering due to the presence of precipitated salts. The solution is cooled after the appearance of copious SO_3 fumes and is diluted with 46 ml. of water giving a 1–10 dilution containing insoluble salts (2 ml. of sulfuric acid are boiled off during the digestion). Place 1 to 5 ml. of this well-mixed dilution into a 125-ml. flask and add 3 ml. of sulfuric acid.

5. *Reduction*

Maren's procedure is used.

6. *Color development*

In order to obtain the maximum color and consistent results, it is essential to develop the color as rapidly as possible at a low temperature and to keep the colored extracts out of direct sunlight. The reagents and glassware used are kept in ice water until used. To the digest flask in an ice water bath, add 5 ml. of 6NHCl and mix. When the mixture is cold, add 2 drops of 0.02 N ceric sulfate and mix. After 2 minutes add 8 ml. of 3 N phosphoric acid and 5 ml. of 0.02 per cent Rhodamine B. Mix and pour all of the mixture into a cold 50-ml. glass-stoppered bottle containing 10 ml. of cold benzene. Shake 200 times in order to extract the red antimony-dye complex. Aspirate off the aqueous layer, decant the benzene layer into a cuvette, and centrifuge about 5 minutes. Since the optical density was proportional to the concentration only when 0 to approximately 5 micrograms of antimony were present, specimens containing more than 5 micrograms were extracted with 20 or 30 ml. of benzene instead of 10 ml., and the results obtained were corrected accordingly.

Because of the small daily variation of color intensity due to varying speeds of color development and room and water temperature, standards were prepared daily by adding known amounts of antimony to normal plasma, blood, et cetera, and carrying these through the entire procedure concurrently with the unknowns. The digestion process was included in the preparation of the standards in order to compensate for possible traces of contaminants in the large amounts of acid used and for the small loss due to spattering during the digestion (probably less than 5 per cent). Reagent blanks and plasma, blood, and other blanks were also prepared in a similar manner.

7. *Note on blood and feces*

The reduced blood digest contains a precipitate of iron salts which interferes in the subsequent color development probably by adsorbing some of the colored complex. This precipitate is dissolved by adding 6 ml. of 4.5 N sulfuric acid and boiling the mixture until SO_3 fumes begin to appear. The yellowish-green solution remains clear and becomes almost colorless on cooling, but precipitation will again occur after several hours. The iron now in solution in the blood digest interferes by giving a blank; so it must be removed in order to obtain precise results. This iron may be removed by precipitation as ferric ferrocyanide, but in the presence of less than 2 mgm. of iron, low recoveries are sometimes obtained, presumably because of adsorption of the colored complex on the semi-colloidal precipitate. In the last 2 sets of determinations, excellent results were obtained by adding enough iron to insure the development of a quickly-flocculating precipitate.

The final changes in the regular procedure when applied to blood are as follows: After reduction the iron salts are first brought into solution. The hydrochloric acid used contains 1 mgm. of ferric iron per ml. (total 5 mgm.). In order to prevent the precipitation of some of the potassium ferrocyanide by the strong acid present in the digest, this reagent is added in combination with the Rhodamine B as a 2 per cent solution. Under these conditions the precipitation is complete and almost instantaneous. Blanks to which have been added as much as 5 mgm. of iron give readings practically identical with those obtained in the absence of iron.

In stools, interference by precipitated salts in the digest was partially eliminated by adding 2 ml. of water after the reduction and heating as with the blood digest. Color was developed in the usual manner with the exception that 12 ml. of phosphoric acid were used to help prevent the precipitation of salts during the process. It is believed that any slight interference by the presence of small amounts of iron can be prevented by following the procedure used with blood.

8. *Calculations*

The optical densities are read in 19 mm. cuvettes on a Coleman Junior Spectrophotometer at a wave length of 565 mu. Reagent blanks, prepared by carrying 5 ml. of water through the entire procedure, usually gave transmittance readings of approximately 98.7 per cent against benzene at 100 per cent. The reagent blanks are set at 100 per cent, and the unknown are read against them. The plasma standards are read against the plasma blanks set at 100 per cent because of the possible presence of traces of antimony in the plasma used. The optical density of the unknown is divided by the optical density per microgram of antimony present in the standard to give the number of micrograms of antimony present in the sample.

9. *Precision of the method*

The precision of the method may be gauged by the data in Table I, in which are recorded the results of recovery experiments done in the last 4 series of determinations of the antimony concentrations of plasma, red blood cells, urine and feces made during a period of over 1 month. The mean error of the plasma recoveries in a range of 1–5 micrograms was 3 per cent. The mean error of the other recoveries was approximately 5 per cent, although the variations encountered on some of these particular days were somewhat greater than usual.

D = Average optical density per microgram of added antimony.
( ) = Number of determinations.

RESULTS

1. *Plasma concentrations*

Plasma antimony concentrations were determined at various intervals during and after treatment with both tartar emetic and fuadin. The average pre-dose 48-hour values are shown in Figure 1. At the beginning of treatment the average concentration was about 8 micrograms per liter probably as a result of previous courses of treatment. As the course of treatment progressed the plasma concentrations increased rather rapidly to about 85 micrograms per liter after 3 weeks of treatment, and then more slowly to a final concentration of approximately 100 micrograms per liter. The concentrations in the fuadin group increased more rapidly in the early stages of treatment because larger amounts of antimony were given at this time. When the 2 groups of values are compared on the basis of the total amount of antimony administered by each particular time, they are nearly identical. Apparently, equal amounts of antimony given as either tartar emetic or fuadin in approximately equal periods of time result in nearly identical equilibrium plasma antimony concentrations.

After the discontinuance of treatment both groups of plasma concentrations decreased at about the same rate. By 6 days after the final dose (4 days after the 48-hour equilibrium level had been attained) the average concentrations had decreased by about 35 per cent, at 12 days by 52 per cent, and at 28 days by 80 per cent. At 100 days after the end of treatment the average plasma concentration was still 7 micrograms per liter, nearly identical with the pre-treatment value.

The variations of the plasma, blood cell, and urine concentrations at intervals of from 15 minutes to 6 hours after administration of the first dose, the first maximum dose, and 3 other doses including the last one were studied in groups of 4 patients being treated with each drug. The results obtained are shown in Figures 2 and 3. As one would suspect, the maximum plasma concentration was found at the 15-minute interval for tartar emetic and somewhat later for fuadin. The tartar emetic values dropped rather rapidly to nearly the equilibrium levels, but the fuadin plasma concentrations dropped more slowly. The latter values were considerably greater than those of the tartar emetic group at each time interval, although by 4 hours they were approaching the equilibrium values. Apparently, tartar emetic is removed from the plasma more rapidly than is fuadin.

2. *Blood cell concentrations*

At all stages of treatment with both drugs the concentration of antimony in the blood cells was

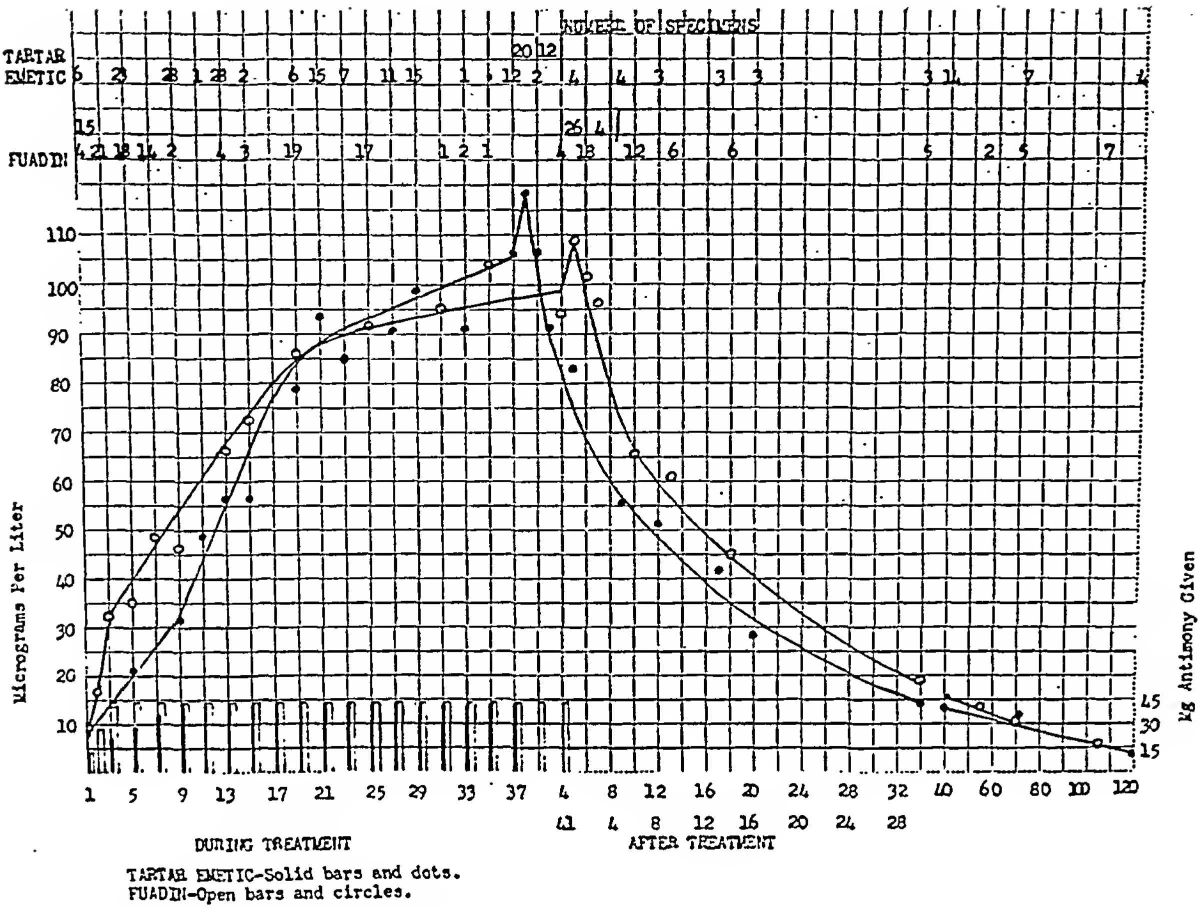

FIG. 1. AVERAGE PRE-DOSE PLASMA ANTIMONY CONCENTRATIONS DURING AND AFTER TREATMENT

definitely greater than that in the corresponding plasma, although the cell-plasma ratios varied during and after the courses of treatment. In the case of tartar emetic the pre-dose cell-plasma ratio decreased from a value of approximately 4 just before treatment to about 1.7 at the completion of treatment. The average pre-dose (48-hour) cell concentrations on various days of treatment were as follows: Day 1, 29; 5, 77; 9, 94; 13, 105; 19, 138; 27, 157; 29, 183; and 37, 195 micrograms per liter. After treatment the cell-plasma ratios again increased with the average cell concentrations being as follows: Day 2, 214; 3, 182; 6–10. 103; 39, 49; 72, 39; and 110, 47.

The pre-dose cell-plasma ratios in the fuadin group varied from about 4 on day 3 of treatment to approximately 1.8 after day 10. The pre-dose cell concentrations on various days were as follows: Day 3, 126; 5, 51; 9, 82; 13, 134; 19, 133; 25, 182; and 41, 165 micrograms per liter. After treatment the ratios again increased to about 4 at 70 days with the average cell concentrations being as follows: Day 1, 215; 2, 186; 3, 206; 6, 131; 35, 68; and 70, 45.

The variations in blood cell concentrations at short intervals after the administration of doses of the drugs were considerably different in the 2 groups. In the tartar emetic group the maximum cell concentrations at 15 minutes were 7–15 times the pre-dose levels and were 6–8 times greater than the plasma concentrations at the same times. The cell concentrations decreased by approximately 50 per cent in the ensuing 45 minutes and more slowly thereafter so that the average cell-plasma ratio at 4 hours was about 10 after the first dose and 3 at the end of treatment.

With fuadin, the cells reached their peak antimony concentrations at about the time of the maximum plasma concentrations. The cell concentrations rose somewhat higher than did those

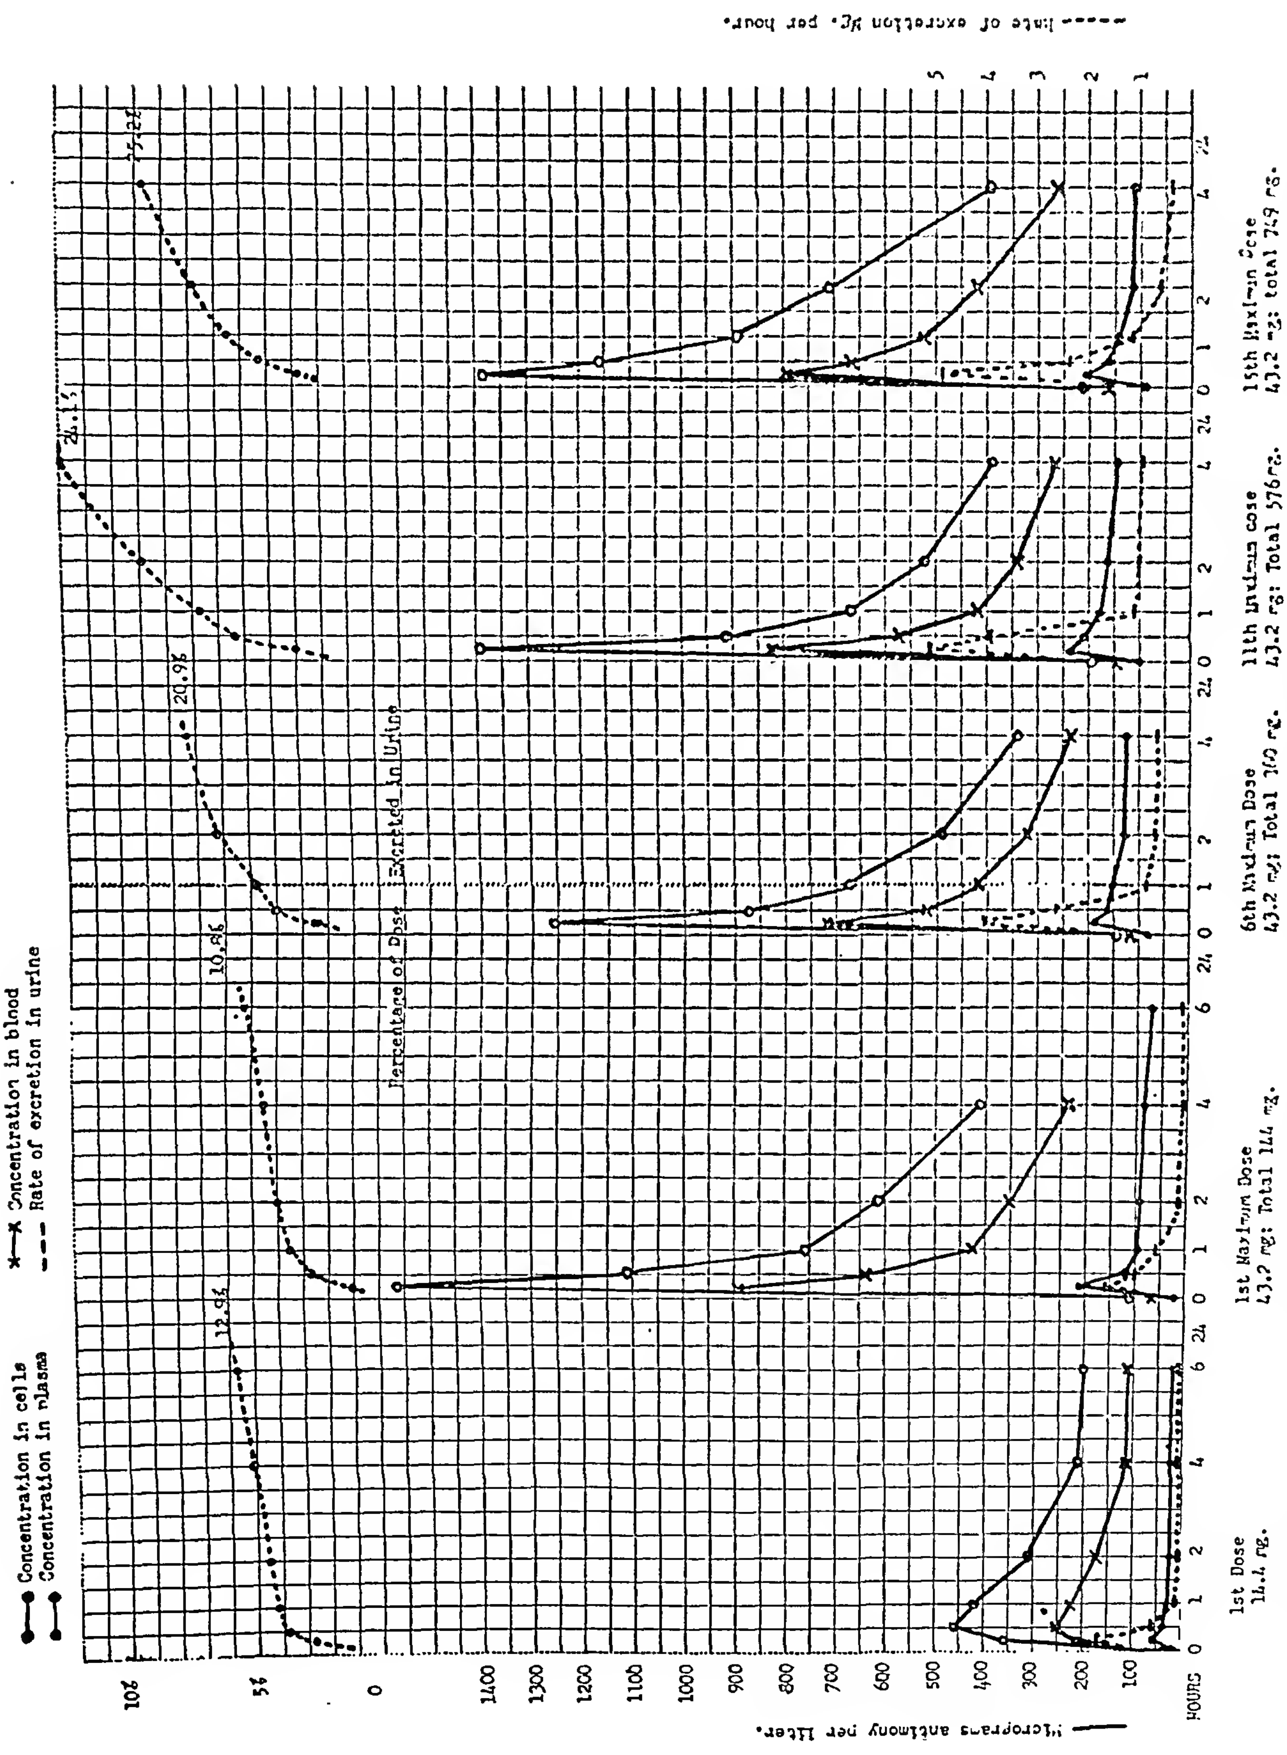

FIG. 2. DISTRIBUTION OF ANTIMONY BETWEEN BLOOD CELLS, PLASMA AND URINE AT INTERVALS AFTER THE ADMINISTRATION OF TARTAR EMETIC

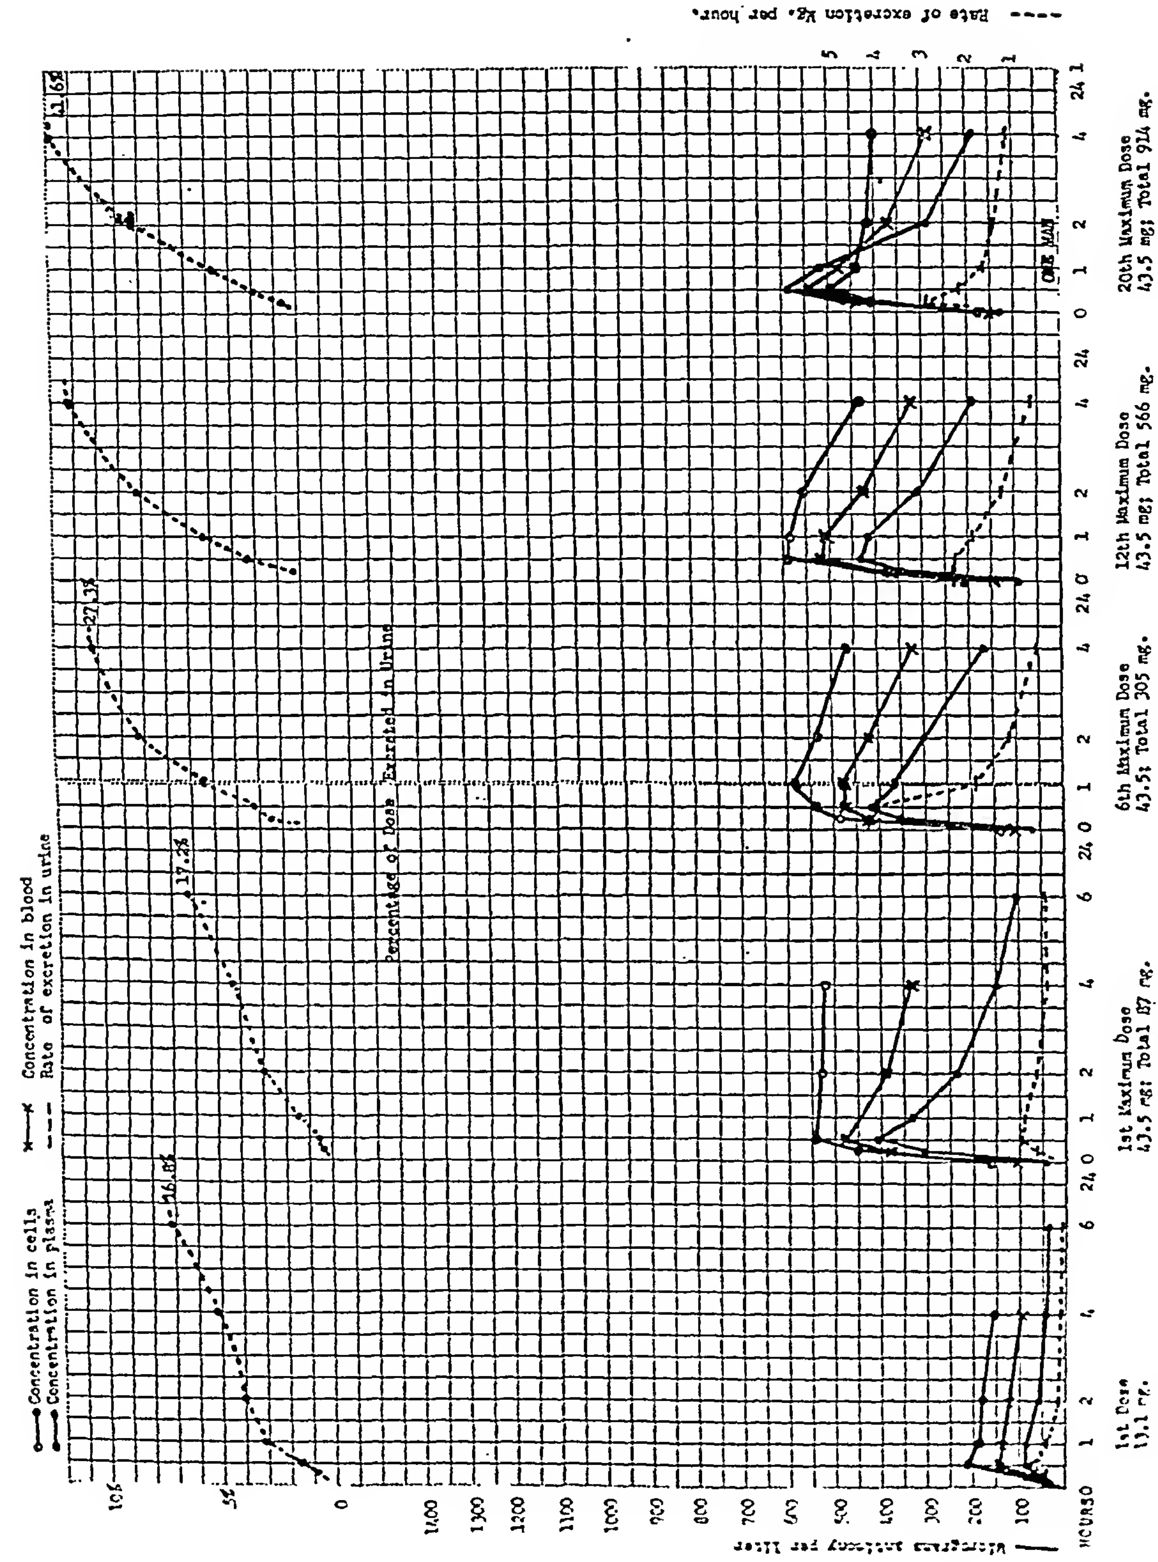

FIG. 3. DISTRIBUTION OF ANTIMONY BETWEEN BLOOD CELLS, PLASMA AND URINE AT INTERVALS AFTER THE ADMINISTRATION OF FUADIN

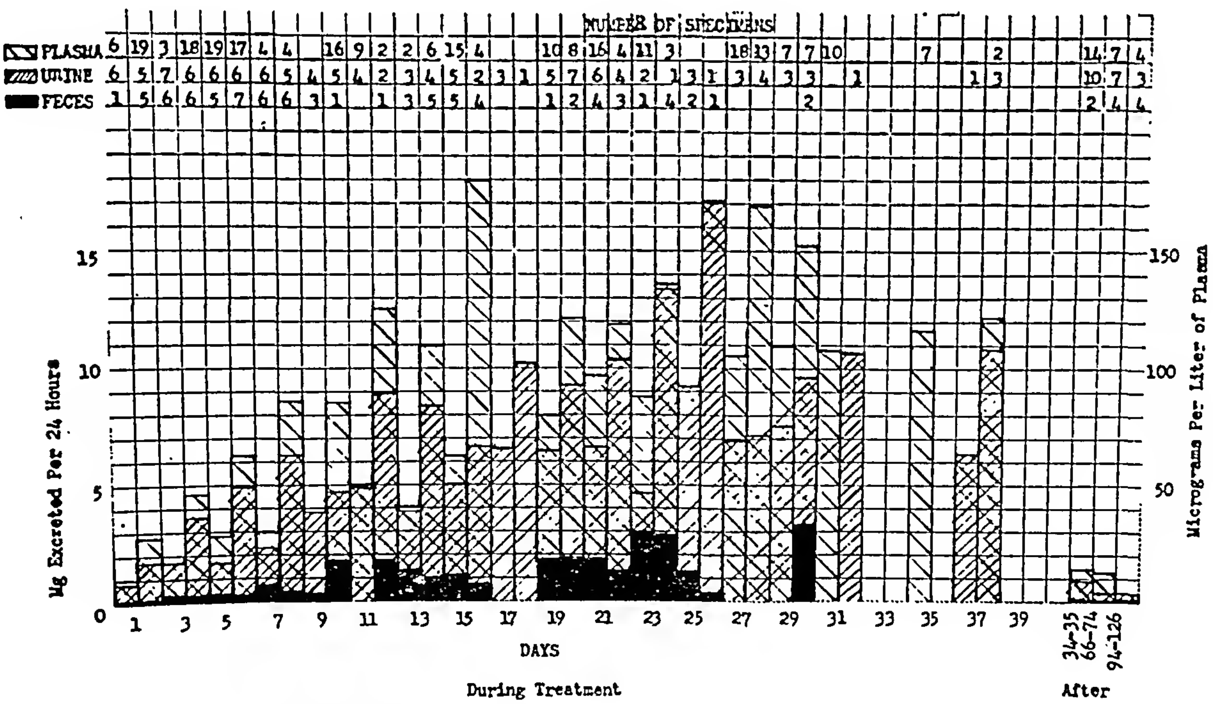
of plasma and they dropped slightly more slowly. The peak concentrations were roughly half as great as those found with tartar emetic and they decreased more slowly so that by 4 hours they were approximately the same as the tartar emetic values. The maximum cell concentrations were 3–4 times the pre-dose levels and were 1–4 times greater than the plasma concentrations at the same times. The average cell-plasma ratio at 4 hours was approximately 3.

Apparently, the early, more rapid decrease of the plasma concentration in the tartar emetic group is at least partially due to a more rapid uptake of tartar emetic by the blood cells. Subsequently this antimony is transferred somewhere else without appreciably affecting the plasma antimony concentration.

3. *Excretion in urine*

In Figures 4 and 5 are plotted the average 24-hour antimony excretions of a few patients at different times during and after treatment. For comparative purposes are shown the average plasma concentrations of larger groups of patients at 2 or at 4 hours after drug administration and also 24 hours later. As is to be expected, the plasma concentration and the urinary excretion on the day of drug administration were greater than on the following day. The excretion increased from nearly 2 mgm. on the day of the first dose to approximately 6 mgm. on the day of the first full dose, to roughly 10 mgm. per day in the latter part of the treatment period. There were no marked differences in the 24-hour excretions of these 2 small groups, although the fuadin values tended to be slightly greater. At approximately 40 days after completion of treatment the average daily excretion was still roughly 1 mgm. per day in both groups while at about 100 days 0.2 mgm. was being excreted per day.

The average urinary antimony excretions of the 4 men in each group studied at short intervals after drug administration are also shown in Figures 2 and 3. In the tartar emetic group the maximum rate of excretion was found in the first 15-minute period at the time of the maximum plasma and blood cell concentrations. The rate rapidly decreased to a fairly constant level by 1 to 2 hours after the dose. The actual urinary antimony concentrations did not follow the same pattern for



Plasma - 2 hours after dose

FIG. 4. COMPARISON OF ANTIMONY EXCRETION WITH PLASMA CONCENTRATION DURING AND AFTER TREATMENT WITH TARTAR EMETIC

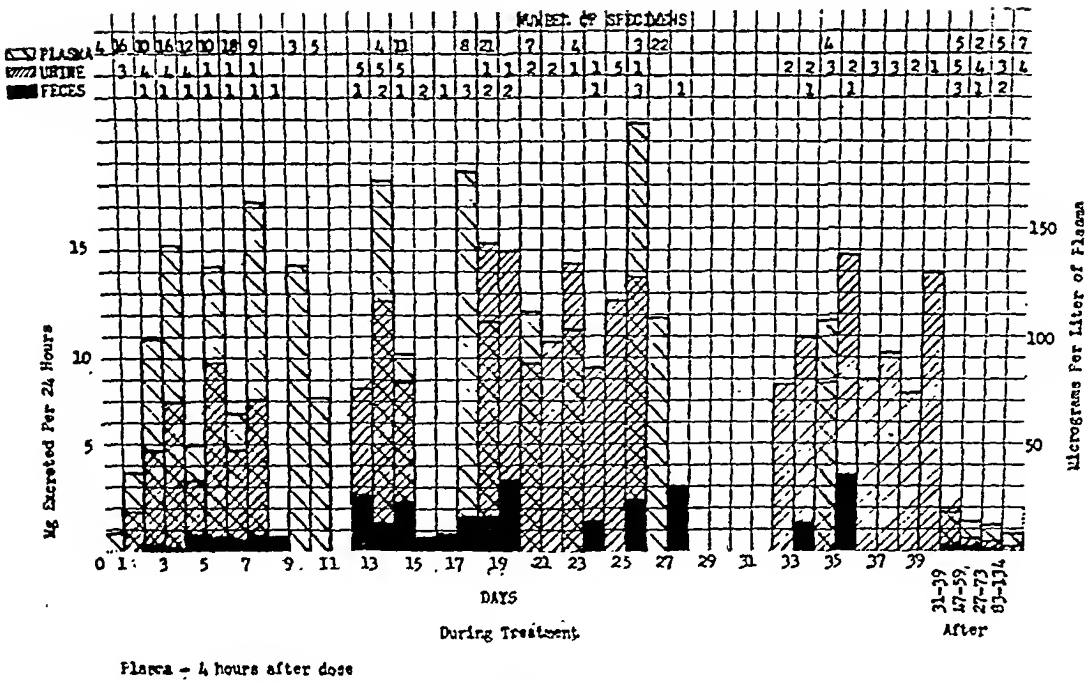


Fig. 5. Comparison of Antimony Excretion with Plasma Concentration During and After Treatment with Fuadin

they tended to be smaller in specimens with larger volumes and lower specific gravities. In a few cases the forcing of fluids before and shortly after drug administration had no marked effect upon the rate of urinary antimony excretion. The average excretion in the first 15 minutes was about 3 per cent of the injected dose; in the first 2 hours it was 6 per cent and the 24-hour excretions ranged from approximately 12 per cent at the beginning of treatment to 25 per cent at the end of treatment.

In the fuadin group the maximum rate of excretion occurred at about the time of the peak plasma concentration. As a rule the maximum rates were lower than those of the tartar emetic group, but the rates of excretion decreased more slowly so that after about 2 hours they were greater than the corresponding tartar emetic rates. The actual urinary antimony concentrations in this group also varied with the specific gravities of the specimens. The average excretion in the first 15 minutes was about 1.3 per cent of the injected dose; in the first 2 hours the excretions increased from about 4 per cent after the first dose to 8 per cent after the last dose. The 24-hour excretions increased from about 17 per cent after the first dose to 27 per cent after the sixth maximum dose, and in one case to 42 per cent after the twentieth maximum dose.

4. *Excretion in feces*

In Figures 4 and 5 are shown the average 24-hour excretions in a limited number of specimens. The average excretion varied from about 0.5 mgm. per day during the first week of treatment to approximately 2 mgm. daily toward the end of treatment. Small amounts were still being excreted at more than 100 days after the completion of treatment.

The combined excretion in urine and feces toward the end of treatment was roughly 24 mgm. in the 2 days following a dose, or approximately 55 per cent of the amount administered in the dose. The remainder presumably was stored in the body.

5. *Concentration in bile*

Interval specimens obtained from 1 patient in each group by duodenal drainage contained definite amounts of antimony. The concentration of antimony increased shortly after drug administration and then slowly decreased.

RESULTS OF TREATMENT

Following the end of a course of treatment 92 of the 138 patients were followed by serial stool examinations (not less than 18 per patient) until the stools again became positive or for a period of 3 months if the stools remained negative. The various technics used on the same specimens consisted principally of the direct smear, gravity sedimentation, and centrifugalization methods. There were 33 patients treated with fuadin and, of these, 27 men, or 82 per cent, were again passing eggs within 3 months or less, after cessation of treatment. These 27 men were again treated with fuadin and 24 of them were again passing eggs in 3 months' time or less. Of the 59 patients treated with tartar emetic only 11, or 19 per cent, were again passing eggs in their stools within 3 months or less.

SUMMARY AND CONCLUSIONS

1. The method of Maren for the determination of microgram quantities of antimony has been modified in order to make it more sensitive and specific. When 0.5- to 5-microgram quantities of antimony were added to 5-ml. portions of plasma, urine, and blood and to 0.5 gram of feces they were recovered with an average error of less than 5 per cent.

2. One hundred thirty-eight patients were given 156 courses of treatment consisting of the administration on alternate days of tartar emetic or of fuadin equivalent to 45 mgm. of antimony. After 0.75 gram of antimony had been given in approximately 5 weeks the average plasma antimony concentration in both groups was about 100 micrograms per liter. Four weeks later the concentration was 20 micrograms per liter. From 15 minutes to 4 hours after drug administration, the fuadin values were considerably greater than those of the tartar emetic group.

3. At all stages of treatment with both drugs the antimony concentration in the blood cells was definitely greater than that of plasma. For several hours after drug administration the tartar emetic group had decidedly higher blood cell concentrations than did the fuadin group.

4. The combined excretion in urine and feces toward the end of treatment was roughly 24 mgm. in 2 days or about 55 per cent of the amount administered in the preceding dose. The remainder presumably was stored in the body. Small amounts were still being excreted more than 100 days later.

5. Ninety-two patients were followed by serial stool examinations for an average of 3 months after completion of treatment. Within this period 82 per cent of 33 patients treated with fuadin were again passing eggs, whereas only 19 per cent of 59 patients treated with tartar emetic were again passing eggs.

6. The question is raised as to whether the higher antimony content in the red blood cells of patients treated with tartar emetic within the first 2 to 4 hours after drug administration than in those treated with fuadin is a factor in the greater therapeutic efficiency of this drug since it is known that the adult worms digest the host's erythrocytes. On the other hand, the known differences of distribution of the two drugs may be directly related to this question.

(Received for publication September 9, 1946)

While staphylococci are among the species of gram-positive bacteria considered to be susceptible to the antibacterial action of penicillin, a number of investigators have reported that there are some strains of coagulase-positive staphylococci which are naturally resistant to penicillin (1 to 11). Of added clinical importance is the fact that pathogenic strains originally sensitive to therapeutic concentrations of penicillin may become resistant to the antibiotic in patients who have received treatment with penicillin (7, 12 to 19). In an attempt to define the nature of the resistance of staphylococci to penicillin, the results of several studies have appeared in which sensitive strains have acquired a high degree of resistance by *in vitro* methods (4, 11, 13, 18, 20 to 24). Todd and Turner (25) succeeded in adapting 2 strains of staphylococcus resistant to penicillin by making repeated subcultures of the cocci in increasing quantities of penicillin. When the strains had acquired resistance, they subcultured the organisms daily in broth without penicillin and observed that there was a rapid decline in resistance. As a result of these observations, they assumed that the resistance of staphylococci which developed in the body was not a permanent characteristic of the organisms and that, upon withdrawal of the drug, the bacteria would quickly revert to a state of sensitivity. On the other hand, Spink and Ferris (26) showed independently that staphylococci which had acquired resistance *in vitro* lost this resistance when grown and transferred in the absence of penicillin, but that penicillin-resistance attained in the body appeared to be a permanent characteristic of the bacteria. This distinction between acquired *in vitro* and *in vivo* resistance has been confirmed by others (11, 18).

One of the major problems related to penicillin-resistance is whether penicillinase plays a role in the resistance displayed by staphylococci. Abraham and Chain (27) first showed that *E. coli* produced an enzyme, designated as penicillinase, which destroyed penicillin, but in a later observation by Abraham and others (4), a strain of *Staph. aureus* adapted by *in vitro* methods to grow in the presence of high concentrations of penicillin did not produce penicillinase. McKee, Rake, and Houck (28) encountered a strain of *Staph. aureus* which was resistant to penicillin and which formed a filter-passing enzyme capable of destroying penicillin. Bondi and Dietz (8) concluded that penicillinase was responsible for the resistance to penicillin of naturally resistant strains of staphylococci, but they (21) also pointed out that other species of bacteria, notably gram-negative organisms, did not owe their resistance to the production of penicillinase. Kirby (29) demonstrated that strains of staphylococcus which were naturally resistant to penicillin possessed a potent inactivator for penicillin, whereas this property was absent in sensitive strains. This observation was extended by Spink and Ferris (26, 30), who showed that strains of staphylococcus made highly resistant to penicillin by *in vitro* adaptation did not produce an inactivator for penicillin; and, in addition, there appeared to be a quantitative relationship between the degree of resistance and the production of an inactivator for penicillin for naturally resistant strains or strains which had acquired resistance *in vivo;* that is, the more resistant a strain, the more potent the inactivator. Demerec (24) has approached the problem of penicillin resistance with a different type of experiment than that used by the foregoing investigators. Starting with a strain of staphylococcus sensitive to the action of penicillin, subcultures were made on agar plates containing penicillin. In this manner, he observed that the sensitive strain gave rise to small numbers of variants which were resistant to low concentrations of penicillin. When these variants were permitted to grow, there was

[1] Aided by grants from Sharp and Dohme, Inc.; the Committee on Scientific Research of the American Medical Association; and the Graduate School, University of Minnesota Medical School.

a gradual increase in variants which were highly resistant to penicillin. Demerec concluded that acquired *in vitro* resistance occurred independently of penicillin and involved a number of mutations and genic changes. In other words, resistance is an inherited characteristic of a given strain, and not acquired through the interaction of the bacteria and penicillin. Although he stated that the resistance persisted for the period of the experiments, it is not known from the data presented whether the resistance was of a permanent nature. Furthermore, it is not known whether the resistant mutants produced an inactivator of penicillin. In a follow-up study of Demerec's work in the same institution, Luria (31) has indicated that there are two types of penicillin-resistance as far as the staphylococcus is concerned, namely, resistance that develops as a result of mutation and resistance that is associated with penicillinase-producing strains. In other words, penicillinase apparently plays no role in the inherited and permanent type of resistance, a conclusion which is at variance with the observations of others and the results in this report. Luria has emphasized that if a small inoculum of organisms is used in the *in vitro* test for sensitivity, penicillinase-producing strains have individual cells which are sensitive to penicillin. However, as will be pointed out shortly, the degree of resistance is related to the *potency* of penicillinase produced by a given strain.

Because there appears to be a lack of general agreement concerning the mechanism or mechanisms whereby penicillin-resistant strains of staphylococcus are established, the present report includes a series of studies which have been carried out over a period of 4 years. Two fundamentally different types of resistance have been observed repeatedly. First, resistance that is acquired *in vitro* by adapting the organisms to grow in increasing concentrations of penicillin. This type of resistance is only a temporary property of the bacteria and is not associated with the formation of penicillinase. The second type of resistance appears to be a permanent characteristic of the strains and is always associated with the production of penicillinase. Furthermore, the degree of resistance is quantitatively related to the potency of penicillinase produced by a given strain. This type of resistance is an inherent property of some naturally resistant strains and of strains which have acquired resistance in the human body as a result of treatment. The methods for obtaining penicillinase from staphylococci and the properties of this penicillinase will be described.

MATERIALS AND METHODS

Strains of staphylococcus

A total of 45 strains of coagulase-positive strains of staphylococcus was studied. All of the strains were recovered from human patients. Of these strains, 25 were sensitive to the action of penicillin; 9 showed a natural type of resistance; and 5 had apparently acquired resistance in the body as a result of treatment.[2] Each of the strains was cultured on veal infusion or tryptose phosphate agar slants and stored in the refrigerator and subcultures were made monthly.

Penicillin

Nineteen lots of commercial sodium penicillin as marketed by 8 different companies were utilized. In the majority of instances, serial and comparative studies of penicillin-resistance and similar studies on the mode of action of penicillinase, were carried out with the same lot of penicillin. It was observed that sodium penicillin could be dissolved in sterile physiological saline, frozen, and then stored in a deep-freeze refrigerator for weeks without loss of potency. Comparative studies were made between commercial sodium penicillin and crystalline sodium penicillin supplied by Merck & Company.

Determination of in vitro *penicillin resistance*

The sensitivity of each strain for penicillin was determined by adding a standard inoculum of organisms to test tubes with liquid medium containing increasing concentrations of penicillin, and then selecting as the end point that tube which showed no turbid growth with the lowest concentration of penicillin. Three types of medium were used for growing the staphylococcus. In the initial experiments, Gladstone's synthetic medium was employed, the preparation of which has been described elsewhere (32). In later studies, veal infusion broth and tryptose phosphate broth were utilized because these media were prepared with less difficulty than Gladstone's medium. The results of the sensitivity tests were essentially the same with all 3 media. The details of determining the *in vitro* sensitivity of each strain to penicillin were as follows: a loopful of culture was taken from an agar slant and grown for 2 to 3 generations in liquid medium. A standard inoculum of 0.1 ml. of 10^{-3} dilution of a 24-hour culture was seeded into each of several test tubes containing one of the foregoing liquid media.

[2] Dr. Donald G. Anderson of Boston kindly supplied us with 3 of the 5 strains which had developed *in vivo* resistance.

Such an inoculum contained between 300,000 to 900,000 organisms. Then 1 ml. of freshly prepared aqueous solution of sodium penicillin was added in ascending concentrations to each of the tubes with the bacterial suspensions. The final volume in each tube was 10 ml. Incubation was carried out for 48 hours at 37° C. and then growth of the organisms was determined by the presence of turbidity. The results of previous studies had emphasized the importance of using a standardized and small inoculum of organisms in performing tests for penicillin sensitivity (5). A large inoculum of organisms required a higher concentration of penicillin for the inhibition of growth than a small inoculum.

Development of in vitro *resistance to penicillin*

Strains of staphylococcus were made resistant to penicillin by exposing succeeding generations of organisms to increasing concentrations of the same lot of commercial sodium penicillin in Gladstone's medium or veal infusion broth. The method was as follows: to each of several tubes containing 9 ml. of liquid medium and 1 ml. of sodium penicillin dissolved in isotonic saline solution was added a standard loopful of a 24-hour culture which had been grown in liquid medium. The initial concentration of penicillin permitted turbid growth when the cocci were incubated for 24 hours at 37° C. When maximum growth was obtained with a given concentration of penicillin after loopful transfers every 24 to 48 hours, the concentration of penicillin was increased and the serial transfers repeated. Of considerable importance was the simultaneous transfer of control organisms from each strain in liquid medium without the presence of penicillin.

Detection of penicillinase production

The presence of crude penicillinase was determined for strains sensitive to the action of penicillin, strains made resistant *in vitro* to penicillin, naturally resistant strains, and strains which had become resistant in the human body. The method of obtaining penicillinase was that of Harper (33) as used for the paracolon bacillus, and as adopted for the staphylococcus by Kirby (34). Essentially, the method consisted of growing each strain on the surface of several agar plates for 24 hours at 37° C., preparing a thick emulsion of the organisms with distilled water, extracting the cocci with acetone and ether, and then drying the bacterial residue *in vacuo*. After testing for sterility, the dried material was stored in the refrigerator.

The potency of the penicillinase was ascertained in the following manner: a standard strain of staphylococcus sensitive to penicillin was grown for 24 hours in Gladstone's medium or broth. Then 0.1 ml. of a 10^{-3} dilution was added to each of several tubes containing synthetic medium or broth with 0.001, 0.01 or 0.1 mgm. per ml. of dried, extracted cells and increasing concentrations of penicillin. The mixtures were incubated at 37° C. for 48 hours and that tube which showed turbid growth with the highest concentration of penicillin indicated the number of units of penicillin destroyed by penicillinase.

RESULTS

I. *Penicillinase from staphylococci*

Kirby (34) first designated the material obtained from the cells of staphylococci which destroyed penicillin as a "penicillin inactivator," and subsequently described some of the properties of this substance (29). Broth suspensions of the inactivator were completely inactivated at 56° C. in 5 minutes. The inactivator could not be obtained in a cell-free filtrate. The rate of destruction of penicillin by the inactivator was the same at 2° C., 22° C., and at 37° C. In contrast to one of these properties, McKee, Rake, and Houck (28) obtained a strain of *Staphylococcus aureus,* appearing as a contaminant in a culture of *Aspergillus flavus,* which produced an enzyme capable of destroying penicillin. This enzyme was obtained in Seitz filtrates of broth cultures. More recently, Luria (31) reported that no inactivator for penicillin was obtained from filtrates of cultures of resistant staphylococci when sintered glass, Seitz, or Mandler filters were used. It appeared desirable to obtain more information concerning the properties of the inactivator of penicillin produced by staphylococci and to study its mode of action. In the following discussion this inactivator will be referred to as penicillinase.

Intracellular nature of staphylococcic penicillinase

It was observed repeatedly that bacterial cells from cultures of staphylococci with the permanent type of resistance contained a potent penicillinase after the cells had been extracted with acetone and ether and then dried. Several attempts were made to obtain the penicillinase in cell-free filtrates by growing the organisms in broth and filtering portions with Berkefeld, fritted glass and Seitz filters. The sterile filtrates contained no active agent against penicillin, thus confirming the findings of Luria (31). Penicillin-resistant organisms were grown in broth for 24 hours, and then the flask shaken vigorously on a shaking machine for 8 hours. When this material was filtered, the sterile filtrate did not contain penicillinase.

Sterile supernatants of penicillin-resistant staphylococci were obtained only after considerable difficulty. Organisms were grown for 24 hours in broth and then the majority of the cells removed

by centrifuging in the usual type of laboratory centrifuge. The supernatant was then centrifuged in a high speed centrifuge (13,000 r.p.m.) in the cold for 1 hour. The top layer of the supernatant was carefully drawn off and this material was centrifuged for another hour. This sterile supernatant did not contain penicillinase.

One hundred milligrams of dried bacterial cells from strain Rosen contained highly active penicillinase. The finely dried powder was added to 100 ml. of tryptose phosphate broth in a flask and the contents shaken vigorously. The powder did not go into solution but was dispensed through the broth as a fine suspension. After equal parts of the broth were filtered through Berkefeld, fritted glass, and Seitz filters, no active penicillinase was present in the filtrates.

The foregoing observations indicate that staphylococcic penicillinase is intimately associated with the bacterial cells and active material could be investigated only with dried cells.

Stability of staphylococcic penicillinase

Sterile dried preparations maintained their potency for several weeks when kept at room temperature or in the refrigerator. When the powder was suspended in sterile physiological saline solution and quickly frozen, there was no diminution in activity. Though no observations were made over an extended period of time, there was no loss of activity of aqueous or broth suspensions kept at room temperature for several days. Penicillinase was found to be heat labile. After 0.01 mgm. per ml. of dried powder prepared from a highly resistant strain was suspended in physiological saline solution and heated at 56° C. for 30 minutes only, 1 unit per ml. of penicillin was destroyed by the heated product, whereas the unheated control inactivated 40 units. After heating at 80° C. for 30 minutes, only slight inactivation of penicillin was noted by the same amount of material.

Effect of pH on action of staphylococcic penicillinase

One mgm. per ml. of a dried preparation from a resistant strain was suspended in physiological saline solution in each of 3 tubes. The pH was adjusted to 2.04, 6.90, and 11.30 and the contents incubated at 37° C. for 30 minutes and for 3 hours. At the end of these periods, the solutions were brought back to neutrality and the activity of the preparations tested against penicillin. The results are tabulated in Table I. It is to be noted that there was a 50 per cent reduction in activity at the end of 30 minutes. In 3 hours, there was complete inactivation at a pH of 11.3 and a 90 per cent reduction in activity at 2.04.

TABLE I

Effect of pH on activity of 1 mgm. per ml. of penicillinase

pH	Per cent reduction in activity after incubation at 37°C.	
	30 minutes	3 hours
2.04	50	90
6.90	0	0
11.30	50	100

In the second experiment, the same concentration of material was incubated at 37° C. for 4 hours at a pH of 3.0, 7.4, and 9.0. Table II shows a 50 per cent reduction of activity on the acid side and complete inactivation in an alkaline medium.

TABLE II

Effect of pH on activity of 1 mgm. per ml. of penicillinase

pH	Per cent reduction in activity after incubation at 37°C. for 4 hours
3.0	50
7.4	0
9.0	100

These results indicate that penicillinase from staphylococcus is more susceptible to changes in hydrogen ion concentration than the penicillinase obtained from an aerobic spore-forming bacillus belonging to the *B. subtilis* group as reported by Woodruff and Foster (35). They observed no change in activity of the enzyme over a range of pH from 3.0 to 11.0. On the other hand, staphylococcic penicillinase appears to be more resistant to changes in hydrogen-ion concentration than the penicillinase studied by McQuarrie and his associates (36) prepared from a gram-negative rod.

Factors influencing the action of staphylococcic penicillinase on penicillin

The inactivation of penicillin by penicillinase was found to be dependent upon 2 main factors. First, the *potency* of the penicillinase utilized in a given

observation, and, second, the period of *time* in which penicillinase was in contact with penicillin. The significance of these 2 factors is illustrated by the following experiments. Preparations of strain Bernardo II in concentrations of 1 mgm. per ml. and 0.1 mgm. per ml. were mixed with 100 units per ml. of penicillin in physiological saline solution and permitted to stand at room temperature for 5 hours. At the end of this period, the penicillinase was removed by filtration and the filtrate tested for penicillin activity. There was only a slight diminution in the potency of penicillin which had been in contact with 0.1 mgm. per ml. of dried cells, whereas there was almost complete destruction of activity with the mixture containing 1 mgm. per ml. When mixtures containing the same quantities of penicillinase and penicillin were allowed to stand for 18 hours at room temperature, there was complete loss of penicillin activity with both preparations.

Pencillinase prepared from strain Rosen always yielded a more potent material than that obtained from strain Bernardo II. When 0.2 mgm. per ml. of Rosen extracted cells were mixed with penicillin and tested for penicillin at the end of 1 and 3 hours, it was observed that there was no loss of penicillin activity in 1 hour, but the potency of penicillin was considerably reduced in 3 hours.

In a preliminary communication (30), this relationship of the potency of penicillinase and the time necessary for inactivation of penicillin was illustrated in another type of experiment. A constant amount of extracted cells was added to each of several tubes containing increasing concentrations of commercial penicillin dissolved in Gladstone's medium. A small inoculum of a penicillin-sensitive strain of staphylococcus was seeded to each of the tubes and the mixtures incubated at 37° C. Growth curves of the organisms were determined by measuring the density of the bacterial cultures with a photoelectric colorimeter at appropriate time intervals. It was shown that with increasing concentrations of penicillin a longer period of time was necessary for inactivation of it. The same type of experiment was repeated in the present study comparing the effect of 0.005 mgm. per ml. of dried Bernardo II cells upon increasing concentrations of commercial penicillin and a purified preparation of crystalline sodium penicillin (Merck). The results are illustrated in Figure 1. The test strain used in this experiment was inhibited in growth by 0.05 unit per ml. of penicillin and

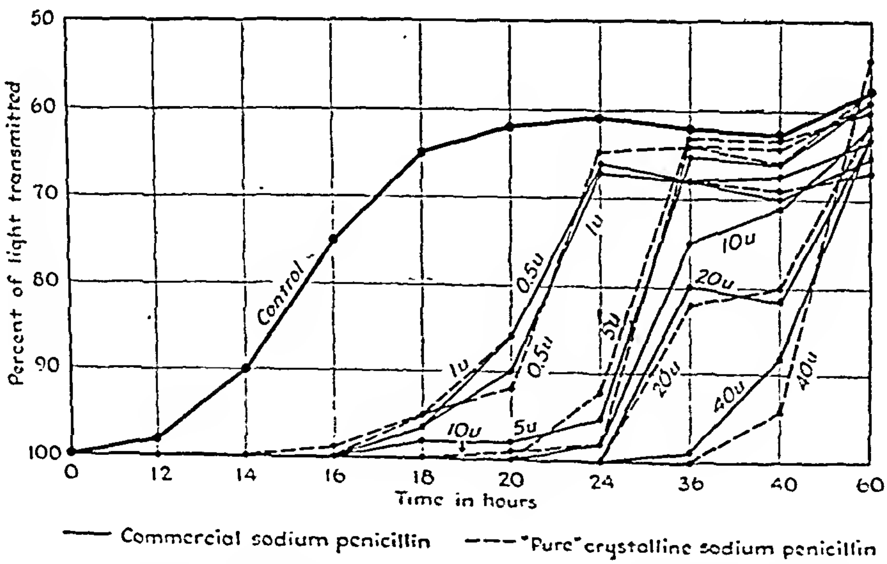

FIG. 1. COMPARATIVE EFFECT OF 0.005 MGM. PER ML. OF STAPHYLOCOCCIC PENICILLINASE ON THE GROWTH CURVES OF A PENICILLIN-SENSITIVE STRAIN OF STAPHYLOCOCCUS IN THE PRESENCE OF INCREASING CONCENTRATIONS OF COMMERCIAL SODIUM PENICILLIN AND "PURE" CRYSTALLINE SODIUM PENICILLIN

Concentrations of penicillin expressed in units per cubic milliliter.

yet, if 0.005 mgm. per ml. of extracted cells containing penicillinase was allowed to remain in contact with penicillin for 40 hours, this strain finally grew out in the presence of 40 units per ml. of penicillin.

Several attempts were made to determine if there was a linear relationship between the inactivation of penicillin by penicillinase. However, no close correlation between these 2 factors was found, probably due in part to the fact that only crude preparations of penicillinase were available. The results of 1 experiment are given in Table III.

TABLE III

Growth of penicillin-resistant strain of staphylococcus in relation to increasing concentrations of penicillin and penicillinase

Incubation at 37°C. for 48 hours

+ = turbid growth.
0 = no turbid growth.

Each of several tubes contained a standardized small inoculum of a penicillin-sensitive strain of staphylococcus in Gladstone's medium to which were added increasing concentrations of extracted cells and sodium penicillin. The mixtures were incubated for 48 hours at 37° C. and then bacterial growth determined by the presence of turbidity.

Continued action of staphylococcic penicillinase

It was of importance to determine if a preparation of penicillinase would continue to inactivate penicillin after one or more exposures to the antibiotic. This was determined by adding 1 mgm. per ml. of extracted cells to a flask containing tryptose phosphate broth with 100 units per ml. of penicillin. After standing for 24 hours a portion of the mixture was filtered to remove penicillinase, and tested for penicillin activity. Then fresh penicillin was added to the flask and the mixture allowed to stand for another 24 hours, and a filtrate again tested for the presence of penicillin. It was observed that the preparation of penicillinase continued to inactivate penicillin completely until sampling of the mixtures had reduced the concentration of penicillinase to ineffective levels. The contents of a control flask containing only broth and added penicillin did not reveal any loss of penicillin activity when handled in the same manner.

II. Comparison of properties of resistant strains

Staphylococci with resistance acquired by in vitro *methods*

Four strains of staphylococcus isolated from patients were adapted to grow in increasing concentrations of penicillin. Strain Rutgers was cultured from a suppurative skin lesion, while strains Nelson, Ked, and Eden were isolated from patients with osteomyelitis. The initial sensitivity of these strains and the degree of resistance obtained after multiple transfers in Gladstone's medium containing penicillin are shown in Table IV. A significant feature is that the degree of resistance acquired by the strains varied. Strains Rutgers and Nelson required only 6 units per ml. of penicillin to inhibit growth while strains Ked and Eden necessitated 120 and 80 units respectively. It was assumed at the time these observations were made that this acquired penicillin resistance was a relatively permanent property of the strains. Subcultures of these strains were made on veal agar slants and stored in a refrigerator, and transfers were carried out at monthly intervals. At the end of 11 months, the strains were tested for their sensitivity to penicillin and repeated observations revealed that the acquired resistance was not present.

TABLE IV

Development of resistance after multiple transfers in Gladstone's medium with increasing concentrations of penicillin

Strain	No. of transfers in increasing concentrations of penicillin	No. of units per 1 ml. required to inhibit growth	
		Initial sensitivity	After acquisition of penicillin resistance
Rutgers	117	0.05	6
Nelson	117	0.05	6
Ked	115	0.10	120
Eden	113	0.10	80

In order to confirm these observations, the foregoing strains which had acquired and lost their resistance to penicillin were again adapted to

Subculture ... TABLE V

Strains which had acquired resistance to penicillin (Table II) and then had lost this property adapted a second time to grow in the presence of increasing concentrations of penicillin

Strain	No. of transfers in increasing concentrations of penicillin	No. of units per 1 ml. required to inhibit growth	
		Initial sensitivity	After acquisition of penicillin resistance
Rutgers	72	0.05	80
Nelson	72	0.05	40
Ked	72	0.10	600
Eden	72	0.10	20

grow in increasing concentrations of penicillin. This time, these strains became resistant in a shorter period of time and, with the exception of strain Eden, a much greater degree of resistance was attained. The comparative resistance of these strains after 72 transfers is shown in Table V. The strains were then transferred to veal agar slants and placed in the refrigerator for 80 days. At the end of this period, sensitivity tests were carried out and the results revealed no loss of resistance after this one subculture and storage. But after multiple transfers, the resistance was lost.

During the period when the 4 strains were being adapted to penicillin, investigations were made with strain Ked. After 29 transfers in increasing concentrations of penicillin, the culture was plated out on agar, and 10 colonies were picked off the plate and tested for their sensitivity to penicillin. The results are presented in Table VI. It is apparent that in such a culture there are cells possessing different degrees of resistance. This is of

...g III, ...ococci ... noted th... the presence of body fluids, such as hum... ...a, would influence the properties of staphylococci made resistant by *in vitro* methods, strains Ked and Eden were transferred in a medium with penicillin and equal parts of human plasma and veal infusion broth. Although resistance to penicillin was acquired in this manner, the resistance was of only a temporary nature. These results are in agreement with the findings of Blair and his associates (11) who used human serum.

Repeated attempts were made to obtain penicillinase from the cells of those strains with acquired resistance, but in no instance was the material obtained.

In summary, the resistance to penicillin of staphylococci established by *in vitro* methods is characterized by a temporary type of resistance, and the resistance is not associated with the production of penicillinase.

Staphylococci with natural resistance

Nine strains of coagulase-positive staphylococcus were isolated in 1942, or before, from the lesions or blood of patients, subcultured on veal agar slants and stored in the refrigerator. These strains, then, were isolated before penicillin was available for clinical use. In 1943, sensitivity tests were carried out with these strains and it was observed that more than 0.5 unit and less than 1 unit per ml. were required to inhibit growth. These strains were subcultured on agar slants every 2 to

TABLE VI

...sensitivity: penicillinase. ... s observed that a concentration of 0.01 mgm. per ml. of extracted bacteria destroyed 20 to 40 units of penicillin per ml.

Briefly, then, staphylococci possessing a natural resistance for penicillin have 2 properties different from strains which have been adapted by *in vitro* methods to resist penicillin. The resistance appears to be a permanent characteristic of the strains and is associated with the production of penicillinase.

Staphylococci with acquired resistance from patients treated with pencillin

Over a period of 2 years, cultures isolated from 5 patients have been studied extensively. In 4 of the 5 patients staphylococci were obtained before and after treatment with penicillin. Because of the significance attached to these coagulase-positive strains in the present studies, the history of these cultures is presented. Strain Eden was cultured in 1942 from the blood of a young child who had staphylococcic bacteremia and acute osteomyelitis of the tibia. Strain Eden II was obtained from a draining osteomyelitic sinus in the same year after the child had received slightly over 2 million units of penicillin. Strain Long was isolated from a draining lesion in the right costovertebral region originating from a perinephritic abscess. Strain Long II was cultured from the same area after 2 million units of penicillin had been administered. The strains from patients Janson, Bernardo, and Rosen were supplied to us in 1944 through the courtesy of Dr. Donald G. Anderson of Boston. Strain Janson was isolated from an osteomyelitic sinus of a young adult in 1942. After approximately 2 million units of penicillin, strain Janson II was cultured from the same sinus. Strain Bernardo was also isolated from an osteomyelitic lesion at approximately the same time as Janson, and after the administration of 600,000 units of penicillin Bernardo II was cultured from the sinus. It is significant, as Anderson and his associates (14) have pointed out, that cultures of lesions made a year after the completion of treatment with penicillin showed the presence of resistant organisms. Strain Rosen was isolated from the blood lion units of penicillin before the onset of bacteremia. With the exception of Rosen, the comparative increase in resistance of the foregoing strains is given in Table VII.

TABLE VII

Sensitivity of strains of staphylococcus isolated from patients before and after treatment with penicillin

No culture obtained from patient Rosen before treatment

Strain	Units per ml. of penicillin inhibiting growth before treatment	Units per ml. of penicillin inhibiting growth after treatment
Eden	0.10	0.8
Long	0.05	1.0
Janson	0.05	1.0
Bernardo	0.05	2.0
Rosen		20.0

One of the outstanding features of these strains is that the resistance has persisted for up to 4 years, although repeated subcultures have been made. In fact, as will be pointed out shortly, there has been an increase in the degree of resistance. In addition to the characteristic of a persistent resistance, these strains with acquired *in vivo* resistance produce penicillinase. The parent sensitive strains did not yield demonstrable penicillinase.

Attempts to increase resistance of staphylococci with permanent type of resistance by in vitro *methods*

The preceding studies have shown that sensitive strains of staphylococci may be adapted to grow in increasing concentrations of penicillin but that this acquired resistance was only temporary. In view of this, strains with the permanent type of resistance were adapted to grow in increasing amounts of penicillin by methods already described. While these strains were being adapted, simultaneous transfers were made in culture medium without the presence of penicillin.

The first series of observations were made with strain Long II, which had acquired resistance *in vivo* in association with treatment of the patient with penicillin. On 3/3/45, a culture of Long II was divided into 2 parts. Daily transfers were made with one part thereafter in Gladstone's medium, while the other part, known as Long III, was transferred daily in the same medium contain-

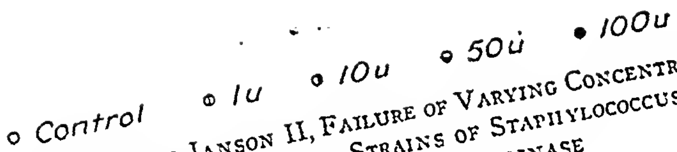

FIG. 3. WITH EXCEPTION OF STRAIN JANSON II, FAILURE OF VARYING CONCENTRATIONS OF PENICILLIN TO INHIBIT GROWTH OF LARGE INOCULUM FROM STRAINS OF STAPHYLOCOCCUS WITH PERMANENT TYPE OF RESISTANCE AND WITH PROPERTY OF PRODUCING PENICILLINASE

ase produced by them are shown in Table IX. iter the 3 strains had acquired further resistance penicillin by methods already described, there ras an associated increase in the potency of penicillinase production as seen in Table IX. Thus, strain Rosen with an acquired resistance which required 400 units of penicillin to inhibit growth produced such a highly active penicillinase that 0.0001 mgm.

TABLE IX

Relationship between the in vitro *resistance of staphylococci and the inactivation of penicillin by penicillinase*

Strain	Strains isolated from patients after treatment with penicillin		Strains isolated from patients after treatment with penicillin and which had acquired further resistance to penicillin *in vitro*	
	No. of units of penicillin per ml. required to inhibit growth	No. of mgm. of dried bacteria which inactivated maximum no. of units of penicillin per ml.	No. of units of penicillin per ml. required to inhibit growth	No. of mgm. of dried bacteria which inactivated maximum no. of units of penicillin per ml.
Long	0.8	0.01 mgm.— 40 units	60	0.001 mgm.— 400 units
Bernardo	2.0	0.01 mgm.—200 units	60	0.001 mgm.— 400 units
Rosen	20.0	0.01 mgm.—600 units	400	0.001 mgm.—1,800 units
				0.0001 mgm.— 400 units

of dried cells inactivated 400 units per ml. of penicillin. The important feature of these observations is that resistance is correlated with penicillinase. The more resistant a strain, the more potent is the penicilli[illegible] produced by that strain. Furthermore, re[illegible] small amounts of penicillinase inactivated large concentrations of penicillin. It should be pointed out, however, that the results as given in Table IX show only a relative quantitative relationship between the degree of resistance and the inactivation of penicillin. This is very probably due to the fact that the method of preparing penicillinase permitted only the use of crude material.

DISCUSSION

These studies emphasize the distinction between the 2 types of resistance to penicillin manifested by staphylococci. A clarification of these differences has been desirable, particularly from the viewpoint of the development of resistant strains of staphylococci in patients as a result of treatment with penicillin. The type of resistance which results from adapting strains *in vitro* to grow in increasing concentrations of penicillin is not a permanent characteristic of these strains, and this resistance is not associated with the production of penicillinase. It is not definitely known whether this type of temporary resistance occurs in the human body following therapy with penicillin. If the phenomenon does occur, it is probably of little clinical significance, since such strains have been shown to be less virulent than the sensitive parent strains (22, 11, 18). The underlying mechanism whereby penicillin-sensitive strains acquire a temporary resistance to the action of penicillin is not clear.

The second type of penicillin resistance, which appears to be a permanent characteristic of the strains and is accompanied by the production of penicillinase by these strains, is of considerable importance in the clinical use of penicillin. The most acceptable explanation for the origin of strains with the permanent type of resistance is that afforded by Demerec (24) and, independently, by Kirby (9), namely, that cultures of penicillin-sensitive strains contain resistant variants capable of mutating toward a state of a high degree of resistance if these cells are given an opportunity to multiply rapidly. The present studies also show that penicillin-resistant strains may acquire a much greater resistance to penicillin if the cells are permitted to multiply rapidly, even in the absence of penicillin.

In describing the development of penicillin-resistant staphylococci by the mechanism of mutation, Demerec (24) did not state whether the resistant cells produced penicillinase. On the other hand, Kirby (29) isolated cells from penicillin-sensitive strains of staphylococci which proved to be resistant to penicillin and which produced penicillinase. In a follow-up study of Demerec's work, Luria (31) discounted the role of penicillinase in the mechanism of penicillin-resistance by emphasizing that the individual cells of resistant and penicillinase-producing strains were sensitive to small concentrations of penicillin. The fundamental question is not whether a given strain produces penicillinase but rather how quickly and how potent is the penicillinase produced by a strain in relation to the concentration of penicillin and the time necessary for the antibiotic to destroy the cells. It is to be recalled that in their original report, Abraham and Chain (27) found that *M. lysodeikticus* produced penicillinase, and yet this strain was sensitive to penicillin. The present investigations show that strains of staphylococci with a relatively high degree of resistance produce a potent inactivator of penicillin; the greater the resistance, the more potent the penicillinase. This relationship of penicillinase production to the resistance of penicillin has been demonstrated for other species of bacteria. Woodruff and Foster (35) described an aerobic spore-forming bacillus belonging to *B. subtilis* group which at pH 6.0 or above was not inhibited in its growth by several hundred units of penicillin because of the penicillinase produced by that strain. However, when the same strain was grown at pH 5.5, no penicillinase was produced, and growth was inhibited by 10 units per ml. of penicillin. McQuarrie and his associates (36), working with 3 strains of spore-forming gram-negative rods, noted a quantitative relationship between penicillin-resistance and the production of penicillinase. The present discussion relates primarily to the mechanism whereby staphylococci resist the action of penicillin because of penicillinase. It is well established that other

mechanisms are responsible for resistance with other species of bacteria since many gram-negative bacteria are highly resistant and yet do not produce penicillinase (21).

The observations presented here and those of others (35 to 39) indicate that the penicillinases from different species of bacteria are not identical but possess different physico-chemical properties, though they all have the common property of inactivating penicillin. It is of interest that Perlstein and Liebmann (40) produced an anti-penicillinase immune serum by injecting rabbits with purified penicillinase. The significance of this observation must await further investigations.

Clinically, the potentiality of penicillin-resistance in staphylococci should be recognized, with the object of treatment being to destroy all the organisms within the shortest possible time. If inadequate concentrations of penicillin are present in the body fluids or tissues of patients, the more susceptible bacterial cells may be eradicated, providing an opportunity for the resistant variants to multiply.

SUMMARY

1. Two types of resistance to penicillin have been described for staphylococci. The first type is an adaptation that may be reproduced *in vitro*, and the resistance is of a temporary nature and not associated with the production of penicillinase.

2. The second type which occurs in patients as a result of treatment with penicillin results in the establishment of strains with a permanent resistance to penicillin, and these strains produce penicillinase.

3. The mechanism whereby temporary resistance takes place is not clearly understood. The permanent type of resistance involves the presence of resistant cells in a penicillin-sensitive strain, which, when permitted to multiply rapidly, establish a uniformly resistant strain.

4. The magnitude of the resistance to penicillin manifested by the permanent type of resistance is quantitatively related to the potency of penicillinase produced by the strains.

5. The establishment of resistant strains of staphylococcus in the human body can be prevented by the prompt use of adequate quantities of penicillin.

PHYSIOLOGIC ACTION OF *CLOSTRIDIUM WELCHII* (TYPE A) TOXINS IN DOGS [1,2,3]

By PAUL C. ZAMECNIK, IRA T. NATHANSON, and JOSEPH C. AUB

(From the Medical Laboratories of the Collis P. Huntington Memorial Hospital of Harvard University at the Massachusetts General Hospital, Boston, Massachusetts)

(Received for publication September 25, 1946)

Recent work reported from this laboratory (1 to 7) has shown that clostridia grow and produce toxins readily in anoxic muscle *in vivo,* and that they are readily introduced into dog muscles during the course of traumatizing procedures. Moreover, our previous experiments have suggested that these and perhaps other bacteria may be responsible for a toxic factor contributing to shock in traumatizing wounds. Since clostridia are known to be frequent contaminants of war wounds (8, 9) it appeared desirable to study the physiologic action of clostridial toxins in order to determine whether these toxins could produce shock [4] alone or in synergy with blood or plasma loss following trauma.

Since the action of these toxins depends on the amount used, the route of injection, and the rate of injection, we have given attention to these variables. Wright (12) has criticized studies on the pharmacologic effects of *Cl. welchii* toxins in which large doses of toxin were administered rapidly, in a manner unlikely to have a parallel in the clinical disease. Study of the effects of the *Cl. welchii* toxic filtrate has a particular interest in that the specific enzymatic nature of its probable principal component (the alpha toxin or lecithinase) (13) and one of its minor components (hyaluronidase) (14) are known. The lethal properties of *Cl. welchii* (Type A) organisms appear to correlate well with their ability to produce the alpha toxin (15). It is therefore possible to interpret physiologic and pathologic effects of these toxins on the basis of their substrate specificities.

MATERIAL AND METHODS

Three preparations of *Cl. welchii* (Type A) toxins have been used: (1) glycerol dialyzed toxic filtrate of *Cl. welchii,* (2) a more purified lecithinase (alpha toxin) from *Cl. welchii,* and (3) a purified *Cl. welchii* hyaluronidase.[5] The glycerol dialyzed toxic filtrate has assayed from 500 to 1,760 mouse subcutaneous MLD (LD_{50}) per ml. in different batches. The Lb (biological limit) varied from 17 to 43 in the various filtrates. It was made by dialyzing sterile filtrates from *Cl. welchii* (Type A), strain BP6K, against glycerol for 18 hours at 4° C. This toxic filtrate has been found by Logan (16) to contain chiefly alpha toxin, a small amount of theta toxin (accounting for fewer than 5 out of a 1,000 MLD), and 100 to 200 viscosity reducing units and 2,000 to 6,000 mucin clot prevention units of hyaluronidase activity per ml. The *Cl. welchii* hyaluronidase preparation contained no demonstrable alpha toxin, 120 van Heyningen units of theta toxin, and greater than 6,400 mucin clot prevention units of hyaluronidase activity per ml. (16). Another enzyme, a decarboxylase, which converts histidine to histamine, frequently present in strains of *Cl. welchii* (17), was not found in the toxic filtrates used in these experiments.

In the majority of experiments, mongrel dogs weighing between 8 and 15 kgm. were fasted overnight, anesthetized intravenously with 30 mgm. of sodium pentobarbital per kgm. of body weight, and were maintained as indicated under light anesthesia by subsequent small doses of the anesthetic. The trachea was exposed and cannulated so that the oxygen consumption could be recorded by a spirometer; the right carotid artery was cannulated and attached to a recording mercury manometer; and the left external jugular vein was exposed so that a catheter could be inserted to the level of the right auricle, in order to obtain mixed venous blood samples and to measure

[2] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts General Hospital.

[3] Grateful acknowledgment is due the Josiah Macy, Jr. Foundation for a grant for the histopathological studies.

[4] We regard shock as a syndrome in which there is primarily a decline in the effective circulating blood volume, followed by a decrease in the minute volume output of the heart, an increase in peripheral vascular resistance, an eventual fall in mean arterial blood pressure and a progressive increase in tissue anoxia, resulting in death. This definition agrees with conceptions commonly held (10, 11).

[5] The first and third have been generously supplied by Dr. Milan A. Logan, and a limited quantity of purified alpha toxin was obtained through the kindness of Dr. A. M. Pappenheimer, Jr.

venous pressure. Femoral vessels were used for obtaining arterial blood and for intravenous injections. In addition to continuous recording of blood pressure, cardiac output was determined at intervals by Fick's principle, and total peripheral vascular resistance was calculated as the quotient: blood pressure/cardiac output. Body temperature was recorded by a rectal thermometer. Heparinized blood samples were taken to measure hemoglobin concentration, hematocrit, and plasma hemoglobin (when hemolysis was present). Hemoglobins were determined on the Evelyn photoelectric colorimeter using the 540 mu filter.

In several cases, electrocardiograms were taken, using the 3 customary leads. In one case, X-ray pictures were taken for cardiac size and configuration. Plasma volume determinations were performed by the T-1824 plasma dye dilution method (18). Plasma protein was estimated by micro-Kjeldahl nitrogen determination. Prothrombin times were done according to the method of Quick (19). All dogs were carefully autopsied and organ weights were recorded. Sections were routinely fixed in Zenker's solution. Certain tissues were fixed in 10 per cent formalin, and frozen sections were stained with Sudan IV for fat.

Cl. welchii toxic filtrate, which was stored in 30 per cent glycerol, was diluted 1:3 with physiologic saline solution before intramuscular injection, and a control experiment was done by using 10 per cent glycerol in saline. Intravenous administration was either "rapid" (the dose being given within 5 minutes) or "slow" (further diluted with saline and given by intravenous drip over a period of 2 to 3 hours). The level of free alpha toxin in the blood stream was followed by means of a modification of the egg yolk turbidimetric method of van Heyningen (20).

In tabulating results, dosages have been expressed in terms of mouse MLD per kgm. body weight. For comparison between the species, it will be recalled that the lethal dose for a mouse should be in the vicinity of 40 to 50 MLD per kgm.

The control dogs, listed in Table I, were treated in precisely the same way as the experimental animals, with the exception that toxic filtrate was omitted. A number of other controls were run, in which either *Cl. welchii* immunized dogs were used, or in which *Cl. welchii* antitoxin was mixed with the toxic filtrate prior to injection into the animal. The experiments on the effect of toxic filtrates on immunized animals will be discussed at length in a future communication (22).

RESULTS

Lecithinase (alpha toxin)

Purified *Cl. welchii* lecithinase (alpha toxin) was given intravenously to 2 dogs, and intramuscularly to 2 dogs. The results of intravenous administration were similar to those which will be described for the glycerol dialyzed perfringens filtrate: a dose of 40 MLD per kgm. caused almost complete hemolysis (terminal hematocrit 5 per cent) and death in 2 hours, with small amounts of hemolyzed pleural and ascitic fluid and massive intestinal bleeding noted at postmortem examination. Intramuscular administration (60 to 90 MLD per kgm.) resulted in only a very small amount of local edema after 5 hours, in contrast to massive swelling produced by the whole perfringens toxin. This could be due to the absence in the purified alpha toxin of some accessory factor, such as hyaluronidase.

Glycerol dialyzed Cl. welchii *(Type A) toxic filtrate*

Intravenous route: Nineteen dogs were given various amounts of *Cl. welchii* toxic filtrate intravenously, ranging from 6 to 800 MLD per kgm. When lethal doses (over 50 MLD per kgm.) were given, a fairly constant physiological picture resulted. Following rapid injection of large doses, the blood pressure fell precipitously to 30 to 40 mm. Hg within 5 to 10 minutes, and then maintained this level for an hour or more before the terminal decline. When smaller amounts of toxic filtrate were given, or when it was given more slowly, there was no immediate response of the blood pressure, but the pressure declined more gradually.

Table I summarizes a number of changes occurring in animals in this group. It will be observed that the cardiac output, blood pressure, hemoglobin, and hematocrit show significant declines prior to death of the animal. There was, however, no significant change in the peripheral vascular resistance. A decrease in the whole blood hemoglobin and hematocrit levels provided the earliest consistent reflection of the downward trend of the animal. Figure 1 illustrates the interrelationships of these data in a typical animal.

In 2 cases, the level of free alpha toxin in the blood stream was followed by van Heyningen's method (20), while toxin was administered by slow intravenous drip. The rise in the level of free alpha toxin in the blood stream was paralleled by a rise in the plasma hemoglobin and a fall in the hematocrit. In 10 out of the 12 dogs receiving a lethal dose of toxin (in which plasma hemoglobin was quantitated), the plasma was deep red, and the plasma hemoglobin reached levels between 1 and 7 grams per cent. Plasma protein concentration

I.V.—Intravenous.
I.M.—Intramuscular.
P—Is the probability that the changes, as compared with the control series, are due to chance (35). Only the statistically significant figures are given.
* Control II was taken 30–60 minutes after Control I.
** Terminal denotes the last value obtained prior to death. Other details given in footnote, Figure 1.
† Killed.

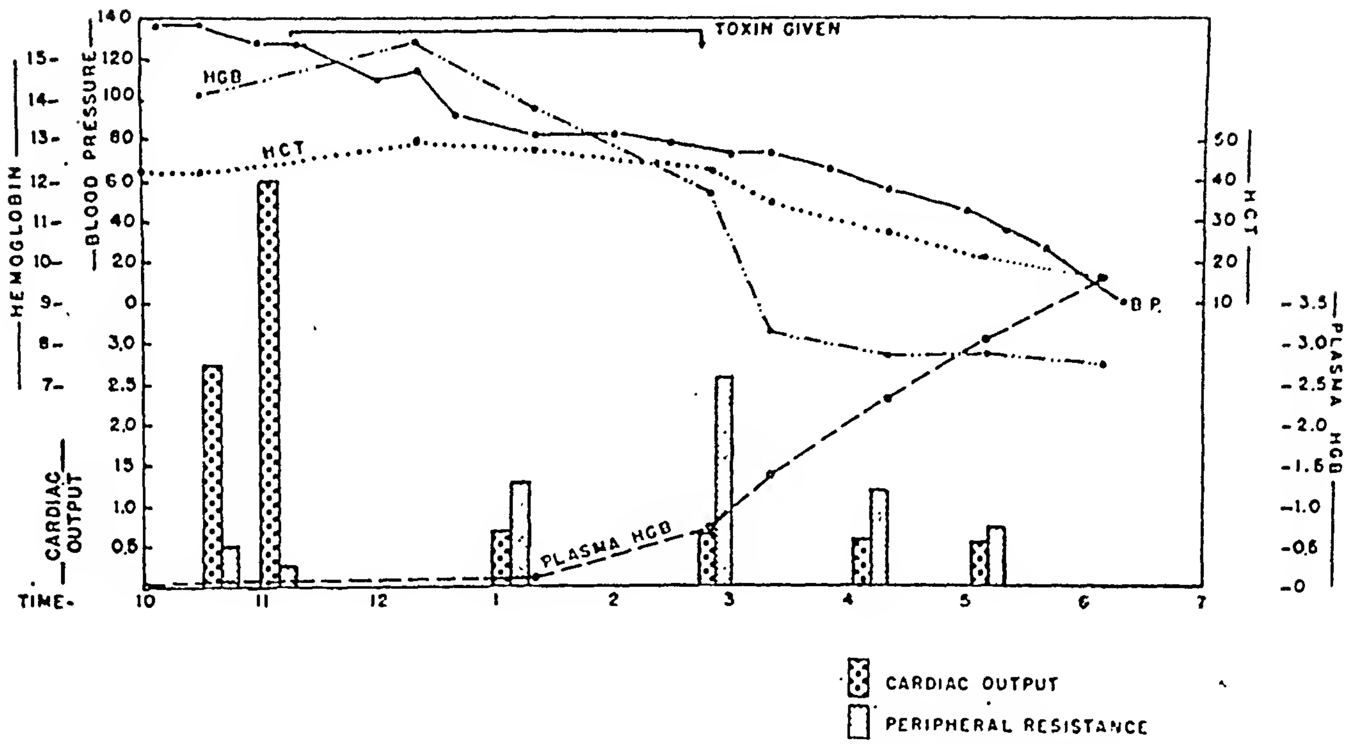

FIG. 1. EFFECT OF *Cl. welchii* TOXIC FILTRATE, ADMINISTERED BY SLOW INTRAVENOUS DRIP

The cardiac output is expressed in liters per minute. The relative peripheral vascular resistance is expressed in arbitrary units as the quotient: blood pressure in mm. mercury/cardiac output in liters per minute. The hemoglobin is expressed as grams per cent.

was measured in 4 such dogs, and (exclusive of hemoglobin) showed no significant change. Plasma volume dye studies were unsatisfactory due to the large amount of hemolysis. No significant change in temperature was observed.

In 4 dogs, electrocardiograms were taken at intervals, after administration of toxic filtrate, up to death 4 to 6 hours later, and failed to show evidence of myocardial damage. X-rays of the heart taken in one animal showed no change in size or configuration as a result of the toxic filtrate. The venous pressure, obtained from the region of the right auricle, was never increased.

Blood clotted poorly following venepuncture in the terminal stages after administration of toxic filtrate. The prothrombin time was tested in 4 dogs given *Cl. welchii* toxic filtrate, with the following results (*cf.* Table II).

Intramuscular route: Twenty-six dogs were injected intramuscularly into one or both triceps surae muscles with *Cl. welchii* toxic filtrate and leg volumes were made on 21 of these animals, according to a technique previously described (4). The most striking effect of the toxins was the development of massive edema, which spread out visibly from the injection site within an hour of the injection and reached a maximum 8 to 16 hours later. By measurement of the increase in volume of the thighs, an estimate of the minimal fluid loss into the limbs was made during a period of 5 to 8 hours after injection. The edema accumulating during this period amounted roughly to 1 to 3 per cent of the body weight, which therefore corresponds to a considerable fraction of the plasma volume. Hemoconcentration was a constant finding, as evidenced by an increase in hematocrit and

TABLE II

Dog no.	Type toxin	Result	Prothrombin time in seconds	
			Before toxin	After toxin
234	alpha	survived (sublethal dose)	13	15
235	alpha	died	13	76
238	glycerol dial. Logan	survived (sublethal dose)	26	81
239	glycerol dial. Logan	died	15	74

a decrease in plasma volume. A consistent fall in cardiac output was present by the sixth hour after injection. The interrelationships of these data are summarized in Tables I and III. It should be pointed out with respect to the intramuscularly injected dogs represented in these tables, that they seldom went into shock in the limited observation period of 6 to 8 hours during which they were under anesthesia and cannulation. The blood pressure (*cf.* Table I) showed no significant change in this group of animals. Two control dogs, injected with 300 MLD per kgm. of toxin mixed with 300 units of antitoxin.[6] showed none of these effects. Only 5 dogs in the series showed any hemolysis, and, in all but 1 case, the hemolysis was under 0.2 gram per cent. Figure 2 illustrates the typical result of this kind of experiment.

* The lack of correlation between the amount of edema and death of the animal is evident here. It is possible that the toxins reached the general circulation in these instances. Among our control animals an occasional death was attributed to a combination of anesthesia and operative manipulations.
** B. W. signifies body weight.
† Due to blood loss from sampling, plus estimated vascular fluid loss as a result of edema.
‡ Immunized animal (22).

To determine whether the toxic filtrate, when injected intramuscularly, produced general circulatory damage as well as local plasma loss, the following experiments were done:

1. Five dogs injected intramuscularly were treated by administration of 5 per cent bovine albumin[7] in amounts sufficient to maintain normal plasma volume and hematocrit values. Eight control (uninjected) dogs were maintained under similar experimental conditions. Six of these controls were also given albumin to prevent the hemoconcentration which usually occurs in dogs anesthetized with sodium pentobarbital under these conditions. The remaining 2 were untreated.

2. Two intramuscularly injected dogs were allowed to go 5 to 6 hours without treatment; at the end of this period sufficient albumin was given to replace lost plasma and blood. Before the albumin was given, tourniquets were placed around both thighs to prevent further local plasma loss.

3. In 2 dogs, casts (Castex) were placed around both legs extending from the foot pads to the groin. The toxic filtrate was injected through the casts into the triceps surae muscles. Since extensive swelling occurred above the casts (in the regions of the abdominal and gluteal muscles where the amount of swelling could not be quantitated), one was given constant albumin injection, as in (1) and the other was given a terminal albumin injection, as in (2).

The results of these experiments indicated that the decrease in cardiac output which occurred following administration of *Cl. welchii* toxic filtrate intramuscularly could largely be explained by the local loss of plasma into the muscle and subcutaneous tissue in the vicinity of the injection site. Replacement of this plasma loss restored the normal cardiac output temporarily, but did not prevent further plasma loss into the damaged area. In fact, the fluid loss appeared to be somewhat increased by administration of plasma albumin, although the cardiovascular state was better maintained (*cf.* Table III). Edema formation was not prevented by the application of casts, as it extended

[6] Lederle's polyvalent gas gangrene antitoxin.

[7] The authors wish to express their indebtedness to Professor Edwin J. Cohn for generous supplies of purified bovine albumin.

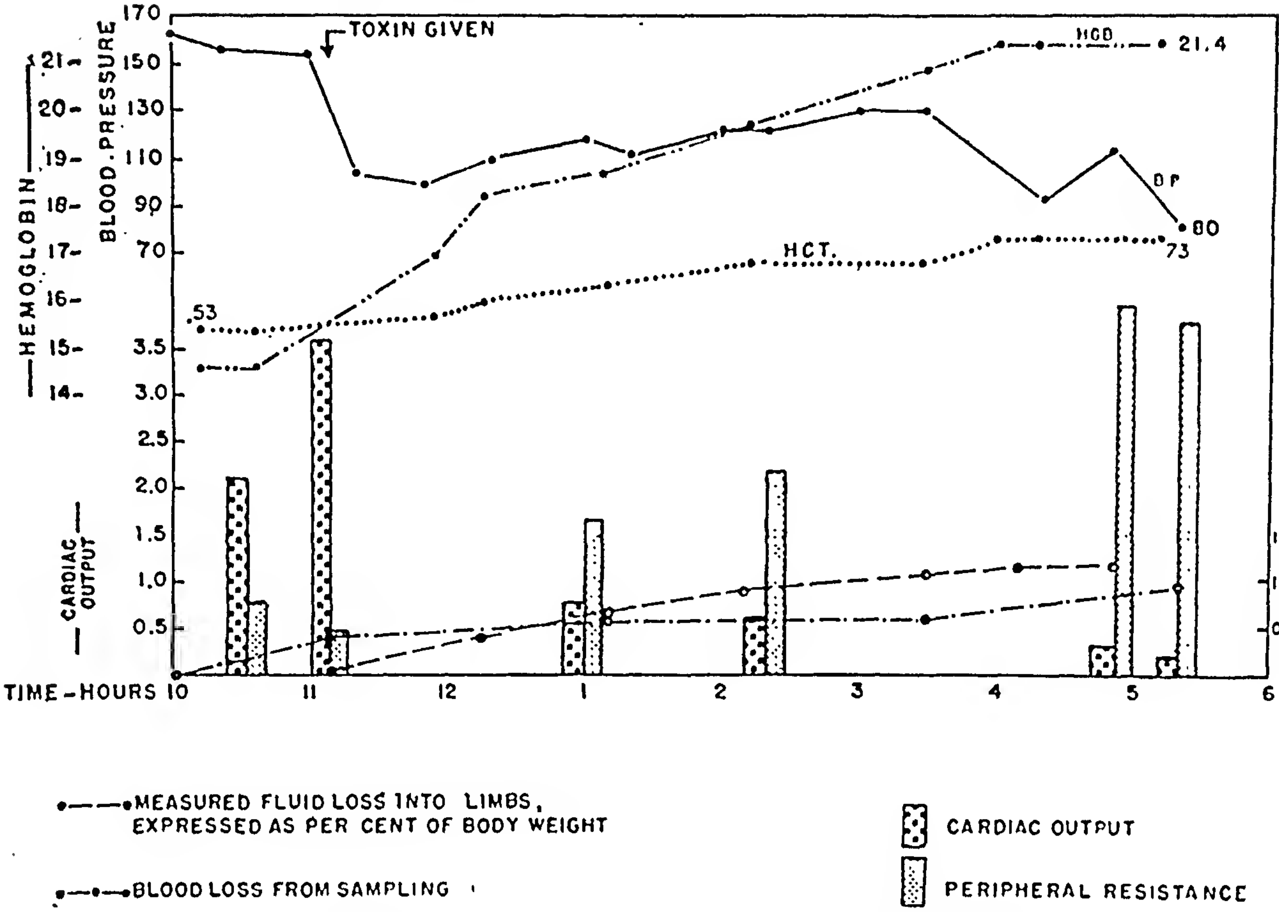

FIG. 2. EFFECT OF *Cl. welchii* TOXIC FILTRATE GIVEN INTRAMUSCULARLY
The blood loss is expressed as per cent of body weight. Other data are expressed as noted in Figure 1.

beyond their confines, occurring in the gluteal, perineal, and retroperitoneal regions if casts were placed about both lower extremities, and toxin was injected through the casts into the underlying musculature. In this case, in a small area immediately adjacent to the injection site, there were muscle necrosis and hemorrhage, but the casted portion of the extremity was edema free.

Three dogs injected subcutaneously with *Cl. welchii* toxic filtrate presented a picture of local edema without detectable generalized effects, similar to the situation seen with the intramuscular injection.

Cl. welchii *hyaluronidase, intramuscular route*

Five-tenths ml. of hyaluronidase was injected into each triceps surae muscle group of an anesthetized dog. During the following 6 hours there was no evidence of generalized effects of the toxin on the cardiac output, peripheral resistance, pulse, respiration, or temperature. There was an area of edema and extravasation of blood 6 cm. in diameter in the region of the injection sites, but no generalized edema of the extremities. Postmortem examination was otherwise completely negative.

Pathologic findings [8]

Cl. welchii toxic filtrate given intravenously in lethal dosage to non-immunized dogs: lungs and liver showed marked congestion and edema. The weights of the lungs were significantly greater than those of control dogs (21). The small intestine, spleen, and kidneys revealed similar findings to a lesser degree. Twenty to 50 ml. of hemolyzed fluid was found in the pleural and peritoneal cavities. Where a similar dosage of toxic filtrate was given to dogs previously immunized there was no congestion of lungs, liver, or other organs. An interesting finding in such animals, however, was the presence of considerable numbers of polymorphonuclear leucocytes in the walls of the pulmonary and adrenal capillaries.

[8] The authors are indebted to Dr. Benjamin Castleman for reviewing and interpreting the pathologic findings.

Cl. welchii toxic filtrate given intramuscularly in lethal dosage to non-immunized dogs: there occurred necrosis and liquefaction of the injected muscle in the vicinity of the injection site, with extensive edema of the surrounding muscle and fascia, and a lesser degree of edema of neighboring muscles. The duodenum showed a marked capillary engorgement. The lungs, liver, adrenal, and spleen were negative. Marked cloudy swelling of the kidney was seen in one animal in this group (No. 240). An excellent, detailed description of the effects of the filtrate on muscle has been given by Robb-Smith (23).

Pathologic findings associated with intravenous injection of *Cl. welchii* toxins have been reported previously (24 to 27). There appears to be some variation among the animal species (dogs, mice, rabbits, guinea pigs) used by the various investigators, in the sensitivity of the erythrocytes to hemolysis and in the localization of the sites of major hemorrhagic manifestations.

DISCUSSION

An attempt has been made to vary the dose, the rate, and the route of administration of *Cl. welchii* toxic filtrate in order to gain a better understanding of its action on the animal. It is impossible to say what quantity of toxic filtrate might be elaborated in gas gangrene or clostridial myositis. It is therefore difficult to transfer information provided by the present experiments to the human problem. It is probable, however, that the closest simulation of clinical conditions is achieved where a relatively small dose of toxic filtrate is administered intramuscularly. Such injections have been demonstrated to evoke vascular fluid loss of considerable proportions. The additive effect of this fluid loss may be sufficient to convert into shock a traumatic condition which would not ordinarily produce this syndrome. Furthermore, the local damage to capillaries resulting from the toxins is long-lasting. If primary shock is averted by adequate therapy, clostridial toxins may introduce the possibility of delayed or secondary shock as a result of continuing fluid loss from damaged capillaries.

The action of the toxic filtrate, administered either intravenously or intramuscularly, is consistent with the damaging effect its lecithinase component might theoretically be expected to have on cell surfaces. In the case of the erythrocyte, the result is rupture of the cell wall; in the case of the vascular endothelium, the result is leakage of whole blood or plasma through a damaged membrane.

It is worth calling attention to the point that either purified *Cl. welchii* alpha toxin or purified *Cl. welchii* hyaluronidase in the absence of the other produced little edema during a 6-hour interval when injected intramuscularly. The edema-forming power of a filtrate containing these 2 toxins (plus a small amount of theta toxin and possibly other unknown toxins) was, however, very great during this time interval. This observation is of interest in connection with the finding of McClean (28) that *Cl. welchii* is able to use hyaluronic acid as a metabolite.

A number of other effects of *Cl. welchii* toxins (Type A) have been described and are discussed in recent reviews on the subject (29, 12). The observation (25) that toxic filtrates of all 4 types of *Cl. welchii* liberate adenyl compounds is especially interesting and may be related to the rupture of cell membranes as a result of the action of the alpha toxin. The recent findings of Cooke *et al.* (9) that fat embolism may occur as a result of *Cl. welchii* myositis suggest that the breakdown products of damaged cells may contribute to the generalized effect of the toxins, even though the toxins themselves may not enter into the general circulation to an appreciable degree.

MacLennan and Macfarlane (30, 31) have been led to consider the possibility "that the profound toxaemia of gas-gangrene is not due solely or primarily to alpha toxin." They point to the ineffectiveness of antitoxin in preventing a lethal outcome once the infection is well established and raise the question as to "whether death is due to the products of tissue breakdown rather than the direct action of bacterial toxin." While the present experiments do not conflict with this interpretation, they offer an additional explanation for the lack of effectiveness of antitoxin in well established cases of gas-gangrene, based on the following 3 points: (*1*) The large amount of fluid lost in clostridial myositis is not repaired by administration of antitoxin. The continuation of fluid loss from damaged blood vessels is likewise

not prevented, since the antitoxin is unable to reverse damage which has already occurred. (2) It has been recently found in this laboratory (32) that once the *Cl. welchii* lecithinase is in contact with its substrate, lecithin, it becomes difficult for antitoxin, when added to the reaction mixture, to prevent the enzymatic process from continuing. It appears that the lecithin and antitoxin compete with each other for the lecithinase. This finding offers a partial explanation for the lack of effectiveness of antitoxin when the disease is well established (*i.e.* when a large amount of lecithinase is in contact with its substrate). (3) It has been found possible to protect mice and dogs from a lethal intravenous dose of *Cl. welchii* filtrate by means of lecithin or total lipids if these are given either in advance of or shortly after the filtrate (33). It is probable that the lecithin protects the animal (by a substrate partition effect) only from the lecithinase component of the filtrate. One may conclude that the lecithinase is in this instance the principal toxic component of the filtrate.

On the other hand, purified alpha toxin produced little edema on intramuscular injection into our dogs. This evidence suggests that collagenase (31), unknown toxins, or a synergistic effect of the combination of toxins plays important roles in the production of edema when a toxic filtrate is given intramuscularly.

An interesting teleological point is raised by the experiments of DeKruif and Bollman (34), who found that the capacity of *Cl. welchii* to invade the animal body was largely dependent on its power to produce toxin. Washed *Cl. welchii* bacilli or spores were infective only in very large numbers; if non-lethal quantities of toxin were added to organisms, only 1/10,000 of the quantity of washed spores or bacilli was necessary to kill the animal. The alpha toxin or lecithinase appears to serve the *Cl. welchii* organism by destroying the surface of animal cells, making the interior available for the nutrition of the *Cl. welchii* organism.

The possibility that effects ascribed to the toxins might be due to substances used in the bacterial culture media has been ruled out by the prevention of these toxic effects both by active immunization of animals and by administration of antitoxin in advance of the toxin (22).

SUMMARY

A number of characteristics of the syndrome of traumatic shock may be produced by *Cl. welchii* (Type A) toxic filtrate given by either intramuscular or intravenous route. Intravenous injection results in intravascular hemolysis, decline in cardiac output and blood pressure, increase in prothrombin time, edema and hemorrhage into the lungs and small intestine, and congestion of the liver, spleen, and kidneys.

Intramuscular or subcutaneous injection is followed by massive edema spreading from the injection site and by severe hemoconcentration. The effects of the toxic filtrate given by this route are chiefly local, and the lack of hemolysis is evidence of the inability of the alpha toxin to reach the general circulation in appreciable concentration.

Purified *Cl. welchii* alpha toxin injected intramuscularly produced little edema. Purified *Cl. welchii* hyaluronidase similarly had little effect on intramuscular injection. The edema-forming property of the unpurified *Cl. welchii* toxic filtrate thus appears to be due to the presence of other toxins or to a synergistic effect of a combination of toxins.

Cl. welchii toxins may play an important role in certain cases of traumatic shock by aggravating fluid loss into the injured region.

The authors gratefully acknowledge the cooperation of Doctors Austin M. Brues and Alfred Pope in the early portion of this work. They are indebted to Mrs. Jean Rubin, Mrs. Barbara Barus, and Miss Lydia Brewster for valuable technical assistance.

P.—Is the probability that the observed changes are due to chance (18). Only the statistically significant figures are given. Data on the control series of animals are given in the preceding paper (14). Other details given in footnote, Figure 1.

* Control II was taken 30–60 minutes after control I.

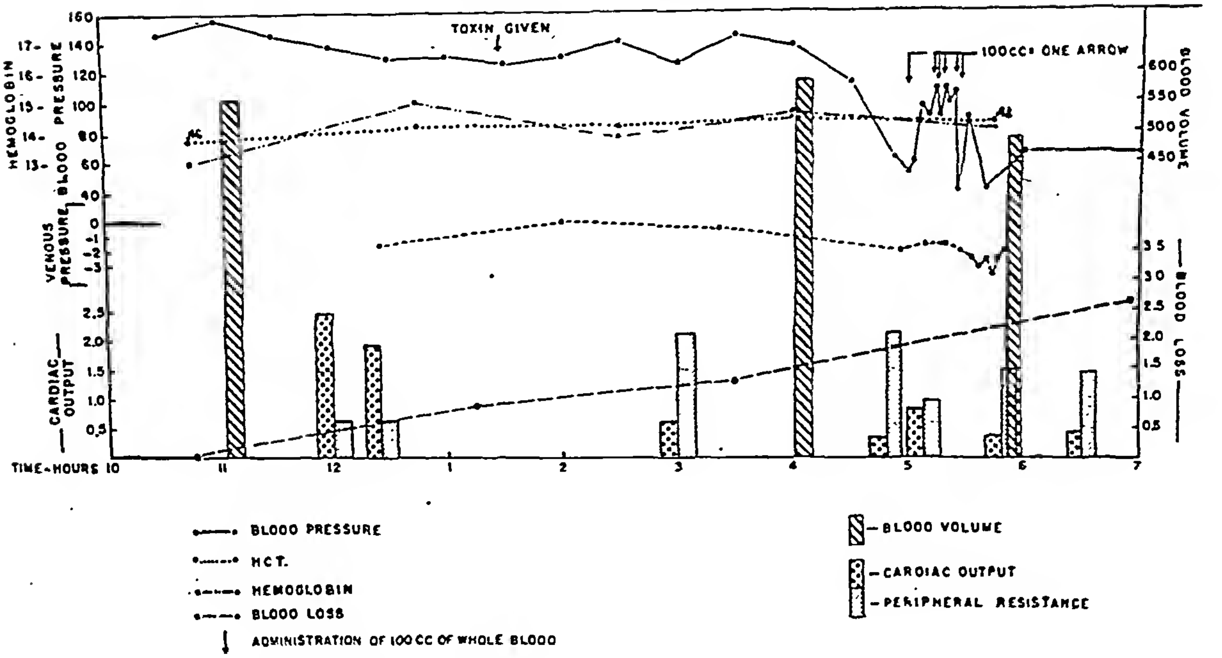

FIG. 1. EFFECTS OF *Cl. oedematiens* TOXIN ADMINISTERED INTRAVENOUSLY

The cardiac output is expressed in liters per minute. The relative peripheral vascular resistance is expressed in arbitrary units as the quotient: blood pressure in mm. mercury/cardiac output in liters per minute. The hemoglobin is expressed as grams per cent. The blood volume is given in cubic centimeters, and the blood loss as per cent of body weight.

ment of a massive edema, which spread from the injection site.

Pathology:[7] The gross autopsy findings associated with intravenous administration of *Cl. oedematiens* toxin in lethal dosage to non-immunized dogs consisted of the following: edema and hemorrhage into the lungs; congestion of the liver; hemorrhage into the adrenals; congestion and submucosal hemorrhage into the small intestine, particularly into the duodenum; small, subendothelial hemorrhages into the cardiac musculature, especially near the attachments of the chordae tendineae. The spleen was uniformly small and contracted. The weights of organs in animals receiving *Cl. oedematiens* and *Cl. welchii* toxins have been recorded in Table II. The liver, lungs, and small intestine showed significant increases in weight, and the spleen a significant decrease, when a lethal dose of *Cl. oedematiens* toxin was given intravenously. If the average change in organ weight is used it appears that there is an increase in weight of the above organs, including the spleen, totalling 2.1 per cent of the body weight. This weight increase, if due to trapping and extravasation of blood into these organs, could represent 20 per cent of the total blood volume.

The microscopic sections revealed a marked engorgement throughout the lungs and viscera, particularly in the former.[8] Capillaries and venules in the submucosal region of the duodenum were extraordinarily dilated and engorged with blood. The mucosa and submucosa of the stomach were spared, and a clear-cut line of demarkation appeared at the pylorus between the relatively normal pallor of the stomach and the red blush of the duodenal mucosa.

Immunized animals (17) injected intravenously with a lethal dose of *Cl. oedematiens* toxin revealed little if any engorgement of blood vessels

[7] According to Doctor A. C. Ivy (15), the capillaries of the duodenum of the dog have been known to be especially sensitive to various toxic substances ingested or produced in the body. The peculiar blood supply of the villi in the duodenal mucosa in the dog (16) appears to offer the best explanation of this phenomenon.

[8] The authors are indebted to Dr. Benjamin Castleman for reviewing and interpreting the microscopic findings.

in the lungs or viscera. Polymorphonuclear leucocytes were found in considerable numbers in the walls of the pulmonary and adrenal capillaries, presenting a picture similar to that seen in immunized animals injected intravenously with *Cl. welchii* toxin (15).

Cl. oedematiens *toxin intramuscularly* (8 dogs)

Following intramuscular injection of toxin into the thigh muscles in dosages ranging from 150 to 12,000 MLD per kgm., there was a latent period of approximately 6 hours, during which little of significance was observed. From this time on there developed an increasing local edema which spread both up and down the thigh, eventually presenting itself in the retroperitoneal, gluteal, perineal, and neighboring regions. This edema became maximal at 18 to 24 hours, associated with a severe hemoconcentration, the hematocrit reaching values up to 75. The animals became progressively sluggish, developed bloody diarrhea, and died 18 to 38 hours after injection. In 1 dog, injected with a 12,000 MLD per kgm. dose of toxin, death occurred in 10 hours, and the amount of edema was not striking, amounting to 1 per cent of the body weight. This latter finding suggests that death of the animal cannot be accounted for on the basis of local fluid loss alone, but that a generalized toxemia is probably present when the intramuscular dose of toxin is enormous.

In 2 dogs injected with a 150 MLD per kgm. dose of toxin, leg measurements were made, with the following results:

Dog no.	Survival time	Terminal edema (per cent body weight)	Hematocrit	
			Control	Final
388	17 hrs.	5	50	73
324	32 hrs.	7	—	62

The amount of edema was increased if the same quantity of toxin was injected fractionally into several sites.

In order to determine the minimum dosage of toxin which would produce edema by the intramuscular route, all 4 legs were injected in a single dog weighing 13 kgm. The volume of fluid injected into a single limb was kept constant at 5 ml. The dosage of toxin injected ranged, however, from 80 MLD to 10 MLD per kgm. Eighteen hours later, there was massive edema (360 ml.) of the limb where the 80 MLD per kilogram dose had been given; moderate edema (210 ml.) in the limb given 40 MLD per kgm.; minimal edema (70 ml.) in the limb with 20 MLD per kgm.; and no visibly recognizable edema (40 ml. by measurement) in the limb given 10 MLD per kgm.

Pathology associated with intramuscular injection of toxin

Local effects: At the site of injection, there was an area approximately a centimeter in diameter where the muscle substance had been almost completely disintegrated. The surrounding muscle tissue was edematous, with separation of the muscle fibers by edema. Small, flame-shaped hemorrhages in countless number were present along

the course of the dilated and engorged smaller branches of the blood vessels supplying muscle tissue near the injection site. Edema was greatest in the fascial spaces and subcutaneous tissue.

Distant effects: There was 20 to 30 ml. of straw-colored fluid in the pleural and peritoneal cavities. The lungs and visceral organs showed much the same picture although less pronounced than that produced by the intravenous route of injection.

Effect on eyes

One MLD of toxin was injected into the corneae of each of 4 rabbits' eyes.[9] Eighteen hours after injection, there was marked chemosis of the conjunctival blood vessels. By means of slit lamp illumination and the high-power dissecting microscope, tiny flame-shaped hemorrhages were seen extending out from a number of the vessels. There were dilatation and engorgement of all vessels.

DISCUSSION

Experiments on the effect of *Cl. welchii* toxic filtrates (14) have demonstrated that the dosage, rate, and route of administration of the toxins determine the type of effects on dogs. The same considerations apply to the present studies on *Cl. oedematiens* toxin. Rapid intravenous administration of a large dose of toxin is a situation far different from the slow elaboration of the toxin by organisms multiplying in a damaged muscle. Intramuscular injection of a small, sub-lethal dose of toxin appears to approach the clinical situation most closely. Here the effect of the toxin is principally local, resulting in edema and hemoconcentration. Such a picture of *Cl. oedematiens* myositis, predisposing to wound shock, has been observed in forward field hospitals (18).

The data gathered on the effects of this toxin after intravenous injection, are consistent with the interpretation that the principal site of its action is on the peripheral vascular system. The toxin appears to act by causing loss of tone and damage to capillaries and other small blood vessels. As a result, the smaller vessels of the lungs and viscera become engorged with blood which then extravasates into surrounding tissues. The quantity of blood actively circulating is thereby decreased, and a fall in cardiac output occurs. There is a compensatory peripheral vasoconstriction, probably in the arterioles, resulting in an increased peripheral resistance. The extravasation of fluid and blood into the pulmonary alveoli produces an interference with oxygenation of the blood which eventually assumes critical proportions. The blood pressure remains unchanged until a point is reached where trapping of blood out of the active circulation and interference with oxygenation become too great for compensation. The blood pressure then falls to shock levels and death follows.

The possibility that the effects observed may be a non-specific foreign protein reaction is ruled out by the protective effect of antitoxin when given intravenously simultaneously with the toxin and by the complete protection against either intravenously or intramuscularly injected toxin provided by active immunization (17).

When the toxin is injected intravenously, blood vessels throughout the animal are exposed to the toxin, and the lungs and visceral organs suffer particularly. On intramuscular injection, however, blood vessels adjacent to the injection site are exposed first and come into contact with the greatest concentration of toxin. This correlates with the observation that edema into the injected area becomes the outstanding feature.

The clinical picture which this toxin produces when injected intravenously is that of shock—apparently as a consequence of 2 factors: (*1*) trapping of whole blood in the viscera, rendering it unavailable to the circulation as a whole; and (*2*) extravasation of plasma and whole blood into vital organs through damaged capillaries. Addition of fluid to the circulatory system under these conditions does not restore the animal to normal, although it has a temporary beneficial effect until the additional fluid has likewise been lost from the circulation.

The inability of antitoxin to protect the animal when given more than a few minutes after the toxin suggests that the toxin produces some irreversible action on the blood vessel wall. One is tempted to reason from analogy with the action of *Cl. welchii* alpha toxin that *Cl. oedematiens* toxin (which appears to be protein in nature) may be an enzyme which acts on cell surfaces, destroy-

[9] These experiments were carried out in collaboration with Dr. David Cogan.

ing some architectural unit of the surface structure. Once the damage is done, antitoxin may neutralize the effects of the toxin still circulating, but the initial damage is irreparable.

The possibility that myocardial failure might contribute to the circulatory failure has not been completely eliminated in these experiments. However, it has been shown by means of heart-lung preparations (19) that the cardiac ability and reserve are adequate up to the very end.

SUMMARY

Cl. oedematiens toxin administered intravenously produced the following picture: a latent period of one or more hours without noticeable change, followed by a progressive rise in peripheral vascular resistance, a fall in cardiac output, and eventually a decline in blood pressure to shock levels and death. Edema and hemorrhage in the lungs and visceral organs were constant findings. *Cl. oedematiens* toxin produced massive local edema, hemoconcentration, and eventual death, when administered intramuscularly in small dosage.

Intravenous fluids were of no permanent benefit in this syndrome. Under the conditions used, antitoxin did not prevent the lethal outcome if given more than 5 minutes after injection of the toxin.

The authors gratefully acknowledge the cooperation of Doctors Austin M. Brues and Alfred Pope in the early portion of this work. They are indebted to Mrs. Jean Rubin, Mrs. Barbara Barus, and to Miss Lydia Brewster for valuable technical assistance.

THE INFLUENCE OF ANTITOXIN UPON THE ACTION OF *CLOSTRIDIUM OEDEMATIENS* TOXIN IN THE HEART-LUNG PREPARATION OF THE DOG [1, 2, 3]

By OTTO KRAYER, JOSEPH C. AUB, IRA T. NATHANSON, AND PAUL C. ZAMECNIK

(From the Department of Pharmacology, Harvard Medical School; and the Medical Laboratories of the Collis P. Huntington Memorial Hospital of Harvard University at the Massachusetts General Hospital, Boston, Mass.)

(Received for publication September 25, 1946)

Previous experiments (1) have indicated that *Cl. oedematiens* toxin produces types of dynamic effects similar to those seen in traumatic shock. Blood volume was not diminished to the same extent as in hemorrhagic shock, but the peripheral vascular resistance rose and the cardiac output was reduced in the characteristic manner. It was not obvious, in the intact dog, whether these difficulties arose in the peripheral circulation or in the heart. Wiggers (2) has discussed a similar type of problem with reference to shock. Thus, in order to evaluate more specifically the factors involved in the circulatory failure resulting from *Cl. oedematiens* toxin, the heart-lung preparation has been utilized.

METHODS

The experiments were carried out on the isolated heart and lungs of the dog in the form of the heart-lung preparation as described by Patterson and Starling (3). Mongrel dogs were used in all experiments and weighed between 7.8 and 11.3 kgm. They were anesthetized for the surgical procedure with sodium pentobarbital in a dose of 35 mgm. per kgm. body weight. The period of preparation was timed so as to be about of equal duration in all experiments and was approximately 1 hour from the time of the first skin incision to the start of recording. The blood temperature varied in the various experiments not more than between 37 and 39° C. and in the same experiment not more than ± 1° C. The method of recording right auricular pressure, pulmonary pressure, and output is described in detail by Krayer and Mendez (4). In the various experiments arterial resistance was between 75 and 85 mm. Hg, assuring a mean aortic pressure of about 100 mm. Hg when the systemic output under basal conditions of blood supply was kept between 400 and 500 ml. (systemic output is output of left ventricle minus coronary flow). The competence of the heart was tested by increasing venous blood supply. This was achieved by raising the level of the blood in the venous reservoir in two steps of 50 mm. each as described in detail by Krayer (5). In the normal heart, at the beginning of the experiment, this led to an increase of systemic output of 40 to 50 per cent of the basal value at the first step, and of 80 to 95 per cent of the basal value at the second step. While the main increase in the work of the heart thus represented an increase in volume work, a certain amount of increase in pressure work was also involved in this competence test, as the arterial resistance was not changed throughout the experiment; and the mean blood pressure, therefore, increased somewhat with an increase in systemic output; likewise pulmonary arterial pressure increased. The increase of pulmonary pressure in experiments of this type becomes more and more pronounced as anatomical changes begin to appear and eventually lead to lung edema. In the present series of experiments, competence tests were made at intervals of approximately 30 minutes until the limit of competence was reached. By definition we consider this to be the case when an increase in venous supply by raising the level of blood in the venous reservoir by 50 mm. no longer leads to an increase in systemic output (5).

Defibrinated blood, taken from a bleeder dog, was used to fill the heart-lung system. The total blood volume usually amounted to 800 to 900 ml. at the beginning of the experiments.

Hematocrit determinations were done by taking 10 ml. of defibrinated blood from the heart-lung system and subjecting the blood to centrifugation at 2,400 revolutions per minute for 15 minutes.

Artificial respiration was carried out with the Starling respiratory pump, using room air; the stroke volume was kept between 125 and 150 ml., and the rate of ventilation was between 14 and 18 per minute.

Twenty-one experiments were conducted, in 16 of which *Cl. oedematiens* toxin was administered. This was given into the blood stream before it entered the venous reservoir, to ensure good mixing with the blood before it

[3] Grateful acknowledgment is due the Josiah Macy, Jr. Foundation for a grant for the histopathological studies.

reached the heart. The dose was 10 or 20 mgm. of *Cl. oedematiens* toxin preparation (45N), 2,500 mouse subcutaneous MLD per mgm., or 100 mgm. *Cl. oedematiens* toxin (N313), 500 mouse subcutaneous MLD per mgm.[4] The material was dissolved prior to the administration in 10 ml. of 0.9 per cent sodium chloride solution and/or in phosphate buffer of pH 7.4. The administration of the toxin was made at the basal inflow level and within a period of about 1 minute. Histamine content of the 2 toxin samples was checked with the use of isolated strips of guinea pig's ileum. The highest concentration tested was 1:15,000. The rise in tone of the gut was not characteristic and was very much less than that due to histamine dihydrochloride 1:60 million.

The antitoxin was a polyvalent preparation (Lederle). It was given in a dose of 7 ml. in 8 experiments and was administered within approximately 30 seconds.

Dogs in 3 experiments were actively immunized against *Cl. oedematiens* toxin according to technics described in detail elsewhere (6). In one of the experiments (Experiment No. 7) the bleeder dog as well as the dog used for the heart-lung preparation was actively immunized, and no antitoxin administered during the course of the experiment. The immunization was carried out as follows: the bleeder dog was immunized with four 1-ml. subcutaneous injections of *Cl. oedematiens* toxoid (Lederle No. 100 × 18A), injections being given at 3-week intervals. The heart-lung preparation dog (H.L.P.) was immunized similarly, with the exception that injections were given at weekly intervals. In Experiment No. 16 the H.L.P. dog was immunized. The bulk of the immunized blood was removed, 500 ml. of blood from a normal dog was then given into the H.L.P. and again removed to the greatest extent ("washout"), and fresh blood from a normal dog was then added to carry out the experiment. In Experiment 17, the H.L.P. dog was a normal animal. The normal blood was removed and the "immunized" blood from the H.L.P. dog of Experiment 16, together with the "washout," was used to carry out the experiment. The H.L.P. dog of Experiment 16 was immunized with *Cl. oedematiens* toxoid (Novyi, No. 101 × 18A, Lederle Laboratories). The dog was given 9 subcutaneous injections of 1 ml. of this toxoid at weekly intervals. In addition it received a dose of 1,250 MLD *Cl. oedematiens* toxin per kgm. intramuscularly, as a booster dose, a week before it was used for the heart-lung preparation.

Five experiments within this series were carried out as controls, using the identical procedure of preparation and testing of competence, but without administering either antitoxin or toxin.

At the end of several experiments, specimens of heart and of lung tissue were taken for pathological studies. They were fixed in Zenker's fluid and were stained with phloxine-methylene blue.

[4] The authors are indebted to Professor Milan A. Logan, University of Cincinnati, for generous supplies of *Cl.*

RESULTS

1. *The action of toxin*

(All the results are given in Figure 1.) When toxin was added to the blood of the heart-lung preparation, no noticeable change in right auricular, pulmonary pressure, or competence occurred for a period of 30 to 50 minutes. After this, within a period of a quarter of an hour, pulmonary pressure increased and simultaneously the lungs became more rigid, indicating the onset of lung edema. In 3 experiments (Experiments 1, 2, and 3) with a dose of 10, 20, and 20 mgm. of 45N toxin respectively, severe lung edema terminated the experiment within 65 to 75 minutes after the addition of the toxin. In Experiments 18 and 19, after the addition of 100 mgm. of *Cl. oedematiens* toxin N313, severe lung edema terminated the experiment after 51 and 52 minutes respectively. No test of competence was performed in Experiment 19 after the administration of the toxin. As can be seen from Figure 1, heart-lung preparations made in the same way but not under the influence of toxin have a long survival time. Five control experiments (Nos. 13, 14, 15, 20, and 21) are plotted in the graph, so that the time 30 minutes after starting the recording arbitrarily was called zero time (since the time between the start of recording and addition of toxin in all the toxin experiments in Figure 1 averaged approximately 30 minutes). In 4 control experiments (13, 14, 15, and 20) it took between 140 and 165 minutes to reach the limit of competence; in Experiment 21, it took 210 minutes. The limit of competence was used as an end point, since, as a rule, lung edema does not terminate a heart-lung preparation before the end of 3 hours or more. Signs of marked lung edema were present only in Experiment 15.

2. *The influence of antitoxin upon the toxin action*

In the 3 experiments with 10 mgm. of toxin 45N and antitoxin (Experiments 4, 5, and 6 of Figure 1), the antitoxin was administered at varying intervals: 73 and 10 minutes before, and 17 minutes after the toxin. In all 3 cases the limit of competence was reached within 142 to 160 minutes, a period of survival significantly longer than in the experiments without antitoxin. Signs of lung edema were marked in Experiment 4. In Experiment 12, in which antitoxin was given 10 minutes

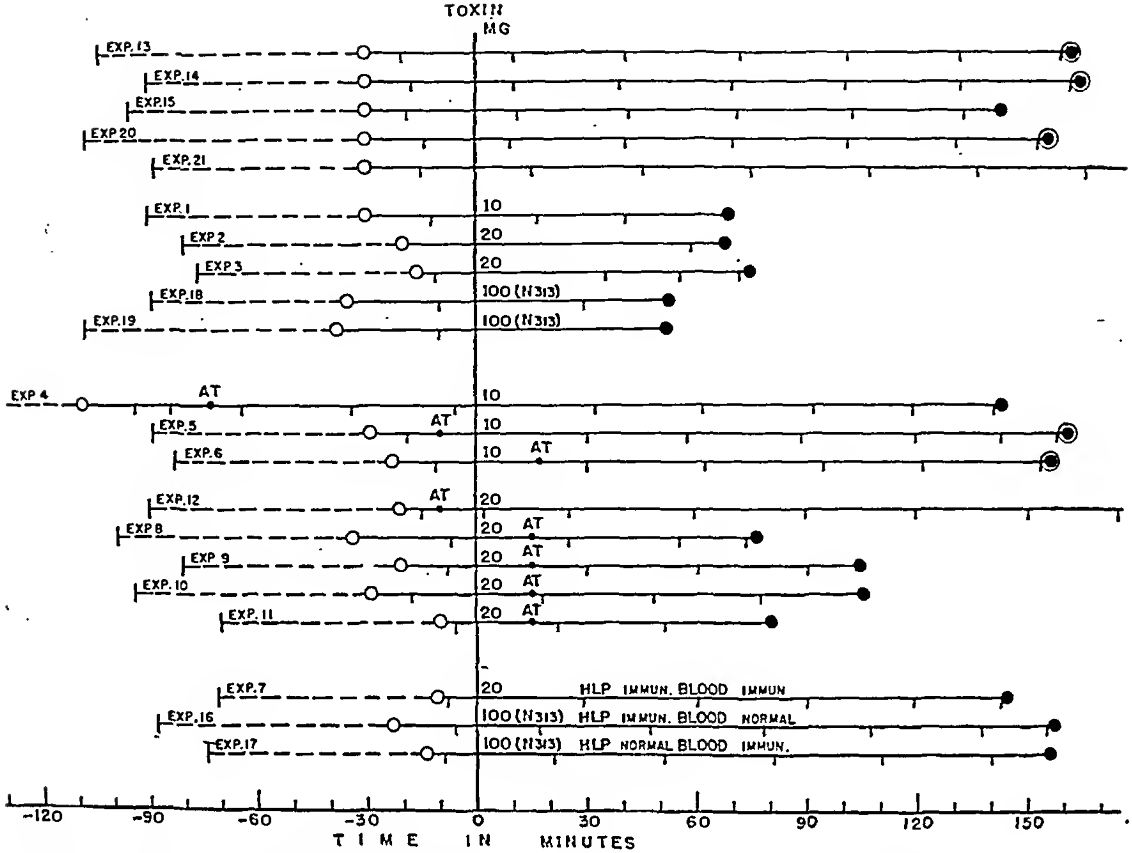

FIG. 1. THE ACTION OF *Clostridium oedematiens* TOXIN UPON THE HEART-LUNG PREPARATION OF THE DOG

The dotted line from the vertical bar to the open circle indicates the time of preparation from skin incision to start of recording. The large full circle at the end of every horizontal line indicates lung edema. Limit of competence reached without marked signs of lung edema is indicated by the full circle placed in an open circle. The small full circle at the letters AT indicates administration of antitoxin. The figures 10, 20, and 100 respectively at the vertical zero time line indicate the administration of 10 or 20 mgm. of toxin (45N) or 100 mgm. of toxin (N313). The signals below every horizontal line indicate the beginning of a competence test. For further information, see text.

prior to the dose of 20 mgm. toxin 45N, the limit of competence was reached only after 200 minutes. On the other hand, in the 4 experiments, 8, 9, 10, and 11, in which antitoxin was given 15 minutes after 20 mgm. of toxin 45N, severe lung edema occurred within 76, 80, 104, and 105 minutes respectively.

3. *Pathological changes*

The microscopic sections of the lungs, in preparation injected with toxin alone, revealed the presence of engorged pulmonary capillaries, and red cells and protein within the pulmonary alveoli. Where antitoxin was given prior to the toxin, the lungs at termination of the experiment (except in Experiment 4) showed either an absence of these findings or their presence to a minor degree. In all cases, the heart on microscopic examination showed no characteristic pathological changes.

4. *The influence of active immunization*

An attempt was made to obtain information on the effect of active immunization upon the response of the heart-lung preparation to toxin (Experiments 7, 16, 17 [Figure 1]). Although 2 different samples of toxin were used, the potency was identical in all 3 experiments (50,000 MLD mouse units). A definite inhibiting effect of immunization to the toxin action was observed not only when the blood as well as the heart and lungs were taken from immunized dogs (Experiment 7) but also when either the H.L.P. (Experi-

ment 16) or the blood (Experiment 17) was from an actively immunized dog.

The alterations of the hematocrit in the heart-lung preparation with respect to administration of *Cl. oedematiens* toxin are tabulated in Table I. The available data suggest that the hematocrit is not a good index of the onset of the pulmonary changes, probably because whole blood as well as plasma is lost into the pulmonary alveoli.

TABLE I

Relationship of hematocrit to administration of Cl. oedematiens *toxin, in the heart-lung preparation*

Dog no.	Dose of toxin in mouse MLD	Time antitoxin given	Hematocrit	
			Original	Terminal
4	25,000	72 min. before toxin	50	41
5	25,000	10 min. before toxin	50	58
6	25,000	17 min. after toxin	61	68

9	50,000	15 min. after toxin	59	59
18	50,000	none given	46	74
19	50,000	none given	48	61

* Immunized dog.
** Blood from immunized dog used.

DISCUSSION

Under the conditions of our experiments, the action of *Cl. oedematiens* toxin is essentially on the pulmonary vessels, producing changes which lead to loss of blood into the lungs. While it cannot be said that the heart muscle is not affected, changes in work of the left heart by increasing the arterial resistance indicate that the left ventricle was relatively little affected. It was still capable of additional work at a time when an increase in venous blood supply led to a marked rise in pulmonary pressure so that lung edema was hastened and it became difficult or impossible to increase venous inflow.

The effect of the toxin does not occur quickly; rather, a latent period of considerable duration elapses before definite changes in right atrial pressure, in pulmonary pressure, or in competence become noticeable. This places these toxin effects in a group of delayed reactions characteristic of various types of other pharmacological agents, for instance, the cardiac glycosides and the thyroid hormone. One has to assume, in these instances, that the substance itself has to enter into or initiate a chain of reactions requiring considerable time before the characteristic effect eventually occurs. Since the toxin appears to be protein in nature, the question may be raised as to whether it may not be an enzyme. The identification of the *Cl. welchii* alpha toxin as a lecithinase (7) provides the best example of a bacterial toxin which is enzymic in nature.

The experiments appear to indicate that 7 ml. of antitoxin was able to afford a considerable degree of protection against the toxic effect of 25,000 MLD of toxin irrespective of whether the antitoxin was administered prior to the toxin or 17 minutes after the toxin. Protective action was also present in the experiments in which injection of antitoxin preceded the administration of 50,000 MLD of toxin. Of the 4 experiments in which the antitoxin followed 15 minutes after the dose of 50,000 MLD of toxin, no protection could be seen in 2; severe lung edema developed in approximately the same period of time as in the experiments without antitoxin. In the 2 other experiments it is possible that some delay in the onset of pulmonary changes may have been caused by the antitoxin.

Protection against the action of 50,000 MLD of toxin was observed in the 3 experiments in which the heart and lungs or the blood used was obtained from immunized animals. While it is not possible to say that all immunized blood was removed from the H.L.P. of Experiment 16, the amount of blood-immune bodies must have been greatly reduced by replacing the blood twice with blood from a non-immunized animal. However, this experiment is not a definite proof that tissue-immune bodies are sufficient to counteract the toxin action even if the blood is not immunized. On the other hand, immunized blood alone appears to give protection (Experiment 17).

SUMMARY

1. In the heart-lung preparation of the dog, *Cl. oedematiens* toxin produces pronounced loss of plasma and whole blood in the pulmonary circulation. This phenomenon is observed only after a definite latent period.

2. The effects on the heart are minimal in comparison, for the heart is capable of increased work

at the time when the pulmonary circulation is greatly impaired.

3. Antitoxin counteracts the change in permeability of the pulmonary vessels if it is present in the system when toxin is given. It is less effective when given early in the latent period.

4. Active immunization markedly diminishes the toxic effects on the pulmonary circulation. In the immunized dog the antitoxin is definitely present in the circulating blood, and the evidence is suggestive of the supposition that it may be present in the heart and lung tissue.

THE SCATTER AND ABSORPTION OF LIGHT BY THE EXCISED CORNEA AT VARIOUS WAVELENGTHS DETERMINED BY A PHOTOELECTRIC METHOD. THE EFFECT OF TRAUMA AND VACCINIAL INFECTION

By J. MAXWELL LITTLE, JAMES W. MANKIN, CHARLES H. REID, AND GEORGE T. HARRELL

(From the Departments of Physiology and Pharmacology, and Internal Medicine, the Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, N. C.)

(Received for publication October 20, 1946)

The effects of immunity and x-ray therapy on the extent of permanent damage to the cornea resulting from the invasion of the cornea by vaccinia have not previously been subjected to experimental study. In preliminary experiments (1) an attempt was made to judge the effects of such treatment by grading the opacities according to an arbitrary scale. It was soon realized that this method was inadequate. In order to obtain a more accurate evaluation of therapy, it was necessary to devise a procedure for estimating objectively the degree of corneal opacity. By utilizing a technique which measures the per cent transmission of light by the cornea *in vitro*, it was possible to estimate the degree of impairment to vision resulting from diminished light transmission due to opacities. This procedure is described here, and in addition data are given on the light transmission of normal rabbit corneas, corneas subjected to trauma, and corneas inoculated with vaccinia but not treated. The effects of therapy will be described elsewhere (1).

PROCEDURE

The degree of opacity was estimated by measuring the transmission of light through the cornea in the Evelyn photo-electric micro-colorimeter (2). The intensity of the incident beam of light was adjusted so that the galvanometer read 100 per cent transmission when the light was passed through 0.9 per cent NaCl solution. Within 15 minutes after the rabbit was sacrificed the cornea was placed in the cell with the convex surface downward. The plunger was inserted, and the per cent transmission of the light was read. The plunger was adjusted to rest lightly on the cornea thus causing it to lie flat. Appropriate filters (red, green and blue[1]) were used so that the visual spectrum was covered at the intervals given in Tables I and II. At least two determinations of transmission were always made on each cornea at each wavelength.

It usually was not necessary to trim the cornea to fit the cell, but on occasion this was necessary. The trimmed edge always showed some opacity resulting from the trauma, but care was taken to exclude the edge from the path of the light beam. After insertion of the plunger the cornea was inspected to exclude the presence of air bubbles and foreign material.

In only a few instances did the opacity cover the entire field. In most instances the opacity was relatively small in comparison with the field, and in these cases the opacity was centered in the field.

Experiments reported here include studies made upon normal rabbit corneas (group Q); corneas which had been anesthetized with a 2 per cent butyn sulfate solution, scratched with a needle and treated with 105 r of x-ray (group L); untraumatized corneas removed from rabbits in which the other eye had been inoculated with vaccinia (group P); and corneas which had been inoculated with vaccinia, but in which no form of therapy was given (group K). Beginning 25 days after the start of the experiment one animal from each group was sacrificed on successive days and the measurements were made. Preliminary experiments (1) had shown that this lapse of time was sufficient for the development of permanent opacities.

RESULTS

Table I shows that in the normal corneas there was a progressive decrease in the average transmission of light as the filters were changed to allow the transition from long to short wavelengths. This decrease could be due to the absorption of light by the cornea, since Wald (3) states that there is some absorption by the normal cornea in the violet region of the spectrum. It could also be due to the scattering of light by the cornea. Rayleigh's law states that the intensity of the scattered light is inversely proportional to the fourth power of the wavelength; therefore, the scattered radiation would be greatly increased at the shorter wavelengths. The data given in Table I have

[1] The filters used were obtained from the manufacturer the microcolorimeter and were designated by the wave-[illegible] in millimicrons of the maximum light transmitted. [illegible]he limits of transmission are indicated in Table I.

† Wavelength transmission limits.

been examined from this viewpoint to see if scattering is a factor.

If T represents the per cent of light transmitted by the cornea, then $100 - T$ would represent the per cent scattered. According to Rayleigh's law then

$$(100 - T) = k/\lambda^4.$$

The constant k was calculated for $1/\lambda^3$, $1/\lambda^4$, and $1/\lambda^5$, using the observed data for the value of $100 - T$ at $\lambda = 420$ mμ, and the above formula. With these values for k, theoretical lines were constructed to show the anticipated relationship between $100 - T$ and the above reciprocal functions. Figure 1 shows that when the observed values for $100 - T$ were plotted against $1/\lambda^4$ for each wavelength the observed data fell either on or very close to the theoretical line. Using $1/\lambda^3$ the observed values were consistently considerably less than those expected from the theoretical line, and using

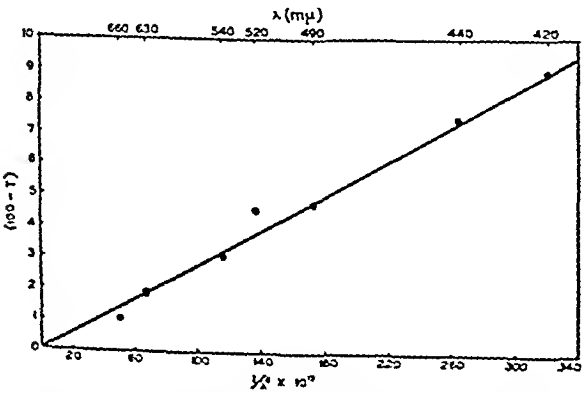

FIG. 1. RELATIONSHIP BETWEEN THE OBSERVED VALUES OF $(100 - T)$, OBTAINED ON NORMAL CORNEAS (GROUP Q), AND THE THEORETICAL LINE CONSTRUCTED FROM THE EQUATION $(100 - T) = k/\lambda^4$. WHEN k, CALCULATED FROM THE OBSERVED VALUE OF $(100 - T)$ AT $\lambda = 420$ mμ, WAS 28×10^{10}

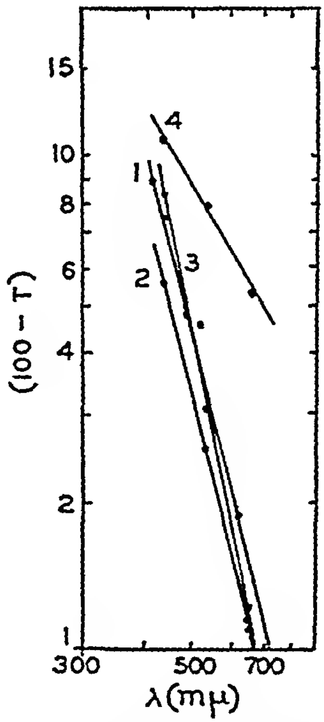

FIG. 2. RELATIONSHIP BETWEEN AVERAGE OBSERVED VALUES OF $(100 - T)$ AND THE WAVELENGTH OF LIGHT

(2) Group P, slope = − 4.0
(3) Group L, slope = − 4.7
(4) Group K, slope = − 1.8

$1/\lambda^4$ they were consistently considerably greater than the expected values at all wavelenths greater than 420 mμ. This is illustrated further by the fact that when the observed values for $100 - T$ were plotted against the wavelengths on double logarithmic paper (Figure 2) the slope of the resulting line was minus 4, indicating that $100 - T$ is proportional to $1/\lambda^4$. Thus it appears that the data obtained on normal rabbit corneas obey Rayleigh's law, and that the decrease in transmission at the shorter wavelengths is due to scattering of light rather than to absorption.

The data obtained for the transmission of light by the untraumatized corneas (group P), the corneas which were anesthetized, scratched and treated with x-ray (group L), and the corneas which were inoculated with vaccinia but were untreated (group K) are presented in Table II. When the average

values for $100 - T$ in these groups were plotted against the wavelengths, using double logarithmic aper (Figure 2), it was found that the lines for roups P and L did not deviate significantly from slope of minus 4. The slight deviation for group is within the limits of experimental error. The lope for group K (inoculated untreated corneas) owever has a value of minus 1.8, which indicates hat some factor in addition to the scatter diminishes the transmission of light when there is an opacity present. In order to get further information about this unknown factor the values obtained on a number of animals in group *K* were plotted on double logarithmic paper. Figure 3 shows that the slope varied from minus 4.5 for the least degree of opacity to minus 1.6 for the greatest degree of opacity. This variability in slope is primarily due to a greater decrease in transmission at the longer wavelengths with increasing opacity.

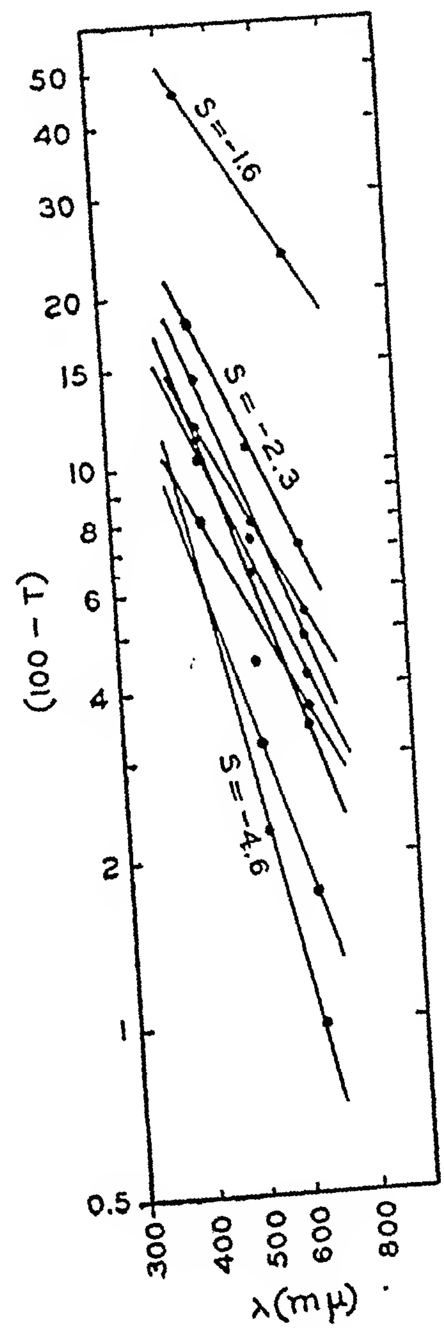

FIG. 3. RELATIONSHIP BETWEEN $(100 - T)$ AND THE WAVELENGTH, FOR 9 OF THE CORNEAS FROM GROUP K. $s =$ SLOPE

The significance of the difference between the mean values of $100 - T$ (Table II) for groups L and P was tested by "Student's" t-test (4) and was found to be not significant for filter 660 (red). For filter 540 (green), the difference was significant at the 5 per cent level only. The difference between the means for groups P and K was significant at the 1 per cent level for filters 660, 540, and 440 (blue).

DISCUSSION

The procedure described here is a simple objective means for determining the effect of a corneal opacity on the transmission of light at different wavelengths by the cornea. In a few instances no opacity was noticed upon visual inspection of the cornea *in situ;* however, the transmission of light was impaired in these corneas, and upon careful inspection a rather diffuse opacity was seen.

It is apparent from these experiments that the decrease in transmission of light by the normal cornea at the shorter wavelengths is probably due to a scattering of the incident light by the cornea. This finding raises the question as to whether or not there is any absorption of light by the normal cornea, as reported by Wald (3). It is also apparent that the presence of an opacity introduces some factor, in addition to scatter, which results in a greater defect of transmission. The nature of this factor is unknown, but the data presented in Figure 3 could be explained by the addition of a neutral filter which would absorb equally at all the wavelengths. If this were true the relative effect of the filter would be greatest at the long wavelengths, because at these wavelengths the effect of scatter is minimal. We would therefore suggest that the effect of an opacity on transmission is due to the equal absorption of light at all wavelengths by the opacity.

The comparison of the means for groups L and P indicates that the trauma associated with anesthesia, scratch, and x-ray produces some permanent decrease in the transmission of light by the cornea, even in the absence of evidence of an opacity. The lack of significance in the difference of the means for filter 660 is probably due to the minimal effect of scattering at the long wavelengths together with the factor of sampling variation. It is clear from Figure 2 that trauma without resulting opacity does not alter the nature of the transmission defect found in normal corneas, since the data for group L obey Rayleigh's law.

SUMMARY

1. The *in vitro* transmission of light by the rabbit cornea was measured with the Evelyn photoelectric microcolorimeter.

2. In the normal cornea the per cent transmission is less at the short than at the long wavelengths of light. Since the decrease in transmission is proportional to $1/\lambda^4$ and is consistent with Rayleigh's law, it is concluded that the decrease is due to scattering of the incident light.

3. Trauma to the eye may result in a permanent impairment of light transmission in the absence of an opacity which can be seen by inspection. This decrease is also due probably to scattering of light rather than to absorption.

4. Inoculation of the rabbit cornea with vaccinia results in opacity which causes a significant decrease in the transmission of light. This decrease is probably due to equal absorption of light at all wavelengths.

SEROLOGICAL STUDIES ON INFLUENZA DURING A NINE-MONTH PERIOD[1]

By SEYMOUR S. KALTER and ORREN D. CHAPMAN (With the technical assistance of CATHERINE BURKHART)

(*From the Department of Bacteriology and Parasitology, College of Medicine, Syracuse University, and the Virus Laboratory, Bureau of Laboratories, Department of Health, Syracuse, New York*)

(Received for publication November 5, 1946)

The anticipated influenza B epidemic materialized late in November, 1945 and reached its peak during the month of December. Sporadic cases were recognized in the United States (1) for a period of some months preceding the actual epidemic. The importance of recognizing this pre-epidemic period is unquestionably a necessity in order to avail ourselves of the prepared vaccines. It has been demonstrated (2–12) that immunization against the influenza viruses elicits an antibody increase and offers protection to the experimental inhalation of the virus strains. Francis and coworkers (13) have demonstrated further that vaccination with inactivated influenza viruses Types A and B offers protection against influenza B during an epidemic. That this epidemic was due to Type B has also been shown by Dalldorf and Rice (14).

It is recognized that other agents are responsible for certain cases of bacteria-free pneumonias. Clinically these various types of virus pneumonia often resemble each other. It is essential, therefore, to determine, if possible, the agent responsible for the infection. Their differentiation may be made by isolation of the virus or by serological studies. In many instances, failure to isolate an organism does not eliminate its possible role as causative agent. On the other hand, the development of specific antibodies in convalescent sera is one criterion that is considered to be conclusive evidence of contact with the specific antigen. Many agents have been isolated and serological technics for their identification have been developed.

These various viral technics available for laboratory diagnosis are now routinely employed in many laboratories. The examination of serum samples for the presence of antibodies to viruses, as well as those producing a clinical syndrome similar to that produced by virus agents, may be made by the Hirst test (15) for influenza; cold agglutination (16) or its modification (17), and the indifferent Streptococcus MG (18) for atypical pneumonia; and the commercial product Lygranum CF[2] (19 to 23) for members of the psittacosis group.

The experiments were designed in order (*a*) to ascertain the approximate time of the epidemics' appearance or an indication of the epidemics' approach by pre-epidemic increases in serum antibodies, (*b*) to determine the nature of the epidemic in this area, (*c*) to determine the effect of vaccination, and (*d*) to determine what antibody titers may be expected in a group of presumably normal individuals.

MATERIALS AND METHODS

Sera were derived from 2 sources. One group was obtained from 52 medical students who were bled each month for a period of 9 months from October, 1945 to June, 1946, inclusive. In this group 3 were females and the remainder were males. Of these, 15 students were given the concentrated A and B influenza vaccine prepared from chick embryos. Except for 1 member of this group, all received their vaccinations after their second blood specimen had been obtained. The lone student was vaccinated after his third blood sample had been taken. The 37 other members of this group were either members of the naval unit or civilians and were not required to be vaccinated.

A careful record of each student's health was maintained with histories obtained before the program was established and at each monthly bleeding. By coincidence, the vaccination program and the influenza epidemic were concurrent.

Another group of sera were obtained from the university student infirmary and consisted of 66 acute phase sera and 25 pairs of acute and convalescent phase sera. The donors of these sera were all university students admitted with upper respiratory infections during the

[1] Aided by a grant from the Hendricks Research Fund.

[2] (E. R. Squibb & Sons.) This antigen is used only because of its convenience, rather than its specificity. The use of a psittacosis antigen would be preferable, but more difficult to obtain.

epidemic period. In all cases, attempts were made to obtain a convalescent phase serum sample. Wherever cooperation was lacking, the acute phase sample was placed in the "single serum group" (these are discussed more fully under results). All acute phase sera were taken upon admission to the infirmary and in most cases were obtained during the first 2 days of illness. The convalescent sera were obtained 2 to 6 weeks following infection. The clinical diagnosis of this group was varied, but all were considered to be respiratory infections. The number of males and females in this group was approximately equal.

All sera were handled in an identical manner. The blood samples were obtained under sterile conditions and maintained in the sterile state. Upon receiving the blood sample, it was allowed to stand at room temperature for several hours, then centrifugated, and the serum removed. All sera were frozen and stored at −70° C. until ready to be tested. Prior to the titration of the serum, it was thawed and sufficient amounts removed and inactivated at 56° C. These were to be used in the agglutination-inhibition and complement-fixation tests. The cold agglutination and the streptococcus agglutination tests were made immediately following the thawing of the serum sample. All sera from the same individual were treated at the same time using the same test preparations.

The sera were stored in sterile vials. All titrations were completed within 24 hours after removal of the sera from the frozen state and the sera were kept at 4° C. when not in actual use.

Cold agglutination: The procedure was essentially that recommended by the Commission on Acute Respiratory Diseases (17). It consisted of adding 0.5 ml. of a 0.2 per cent suspension of fresh type O cells, obtained from the same donor throughout, to 0.5 ml. 2-fold serial serum dilutions starting at 1:5. The tubes were shaken and kept overnight at 4° C. Readings were made on the following day before the tubes had any opportunity to become warm. The end point consisted of that dilution giving definite agglutination of the cells. All titers expressed are reciprocals of the *final* dilutions of the serum.

Streptococcus MG No. 9:[3] From a culture of this organism bacterial suspensions were made and tested in the manner described by Thomas, *et al* (18). The organisms were washed 3 times in saline and a suspension corresponding approximately to a No. 3 McFarland standard was made. The streptococci were killed by heating at 60° C. for 1 hour. To 0.5 ml. serum dilution starting at 1:5, an equal volume of streptococcus suspensions was added. This mixture was placed in a 37° C. water bath for 2 hours, then overnight at 4° C., and then again at 37° C. for 2 hours. Following this, the tubes were shaken and read. The degree of agglutination used as a standard was that of the original workers. The dilution of serum giving a 1 plus reaction was used as the titer and is expressed as a *final* dilution.

Agglutination-inhibition test: The procedure used here is the same as is described by Hirst (15) except that we employed a 1 per cent chicken red cell suspension as used by Henle, *et al* (12). The virus was obtained from the allantoic fluid of 10- to 11-day-old embryos after numerous passages. The fluid from the embryos was obtained in the usual manner and then pooled. This pool was then titrated and separated into smaller amounts for storage. All virus pools were stored at −70° C. until needed. When fresh virus was required, the tube was removed at least 1 day prior to its use, thawed, and allowed to stand at 4° C. A hemagglutination titration was again made and exactly 4 units antigen were used. The pools maintained the same titer for the entire test period.

Sera were tested for inhibitory substances to the influenza viruses A, B,[4] and Swine.[5] The PR 8 and Lee strains of influenza A and B were used respectively. Readings were made after 75 minutes at room temperature and the titers expressed are those giving a 2 plus or better inhibition of agglutination. A standard red cell suspension as well as the degree of clumping was used for comparison. All sera from the same individual were titrated against the influenza strains at the same time. The saline and the red cells were dispensed with an automatic pipetting machine. To avoid possible mixing of influenza strains, the same person worked with the same strains throughout the experiment. Each virus strain had its own glassware. The expressed titers are *final* dilutions.

Henle and coworkers (12) discuss the possibility of crossing the strains, which, on the basis of Ziegler's and Horsfall's work on interference (24), appears to preclude this possibility. However, titrations in immunized mice demonstrated that our virus strains were pure.

Complement-fixation: All sera were tested for antibodies to members of the psittacosis group of viruses with Lygranum CF. To 0.2 ml. inactivated serum dilutions, 0.2 ml. complement (2 units) was added, followed by 0.2 ml. antigen (1 unit). These were placed in a 37° C. water bath for 1¼ hours and then 0.4 ml. sensitized cells were added to all tubes. These were then further incubated for ½ hour and reading made. The usual anticomplementary and non-specific controls were included in all tests. The titers of sera giving 50 per cent or better fixation were considered positive and are expressed as *initial* dilutions.

Included with all tests, *i.e.* cold agglutination, streptococcus-agglutination, agglutination-inhibition, and the Lygranum complement fixation tests, were positive serum controls.

RESULTS

Patients

An increase in admissions to the student infirmary became apparent late in November.

[3] A culture of this organism was received from Dr. Frank L. Horsfall, Jr.

[4] These two strains were supplied by Dr. Werner Henle.

[5] Dr. Gilbert Dalldorf supplied the Swine strain.

TABLE I

Incidence of influenza B among students admitted to the student infirmary with upper respiratory infections, November 1945 to February 1946

Month	Total number of admissions*	Total number of acute and convalescent sera tested	Influenza B	Incidence
				per cent
Nov.	4	1	1	4.0
Dec.	48	18	17	68.0
Jan.	8	5	2	8.0
Feb.	6	1	0	0.0
Total	66	25	20	80.0

These admissions increased rapidly during the month of December, gradually receding during the months of January and February. Table I shows the total number of students admitted into the student infirmary during this 4-month period * for acute upper respiratory infections. Of the 66 admissions, 25 pairs of acute and convalescent sera were obtained. The greatest number of admissions occurred in December with 48 cases. There were 4 cases late in November, 8 in January, and 6 in February. Of the paired sera, we obtained 1 in November, 18 in December, 5 in January, and 1 in February. Upon titration for influenza B, these were shown to have an incidence of 4.0 per cent, 68.0 per cent, 8.0 per cent, and 0.0 per cent for those months respectively. The total of 80.0 per cent shows a 4-fold or better increase in antibodies to influenza B.

The sera were divided into 2 groups for convenience, one group consisting of the paired sera, the other group composed of a single serum sample. The results obtained from the cold agglutination, indifferent streptococcus No. 9 agglutination, complement-fixation (for members of the psittacosis group) and agglutination-inhibition (for influenza A, B, and Swine) tests on the first group are shown in Table II.

Of the 25 paired sera, 3 showed increases in cold agglutinins, whereas 3 showed cold agglutinins but no increases or a drop in titer during convalescence. Of the 3 with titer increases, patients Nos. 58 and 108 were diagnosed clinically as atypical pneumonia with characteristic pulmonary involvement. Case 96, although showing a rise in cold agglutinins, demonstrated a more significant increase in influenza B antibodies. Clinically, this patient did not have any extensive pulmonary involvement and was considered to be influenza B. Patients 79, 85, and 86 all showed the presence of cold agglutinins. These titers, because of their failure to increase, were considered to be of little significance, and therefore, non-specific in nature.

* Because of facilities at the infirmary, this represents only a small part of the university students. Many were entered in other hospitals.

Sixteen patients demonstrated antibodies to the indifferent streptococcus MG No. 9. Their titers ranged from 10 to 40 without any showing significant increases. Of the patients showing increases in cold agglutinins, patients 96 and 108 gave a 2-fold rise in streptococcus antibodies. Patient 58, although diagnosed as atypical pneumonia, did not have any agglutinins for this indifferent streptococcus. Many of the patients with influenza B had low titers for this organism.

In this group, there were no complement fixing antibodies to the members of the psittacosis group. Several, however, were reactive with the normal chick embryo control.

The titers for influenza A and Swine influenza showed no significant increase although several had high antibody levels. When tested against the Lee strain of influenza B, 15 patients showed 4-fold or better increases in their convalescent sera. Five patients showed only 2-fold or even no increase over their acute phase titers. However, inasmuch as the acute phase sera were obtained after several days of illness and the titers were quite high, we have considered them to be indicative of influenza B.

Of the single serum group, 7 patients demonstrated cold agglutinins in titers ranging from 10 to 60. A large number showed agglutinins for the streptococcus; and, as in the other group, they were mainly of low titer. One serum however, had a titer of 160. This titer along with a cold agglutinin titer of 60 and low influenza titers makes one strongly suspect a possible atypical pneumonia. There seemed to be little correlation between the cold agglutinin and the streptococcus titer, as in the other group.

Titrating these sera for antibodies to the psittacosis group gave 3 positives. Two of these were quite low, a 1:5 serum dilution in each case giving better than 50 per cent fixation, while one serum titered to 20.

The influenza results are the usual titers obtained when single serum samples are titrated. A wide individual variation was apparent. Several of the sera did show high titers, one giving a titer of 10,240.

These sera that had high influenza B antibodies were from students who had been ill several days before entering the infirmary. This would account for the high titers due to the rapid production of influenzal antibodies.

Many of the patients from whom only single serum samples were obtained perhaps would have demonstrated antibody increases had convalescent serum been received. In some of these, as stated above, where the acute phase specimen was taken after a few days of illness, significant titers may be noted.

Students: The sera obtained from these students were handled in the same manner as the hospitalized patients. All 9 serum samples from each student were titrated at the same time using the same test materials. Of the 52 students, 3 were unable to continue after their fourth bleeding. Their 4 samples, however, were tested.

The majority of the student serum samples had titers of less than 10 for cold agglutinins. There were a few that showed a titer of 10 and some a titer of 20. There was only 1 student with a titer of 30 and again only one had a titer of 40. No greater titers were obtained. Although there was a greater number of students with titers for the indifferent streptococcus, here, again, relatively low titers were obtained throughout. There seemed to be little correlation between the presence of cold agglutinins and streptococcal antibodies as was noted in the hospitalized group. There may have been a slight correlation between streptococcal antibodies and the presence of upper respiratory infections such as colds and sore throats, but the evidence is insufficient to warrant any definite conclusion.

With regard to the psittacosis group, there were a few sera that gave positive reactions for the group antigen in dilutions of 1:5. In 1 case, all 9 sera, *i.e.*, each monthly sample, were positive at this dilution. The other sera were positives usually for 1 or 2 months at most. These positives did not react with the normal control antigen. In a few other instances, there were some students who had sera that reacted both with the test antigen and the control antigen. These apparently were non-specific, and so were not included with our positive results.

Table III contains the results of titrating sera for antibodies to influenza A, B, and Swine. The results have been summarized on this table and show the titers of the students for each month.

Each number represents the number of students having that titer for the designated antigen in each represented month. Fifteen students in this group were vaccinated with the army vaccine against influenza A and B following their November bleeding. The first two serum samples were quite low when tested for influenza A and in the main showed very little variation during the course of the winter. It may be seen in Table III that the majority of students did not demonstrate titers greater than 320. The unvaccinated group maintained a constant titer with some students showing a 1-tube variation which was considered insignificant. Two members had no demonstrable titers for the entire period, while 5 students, although initially having no titer, developed antibodies during the course of the winter. The vaccinated group demonstrated, in most instances, at least a 4-fold antibody rise. However, 3 members of the group gave only a 2-fold rise and 2 members showed no antibody increase at all. Of those producing increased antibody levels, the levels resulting were variable with relation to the increase and duration. Several maintained constant titers for the 7 tested months following their vaccination, whereas others demonstrated antibody decreases for 1 or more months previous to their last sample.

The titers for influenza B were considerably higher in the majority of cases. Table III shows that the majority of students had antibody titers greater than 320. This was evident before the start of the vaccination program and was considered to be indicative of subclinical infection prior to the beginning of this study. Several unvaccinated students demonstrated 4-fold or better antibody rises to this virus in their December sample. None of these had reported infection or any illness during the preceding month. This would appear to indicate that they had come in contact with the virus during the epidemic without any apparent effect other than the stimulation of influenza B antibodies. As in influenza A, there are individual variations in the duration of the antibody level. Interesting is the fact that the titers of those receiving the vaccine became higher for this virus than for the Type A strain. The high initial titer, *i.e.*, the antibody level of October's serum sample, would seem to indicate that contact to the virus had been made, and makes us feel that the virus was present in the community several months prior to the actual outbreak. We were interested in observing that the general titers for *Swine influenza*, although not comparable to those for influenza B, were usually higher than those for influenza A. There appeared to be little effect resulting from the vaccination; only 3 of the 15 had more than a 2-fold antibody increase. Also, the titers of this group appeared to have very little relationship to the influenza A titers. Three members of this group demonstrated no antibody level during the entire series.

We have averaged the titers of the vaccinated and unvaccinated groups for each month. The averaged titers for each group are represented in Figure 1. It is evident that the titers for influenza

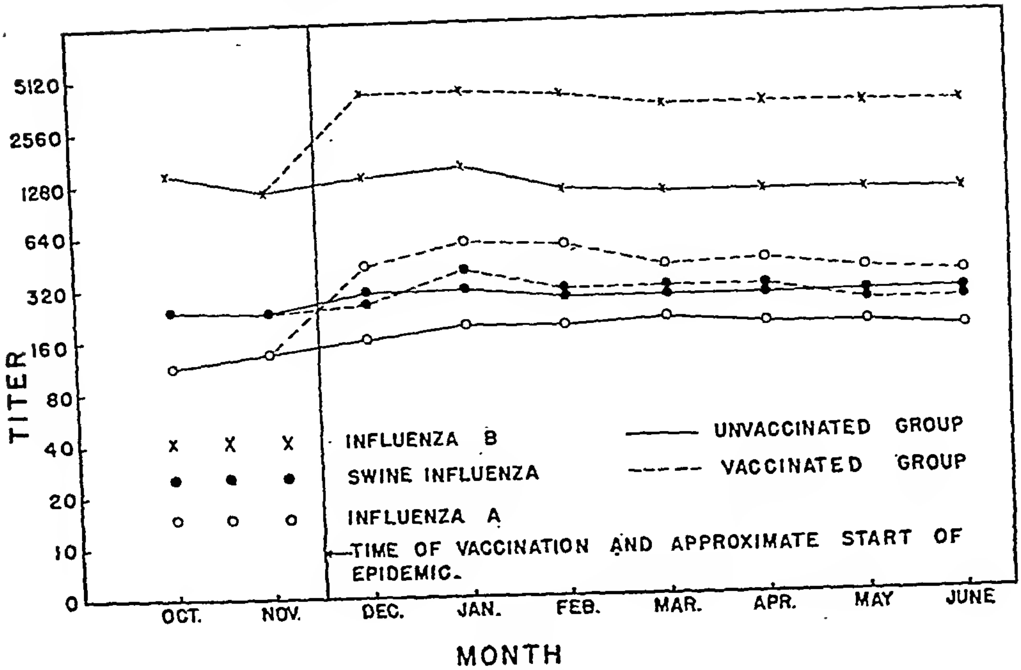

FIG. 1. THE MONTHLY TITERS OF THE VACCINATED AND UNVACCINATED STUDENTS
The points represent the average of the groups

B were higher than the other viruses, even among the unvaccinated group. The vaccinated group (represented by the broken line) subsequent to their vaccination had immediate increases in their titers. Of the 15 students receiving the vaccine, none was hospitalized, although several did report "colds." There was a slight antibody level increase among the unvaccinated group coincident with the time of vaccination. This was probably due to contacts or to cases in this group during the epidemic.

A few of the students were ill with influenza B, as is evident by the increased antibody titers seen in the serum samples following their illness. In some cases, as mentioned above, antibody increases were obtained, but without any history of illness prior to the antibody increase reported.

The individual variation to vaccination is quite apparent in several cases. For example, student 10 (Figure 2) maintained a constant titer for influenza A and Swine, of 160 throughout the test period. On the other hand, his titer for influenza B remained unchanged following his vaccination but jumped from a relatively high titer to a much higher titer 2 months after vaccination. This higher titer was maintained for a period of 5 months before dropping to its original level. Another student, No. 17, also showed no reaction to the vaccination, maintaining the same level for all 3 viruses for some time.

These titers with several other representative titrations may be seen in Figure 2. It is quite apparent that individual variation with response to vaccination and infection may be noted in immunological studies of this type.

DISCUSSION

The evidence presented indicates that the epidemic in the civilian population of this area was due to influenza B. Indications for the presence of this virus in the population previous to the actual outbreak have been mentioned (1, 13, 25), and further evidence is now reported.

The importance of recognition of the virus in advance of the epidemic cannot be stressed sufficiently. The value of vaccination during this epidemic and the importance of the agent's recognition have been stressed by Francis and coworkers (13). We can only speculate, but the use of influenza vaccines at the proper time may well have reduced our number of cases considerably. That there were many more cases among the population

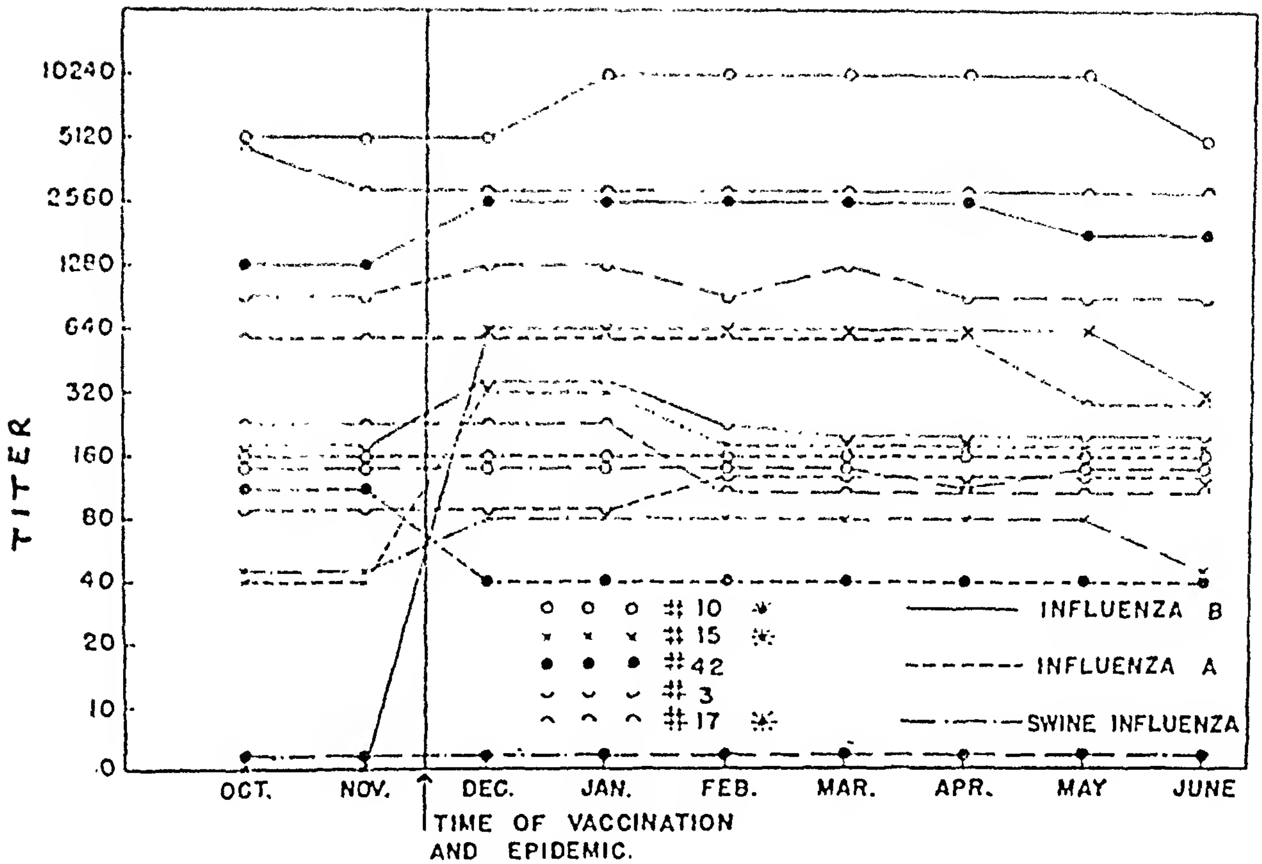

FIG. 2. INDIVIDUAL TITERS OF FIVE STUDENTS OVER THE NINE MONTH PERIOD FOR INFLUENZA A, B AND SWINE

* Vaccinated following their November bleeding.

was recognized, since the disease varies among individuals in its severity and need for hospitalization. The need for studies along these lines is imperative for the early recognition of the etiologic agent in order to administer vaccines at the proper time. The time element for administration of the vaccine is of importance as has been shown by several workers (8 to 11). Reinfection, although in a milder form, may occur after several months have elapsed between vaccination and experimental infection. This is apparent in the antibody decline following vaccination subsequent to its initial increase. The results indicate that the prophylactic administration of the influenza vaccine should be given during the month of September in order to offer the desired protection before the outbreak of the epidemic.

The significance of antibody levels is still questionable in resistance to influenza. What may be considered a high level apparently is relative to the individual. Several individuals in our groups had no initial level. This was evident among the patients and the students. There were several who had no initial titers to one or more of the influenza strains. Then, only because of vaccination or possibly infection, were titers obtained. We are still unable to determine what may be considered as a protective antibody titer to each individual.

Usually, the antibody response to infection with influenza B resulted in the production of antibodies specific for that agent. There were some individuals who developed a 2-fold antibody increase to our PR 8 strains and some to our Swine strain. We feel confident that these slight increases are not due to antibody destruction because all materials were handled in such a manner as to avoid bacterial growth. The possibility of an anamnestic reaction as postulated by Bodily and Eaton (26) must be considered. These authors also suggest that their high titers to the Swine strains may be due to the strain responsible for their cases which have a greater antigenic fraction in common with the Swine strain than

other strains of A. Another consideration may be that some individuals respond with greater antibody levels than others to the antigenic components present in the infecting strains. Henle, *et al* (12), although using sterile sera, also found similar reactions, *i.e.,* the failure to respond to vaccination among certain individuals as well as the increased antibody to the heterologous virus. These factors may be applicable to our cases, except for the usual consideration that there are no related antigenic components between influenza B and Swine. However, there is the possibility that the strain of influenza B causing the epidemic in this locality may have contained some Swine component. The failure to find significant increases to influenza A makes us feel that we are not dealing with a dual infection.

The presence of antibodies to Swine influenza in human sera has been a debatable point for some time. Whether these antibodies are resultant from previous infection with a virus of the pandemic type, as had been postulated by Shope (28), or due to repeated exposure to the human influenza virus of the pandemic type, as proposed by Francis and Magill (29), cannot be answered yet.

Our results would seem to indicate that the titers obtained for Swine influenza could be due only to infection with an agent containing Swine antigenic components. This would be possible only if infection occurred with an A strain composed of some Swine components, a Swine strain which is a variant of influenza A, or a B strain with Swine components. This last possibility is unlikely unless there is a B strain as yet unisolated or untested for the presence of common antigenic fractions with the Swine strain. If the Swine titers are due to infection with an A type, what happened to the A antibodies? Several of our group had no measurable amount of A antibody. Does the A antibody disappear before the Swine antibody? It appears that the probable explanation is that the Swine strain is a type A strain differing from the PR 8 strain in its antigenic structure.

From the results it is evident that the individuals' immunological response to these 3 influenza strains are in many instances completely independent.

With our results, we were able to ascertain many of the answers to our questions. We were somewhat disappointed in the results of the titrations inasmuch as we had anticipated a much sharper antibody increase during the epidemic. However, this was compensated by the fact that the evidence indicated that the virus for the epidemic was present far before the actual outbreak. Also, factors other than the presence of the virus are probably necessary for the outbreak. That the epidemic was due to influenza B has been discussed. There was little need for any differential diagnosis of this epidemic from other syndromes since infections by other agents did not occur to any great extent. That the method we used was satisfactory remains as yet to be determined under conditions other than those present during this study. Perhaps other agents, for example, that isolated by Meicklejohn and coworkers (30), should be tested for at the same time. At any rate, it is felt that studies along these lines would strongly indicate the etiological agent of this type of respiratory infection.

Although the vaccination occurred incidental to our original experiments and the members vaccinated are relatively few, the results of the vaccination confirm the findings of other workers in that usually strong results were obtained. The somewhat ambiguous immunological response demonstrated by a few does not appear to belittle the actual efficacy of vaccination. This seems to be in accord with the findings of other workers (12, 26). As would be expected, the antibody level of such a group would be varied. In all cases, the antibodies present were indicative of the patients' past contacts. In most cases, antibodies were present for the influenza viruses. One must also consider the possibility of other respiratory infections which are clinically similar to influenza. These may be differentiated only by the failure to produce a specific influenza antibody response and the production of an antibody to the particular etiological agent. Such agents are members of the psittacosis group (22, 31, 32, 33) and the virus of atypical pneumonia (30). Florman (23), employing Lygranum CF for studies on these agents as possible causes of virus pneumonias, suggests employment of this type of antigen for the diagnosis of agents of this group. As we have demonstrated, the presence of antibodies to the

patients with this group were few and the titers obtained could easily have been nonspecific. Several workers have reported that a low percentage of normal sera will give positive reactions with antigens of this nature when employed in low dilutions (21, 23, 34, 35). None of the students gave histories to indicate contact with members of this group. The patient who titered to 20, was First negative and unable to give a history of contact with birds. The interpretation of this titer is, therefore, difficult.

The value of cold agglutinins and streptococcal agglutination is still questionable. On the basis of our results, their value still remains an enigma. However, in agreement with Favour (35) and Finland, *et al* (37), we feel that our results demonstrate that normal individuals as well as many conditions cause type O cells to agglutinate in the cold with titers of less than 40. And still more individuals cause the agglutination of the indifferent streptococcus in low dilutions, as also observed by Finland, *et al* (38). We believe that these diagnostic procedures are of aid in atypical pneumonia only when viewed with other procedures such as x-ray and clinical findings.

It is felt that this group of tests may be of value to the laboratory in establishing the etiology of respiratory infections. Also, because of their simplicity, diagnostic laboratories should be able to employ them as routine group tests in the laboratory diagnosis.

CONCLUSIONS

1. The epidemic in this area was due to influenza B.
2. This virus was present for several months before the actual outbreak.
3. Vaccination results in an antibody increase lasting in most cases for at least 5 months. Vaccines should then be administered in the fall of the year in order to prevent infection.
4. Serological studies of this nature are of value in: (*a*) determining the etiologic agent, (*b*) ascertaining the duration of antibody titers, and (*c*) estimating the approximate time for administration of vaccines.
5. These tests may be used as a battery of tests by the laboratory, in order to ascertain the etiology of this type of respiratory infection.

COMPARATIVE ACTION OF ACETYL-BETA-METHYL CHOLINE AND HISTAMINE ON THE RESPIRATORY TRACT IN NORMALS, PATIENTS WITH HAY FEVER, AND SUBJECTS WITH BRONCHIAL ASTHMA [1]

By JOHN J. CURRY

(From the Evans Memorial, Massachusetts Memorial Hospitals and the Department of Medicine, Boston University School of Medicine)

(Received for publication November 16, 1946)

In a recent study (1), it was reported that the parenteral administration of histamine produced a sizable reduction of vital capacity in 8 of 9 actively asthmatic subjects, whereas it produced no significant change of vital capacity in 2 control groups of normal individuals and patients with hay fever. Furthermore, the effectiveness of histamine in producing a reduction in vital capacity varied in different asthmatic subjects and also in the same subject with the degree of asthma present at the time the tests were done. The present communication reports the action of acetyl-beta-methyl choline chloride (mecholyl chloride) on the vital capacity in asthmatic subjects, in patients with hay fever, and in a group of normal individuals and presents a comparison of the effect of mecholyl chloride with that of histamine. These assays were carried out in the hope of further elucidating the underlying mechanisms in asthmatic attacks.

In 1912, Barker and Sladen (2) noted the action of pilocarpine and atropine in bronchial asthma. Alexander and Paddock (3) induced "asthmatic-like" attacks in 10 of 20 patients with asthma by the subcutaneous injection of 3 mgm. pilocarpine. The latter workers observed that the systemic response to pilocarpine, as manifested by salivation, sweating, epiphora, flushing, and a sensation of warmth, was slightly greater in the asthmatic subjects than in the normal subjects. Starr, Elsom, Reisinger, and Richards (4) with the subcutaneous administration of 20 mgm. acetyl-beta-methyl choline inadvertently precipitated an "asthmatic-like" attack lasting 3 minutes in a young subject with a past history of asthma. Starr (5) also produced mild "asthmatic-like" attacks in asthmatic patients with acetyl-beta-methyl choline chloride given orally. Villaret and his coworkers (6) gave 20 to 40 mgm. doses of acetyl-beta-methyl choline subcutaneously to 15 asthmatic patients and produced in all of them "asthmatic-like" attacks which were regularly relieved by atropine. Moll (7) injected 5 to 20 mgm. doses of acetyl-beta-methyl choline subcutaneously in 28 asthmatic subjects and produced in 23 cases "asthmatic-like" attacks of varying intensity. The extra-pulmonary response to the drug in the asthmatic group did not differ from the response in the normal control subjects. Moll therefore made the suggestion that the peculiar tropism of choline derivatives for the lungs in asthmatic subjects was due to a local sensitivity rather than to a generalized state of increased sensitivity. Lung damage was considered an essential factor in determining the abnormal bronchial response. Dautrebande and Philippot (8) induced "asthmatic-like" attacks with aerosols of carbamino choline and studied the effectiveness of aerosols of phenyl amino propane in relieving these attacks. Ellis and Weiss (9) and Carmichael and Fraser (10) noted that when acetyl choline was given intravenously to normal subjects a sensation of substernal constriction was produced which was occasionally associated with coughing. Hurtado and Kaltreider (11) recorded a definite decrease in vital capacity associated with a sensation of substernal constriction and difficult breathing in 2 normal subjects following the intramuscular injection of acetyl-beta-methyl choline in doses of 30 mgm. and 15 mgm. respectively. Eppinger and Hess (12) in 1917 cited asthma as an example of pathologically increased vagotonia. One of the difficulties in accepting this theory of the etiology of asthma is the failure of atropine to give marked relief in the disease. Thus, while we have ob-

[1] This work was supported in part by a grant from the Upjohn Company, Kalamazoo, Michigan.

served notable improvement both in symptoms and in the vital capacity in asthmatic subjects following adequate doses of atropine sulfate intravenously, there is no question that the relief is not so dramatic as that after epinephrine. While there has been no extensive study of blood cholinesterase levels in asthmatic patients, the few that have been determined have been within the normal range (13). More important than blood levels, however, would be a study of lung cholinesterase, since, if there is an excess liberation of acetyl choline in the lungs of the asthmatic subjects, one might expect an increased amount of cholinesterase to be present.

MATERIALS AND METHODS

Acetyl-beta-methyl choline, hereafter referred to as mecholyl chloride,[2] was administered to 3 groups of subjects, and the reaction of the respiratory tract was measured chiefly by recording the vital capacity by a technic already described (1). The first group was composed of 10 normal subjects who had no recognizable symptoms or manifestations of allergy. The second group included 11 patients with seasonal hay fever who had neither a history nor signs or symptoms of asthma. These latter patients were also tested in the same way after the parenteral administration of histamine. The third group was composed of 27 asthmatic subjects, the majority of whom had mild continuing asthma. However, a few patients were included who had a history of typical asthmatic attacks in the past but who had had no recent signs or symptoms of asthma. As in the previous study, an attempt was made to secure young, cooperative subjects with vital capacities not subject to unaccountable variations. In all of these subjects the action of parenteral histamine on the vital capacity was also studied for purposes of comparison. Patient B. R., a 28-year-old, single female with mild chronic asthma, was again very cooperative and repeated studies were made with her assistance.

Mecholyl chloride was dissolved in sterile physiological saline to a concentration of 20 mgm. per ml. for intramuscular injection and further diluted with sterile physiological saline to a concentration of 0.1 mgm. per ml. for intravenous administration. Care was exercised in the preparation of the solutions because of the marked hygroscopic property of the salt. The solution was placed in a sterile rubber capped bottle which was stored in a refrigerator when not in use. A fresh solution was prepared at 2- to 3-week intervals. Unless otherwise stated the drug was injected in the deltoid muscle. In some of the asthmatic group the reaction to the intravenous administration and nebulization of the drug was also observed. The maximum dose employed was 6 mgm. because experience showed that with the patients in the sitting position larger doses sometimes produced untoward systemic effects, such as weakness and dizziness, which interfered with the performance of the vital capacity test. In the asthmatic group when wheezing or respiratory discomfort was present, doses of 0.25 to 0.50 mgm. were first administered to determine the reactiveness of the patient. The dosage was then increased up to 6 mgm. or until a significant reduction in the vital capacity was produced. The intravenous dose ranged from 0.005 mgm. to 0.6 mgm. For nebulization a 1:40,000 solution was used. The degree of flushing, salivation, sweating, and tachycardia which followed the administration of mecholyl chloride was also noted. Histamine acid phosphate,[3] with 1 ml. equivalent to 0.2 mgm. histamine base, was given intravenously to the groups with hay fever and asthma in doses equivalent to 0.01 to 0.04 mgm. histamine base, except in a few instances when the drug was given intramuscularly. In the latter cases the dosage was increased.

RESULTS AND COMMENTS

Intramuscular mecholyl chloride

NORMAL SUBJECTS: In 3 of 10 normal individuals a dose of 6 mgm. mecholyl chloride caused a definite though slight reduction in the vital capacity measuring 4 per cent, 4 per cent, and 6 per cent respectively (Table I). The tests were repeated in these 3 subjects within a few days and similar effects were obtained. All of the normal subjects experienced a sensation of substernal constriction with difficulty in respiration. In spite of this, however, 3 subjects showed a slight increase in the vital capacity after the drug was administered. It is likely that normal individuals have a slight but variable sensitivity of the respiratory tract to

mecholyl and that, if the dosage is sufficiently increased, a reduction in vital capacity might be produced in all, as is suggested by the studies of Hurtado and Kaltreider (11). However, in a subject with mild chronic bronchitis who had no allergic tendencies, the administration of 6 mgm. mecholyl chloride produced a pronounced decrease in vital capacity. Therefore it was important to make certain that the normal group had no demonstrable respiratory tract disease. In the earlier study (1), among the 10 normal subjects given 0.03 mgm. histamine base intravenously, only 1 subject had a reduction in vital capacity of 3 per cent, 2 had a reduction of 2 per cent and 2 a reduction of 1 per cent. In the remainder the vital capacity increased following the administration of the drug.

Hay fever: In the group of 11 patients with hay fever who had neither a history nor signs or symptoms of asthma, the intramuscular injection of 6 mgm. mecholyl chloride produced some decrease in vital capacity in all of the subjects (Table II). Seven had a decrease in vital capacity of 5 per cent or greater. In comparison the intravenous administration of 0.02 to 0.03 mgm. histamine base in this same group produced a decrease in vital capacity in 6 of the 11 subjects and in only 2 instances was the decrease greater than 5 per cent. It is difficult to evaluate changes in the vital capacity of less than 5 per cent since variations of this degree may occur in the resting vital capacities. Nevertheless mecholyl chloride in the dosage used was more effective than histamine in reducing the vital capacity in these subjects. The extrapulmonary response was not different in the hay fever group than in the normal group and in some instances the extrapulmonary reaction was waning as the respiratory tract reaction was increasing. The majority of these tests were performed during the pollen season although none of the subjects complained of symptoms at the time of the tests. This may be important, since Brown and his coworkers (14) have shown that patients with hay fever and no history of bronchial asthma may frequently show a diminished vital capacity during their pollen season. It would appear worthwhile to repeat the tests on the hay fever subjects when the pollen season is terminated. Whether the more reactive patients with hay fever are those who may in later years develop asthma is a matter for conjecture. An attempt to correlate the personal and familial allergic background of a larger group of these patients with the degree of respiratory sensitivity to mecholyl chloride and histamine is planned.

Bronchial asthma: In the group of 27 asthmatic subjects, all had a reduction in vital capacity after the intramuscular administration of from 1 to 6 mgm. mecholyl chloride, and in only 1 instance was this reduction less than 5 per cent. In this same group 22 of the 27 patients had a reduction in vital capacity after parenteral histamine and in only 1 of the reactive cases was the reduction less than 5 per cent. The pattern of response to mecholyl chloride was similar in all the reactive patients although the sensitivity varied greatly from patient to patient and in the same patient varied at different times, depending on the degree of asthma present when the test was performed.

As a rule, in patients with only occasional mild attacks of asthma or in those who had only a history of asthma, the respiratory tract was less reactive to mecholyl than in subjects with active bronchial asthma. Following the intramuscular administration of an effective dose of mecholyl

chloride the vital capacity was reduced when measured 2 minutes later. At the 4-minute period in many instances and especially if the reaction was pronounced, a further decrease in vital capacity was found. At 6 minutes usually there was a return toward the resting levels in the vital capacity except in those cases when the reaction was severe. Depending then on the severity of the reaction, the vital capacity returned to the resting levels in from 10 to 30 minutes. For example, in patient B. R. after the resting vital capacities were determined, a dose of 0.5 mgm. mecholyl chloride was injected into the deltoid muscle. Two minutes later the vital capacity measured 1,881 ml., a fall of 1,233 ml. from the resting level of 3,114 ml. Four minutes after the injection the vital capacity was 1,787 ml., and at the 6-minute period measured 2,080 ml. Vital capacities were recorded at the 10-minute, 15-minute, and 20-minute periods and measured 2,727 ml., 2,968 ml., and 3,114 ml. respectively. The flushing, sensation of warmth, sweating, and salivation produced by the administration of the drug were minimal, but respirations were increased with audible inspiratory and expiratory wheezing. Subject J. H., on the other hand, had a resting vital capacity of 5,454 ml. and 2 minutes after the intramuscular injection of 4 mgm. mecholyl chloride the vital capacity measured 5,298 ml. Vital capacities were repeated at 4 minutes, 6 minutes, 10 minutes, and 20 minutes after the injection and measured 5,026 ml., 2,016 ml., 5,141 ml., and 5,507 ml. respectively.

When increasing amounts of mecholyl chloride were injected intramuscularly an increased response occurred, the vital capacity was further reduced, and the subjective symptoms were increased. In subject P. M., for example, after the resting vital capacities were determined, varied amounts of mecholyl chloride were administered by the intramuscular route. In order to eliminate the possibility of a cumulative effect of the drug, the doses were given at 20-minute intervals in the following order, 2 mgm., 4 mgm., 6 mgm., 3 mgm., and 5 mgm. Vital capacities were measured at the usual intervals of 2 minutes, 4 minutes, 6 minutes, 10 minutes, and 20 minutes. The vital capacities recorded 4 minutes after each injection of the drug showed an increased reduction with increasing dosage of mecholyl chloride (Figure 1). When identical doses of mecholyl chloride were

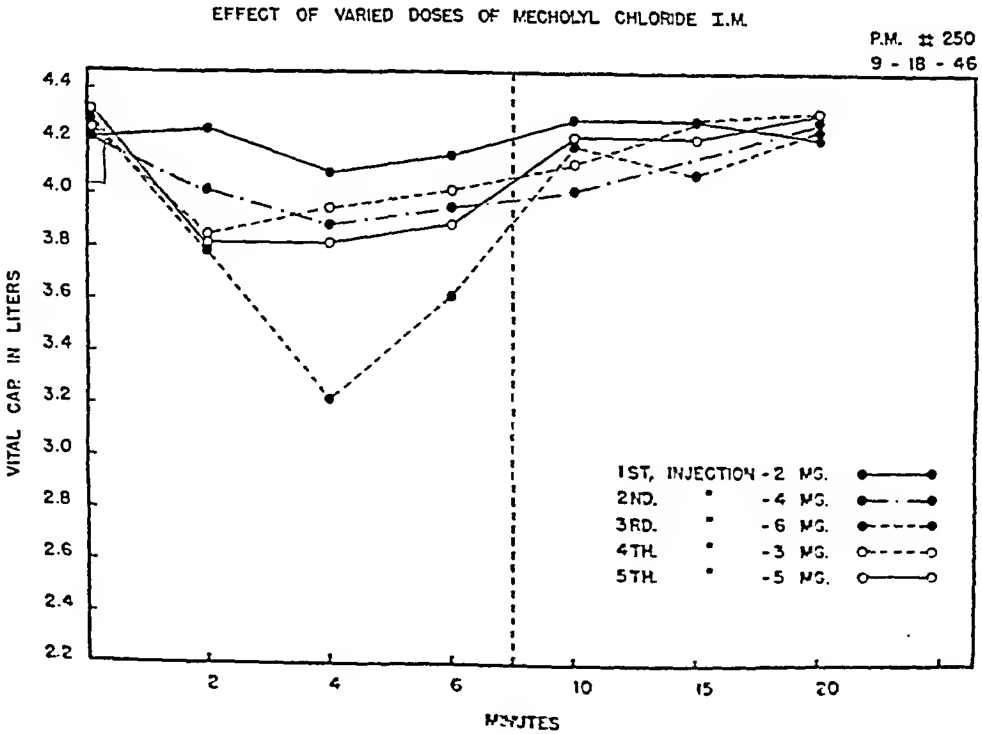

FIG. 1

injected intramuscularly at 30-minute intervals, the decrease in vital capacity which resulted in some cases varied as much as 500 ml. In subject B. R., for example, 5 intramuscular injections of 0.4 mgm. mecholyl chloride at 30-minute intervals resulted in a decreased vital capacity of 846 ml., 857 ml., 1,129 ml., 773 ml., and 658 ml. respectively from a resting level of 3,385 ml. It is possible that these variations may be due to slight differences in the site of injection of the drug in the deltoid area since we have observed a difference in the reaction pattern when the drug is given subcutaneously. There is also suggestive evidence that with a less reactive subject and with larger doses of mecholyl chloride, from 4 to 6 mgm., used, a more uniform reduction in vital capacity is obtained with repeated identical doses of the drug. In a few instances when prostigmin methyl sulfate, in doses of 0.5 to 0.75 mgm., was administered, the effect of mecholyl chloride on the respiratory tract was markedly enhanced. In view of the severe reactions that we produced in actively asthmatic subjects with small doses of intramuscular mecholyl chloride, it is difficult to understand how the subjects given 20 to 40 mgm. mecholyl chloride subcutaneously by Villaret and his coworkers were able to tolerate the reaction. It is possible that the patients were suffering only mild bronchial asthma and that the difference in the site of administration of the drug and the supine position resulted in a lessened response to drug.

In the asthmatic group we were unable to detect any notable difference from the control groups in the extrapulmonary response to mecholyl chloride, as manifested by flushing, salivation, sensation of warmth, or tachycardia. These findings confirm those reported by Moll. However, the occurrence of an increased tracheobronchial reaction to mecholyl chloride in 3 normal patients and many of our hay fever control group and some asthmatic subjects without any obvious respiratory infection would seem to indicate that lung damage was not necessarily an essential factor in determining the abnormal bronchial response as suggested by the same author. While the precise cause of this abnormal tracheobronchial response in asthmatic subjects is not clear, studies are in progress which may throw some light on the mechanism. In one individual, S. G., a very mild asthmatic subject, 6 mgm. mecholyl chloride intramuscularly provoked an attack of uncontrolled auricular fibrillation, confirmed by electrocardiogram, which subsided spontaneously in 1 hour.

Comparison of the effect on the respiratory tract of mecholyl chloride and histamine given parenterally

Since there appeared to be a difference in the response of the tracheobronchial tree to histamine and mecholyl, it appeared worthwhile to ascertain that they acted independently. While it is generally agreed that the pharmacodynamic activity of the 2 drugs in the lungs differs, it seemed possible that in the deranged state of hyperresponsiveness of the respiratory tract one substance might act to some extent through liberation of the other. There also appears to be some relationship between histamine and mecholyl chloride in that antihistamine drugs have some degree of antiacetyl choline activity and antiacetyl choline drugs have some antihistamine activity. Therefore, in patient J. D., 0.02 mgm. histamine base was administered intravenously, and a reduction of 1,944 ml. in the vital capacity followed. When the vital capacity had returned to the resting levels, 1 mgm. mecholyl chloride was given intramuscularly and a reduction of 1,234 ml. resulted. After the vital capacity had again returned to the resting levels, a dose of 30 mgm. benadryl, a potent antihistamine agent (15), was given intravenously. When a dose of 0.02 mgm. histamine base, given intravenously, was now repeated a decrease in vital capacity of only 168 ml. occurred, whereas 1 mgm. mecholyl chloride intramuscularly caused a decrease of 1,348 ml. Benadryl, therefore, afforded remarkable protection against the reduction in vital capacity due to histamine but gave no protection against the reduction due to mecholyl chloride. In patient B. R., after 30 mgm. benadryl had been given by vein and marked histamine protection resulted, a dose of 2 mgm. mecholyl chloride produced a pronounced reduction in vital capacity. In another experiment, in patient J. D., the reduction in vital capacity due to 0.01 mgm. histamine given intravenously was 481 ml. A dose of 0.75 mgm. prostigmin methyl sulfate was administered intramuscularly and a repeat injection of 0.01 mgm. histamine 20 minutes later produced a drop in vital capacity of 481 ml. Prostigmin did not augment the response to histamine. It appeared, therefore, that in the asth-

matic individual the 2 drugs, histamine and mecholyl chloride, operated independently in producing a decrease in vital capacity.

The subjective response to both drugs in regard to the action on the respiratory tract in the asthmatic group was similar when the reaction was pronounced. The majority of subjects were unable to distinguish between them except that the mecholyl chloride response was less apt to disappear quickly. When the reaction was mild, however, the majority of subjects felt that the mecholyl chloride response was "more like a true asthmatic attack" than the histamine response.

In all patients with active bronchial asthma the respiratory tract was hyperreactive to both drugs; but, in the case of R. B., an active asthmatic, the degree of reduction in vital capacity from a dose of 0.02 mgm. histamine intravenously was only 3 per cent contrasted to a reduction in vital capacity of 48 per cent after the intramuscular injection of 2 mgm. mecholyl chloride. It appeared that the tracheobronchial tree was more reactive to mecholyl chloride than to histamine, since small doses of mecholyl chloride from 0.25 to 2.0 mgm. intramuscularly produced regularly a pronounced decrease in vital capacity (Table III).

In the group of asthmatics with only mild occasional attacks or with only a history of asthma, usually in childhood, sensitivity of the respiratory tract to mecholyl chloride was definitely more marked than sensitivity to histamine and sensitivity to both drugs was less than in the former group (Table IV). One patient, W. B., who had a history of asthma was not very reactive to either drug. A dose of 6 mgm. mecholyl chloride in this patient caused a reduction in vital capacity of only 3 per cent and the intravenous administration of 0.03 mgm. histamine was followed by a vital capacity greater than the resting value. In another patient, W. F., who had a history of typical asthma, an intramuscular dose of 6 mgm. mecholyl chloride caused a reduction of 31 per cent in the vital ca-

pacity and 0.03 mgm. histamine base intravenously caused a reduction of 24 per cent. In 3 subjects with only mild occasional attacks of asthma, D. D., C. S., and S. G., mecholyl chloride caused significant decreases in vital capacity, whereas the intravenous administration of 0.03 mgm. histamine produced no decrease in vital capacity. In view of these findings it would appear that attention should be turned more towards discovering anticholinergic agents rather than antihistamine drugs for the treatment of bronchial asthma.

Since there is a possibility that respiratory hyperresponsiveness in the hay fever group may indicate those individuals who are potential asthmatics and since the differences in reaction of the asthmatic group to histamine and mecholyl chloride may serve to differentiate various types of asthma, it is planned to enlarge the group and attempt to correlate the reaction to the 2 drugs with the various clinical characteristics of the allergic state.

Intravenous mecholyl chloride

When mecholyl chloride was administered intravenously to asthmatic subjects, in doses of 0.005 to 0.6 mgm., the maximal reduction in vital capacity was noted in about 30 seconds and the vital capacity returned to the resting levels in 15 to 30 minutes. As might be expected with the larger doses a more pronounced reduction in vital capacity occurred and a longer time was required before the vital capacity returned to the resting levels. Thus, in subject B. R., the intravenous injection of 0.01 mgm. mecholyl chloride produced at the 30-second period a decrease of 760 ml. in the vital capacity, from the resting level of 3,170 ml. to 2,410 ml. Repeated vital capacities recorded at the 1.5, 3, 5, and 10-minute periods after the injection measured 2,510 ml., 2,770 ml., 2,950 ml., and 3,350 ml. respectively. In patient W. G., on the other hand, a dose of 0.6 mgm. mecholyl chloride given by vein produced a reduction of 2,408 ml. in the vital capacity from the resting level of 3,598 ml. to 1,087 ml. in 30 seconds after the injection. Repeated vital capacities were recorded at 1.5, 3.5, 5, 10, 20, 30, and 40-minute periods and measured 1,964 ml., 2,341 ml., 2,623 ml., 2,748 ml., 2,947 ml., 3,322 ml., and 3,469 ml. respectively. The intravenous injection of small amounts of mecholyl chloride produced a much greater reaction in the respiratory tract than much larger doses of the drug administered intramuscularly. Thus, in subject B. R., the intravenous injection of 0.1 mgm. mecholyl chloride caused a reduction of 1,800 ml. in the vital capacity as compared to a reduction of 310 ml. produced by the intramuscular injection of 0.25 mgm. of the drug. When an increased dose of mecholyl chloride is given intravenously, a greater reduction in vital capacity occurs. For example, in subject B. R., the administration of 0.01 mgm. mecholyl chloride intravenously caused a reduction of 762 ml. in the vital capacity, and, when subsequent doses of 0.03 mgm., 0.05 mgm., 0.08 mgm., and 0.10 mgm. of the drug were injected at 20-minute intervals, the following reductions in vital capacity were measured: 869 ml., 835 ml., 1,170 ml., and 1,798 ml. respectively (Figure 2). It may be seen that the 0.01 mgm., 0.03 mgm. and 0.05 mgm. doses produced a similar decrease in vital capacity but with larger doses notable increased reduction in vital capacity was observed. This same lack of sensitivity to small changes in dosage was brought out when increased doses of mecholyl chloride varying by only .005 and .01 mgm. were injected intravenously and but slight variances in reduction of the vital capacity were recorded.

Nebulized mecholyl chloride

Nebulization of a 1 : 40,000 solution of mecholyl chloride produced a profound decrease in vital capacity which suggested that perhaps the respiratory tract is more reactive to the drug when it is administered in this manner. For example, in patient B. R., 4 inhalations from the nebulizer of mecholyl chloride produced a decrease in vital capacity of 2,111 ml. from a resting level of 2,769 ml. to 658 ml. There was no evidence over a period of 5 minutes that the attack was subsiding and 0.85 mgm. atropine sulfate was given by vein with only partial relief and an increase in the vital capacity to 1,943 ml. Five minutes after the administration of 0.3 mgm. 1 : 1,000 epinephrine hydrochloride intramuscularly there was marked subjective relief and the vital capacity measured 3,344 ml. It is interesting to note that in this case the relief afforded by atropine sulfate was not dramatic.

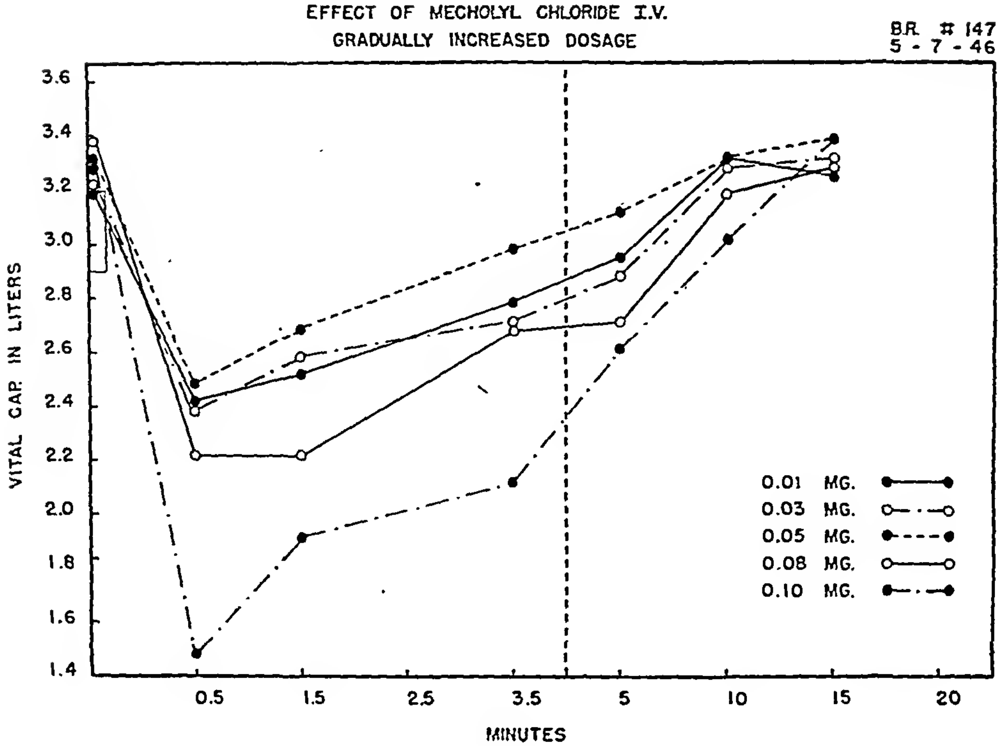

FIG. 2

SUMMARY

The reaction of the tracheobronchial tree, measured chiefly by changes in the vital capacity, to mecholyl chloride administered intramuscularly in doses of 0.25 to 6.0 mgm. was determined in 10 normal subjects, 11 patients with uncomplicated hay fever, and 27 patients with active bronchial asthma or a history of typical asthmatic attacks in the past. In the latter 2 groups, the reaction was compared with that due to parenteral histamine administered chiefly by the intravenous route in doses of 0.02 to 0.04 mgm. of the base. In the asthmatic group the reaction to intramuscular mecholyl chloride was studied in detail. The reaction to mecholyl chloride given intravenously and by nebulization was also studied in a few cases.

In the normal group, 3 subjects had a slight reduction in vital capacity after the intramuscular injection of 6 mgm. mecholyl chloride though all noted a feeling of tightness in the chest. In the group of 11 patients with hay fever, all had a slight reduction in vital capacity following the administration of 6 mgm. mecholyl chloride intramuscularly and in 7 cases the reduction was 5 per cent or greater. By contrast, in this latter group the intravenous administration of 0.02 to 0.03 mgm. histamine base caused a reduction in vital capacity in *6 of the 11 subjects but* in only *2* cases was the decrease 5 per cent or greater.

In the group of *27* subjects with bronchial asthma or a history of typical asthmatic attacks in the past all had a reduction in vital capacity after the intramuscular injection of from 1 to 6 mgm. mecholyl and in only 1 instance was the decrease less than 5 per cent. On the other hand, following the administration of parenteral histamine 23 subjects had a reduction in vital capacity, and in 22 of these cases the reduction was 5 per cent or greater. It appeared that patients with hay fever and asthmatic subjects were more reactive to mecholyl chloride than to histamine and that both drugs acted by different mechanisms on the hyperresponsive respiratory tract of these individuals.

The pattern of reaction of the tracheobronchial tree to mecholyl chloride, as measured by the reduction in vital capacity, was similar in responsive individuals, though the degree of reaction varied from patient to patient and in the same patient with the degree of asthma present at the time the

tests were performed. With increasing doses of the drug, an increased reduction in vital capacity resulted.

The intravenous injection of 0.005 to 0.6 mgm. mecholyl chloride produced a more pronounced decrease in vital capacity than the intramuscular injection, with its most notable effect in about 30 seconds after the injection. Nebulization of a 1:40,000 solution of mecholyl chloride produced a pronounced reduction in vital capacity which suggested that the tracheobronchial tree may be more reactive to the drug administered by this route.

The degree of extrapulmonary reaction to mecholyl chloride as indicated by flushing, sweating, salivation, tachycardia, and a feeling of warmth was no more notable in the asthmatic group than in the hay fever or normal groups. Paroxysmal auricular fibrillation occurred in 1 patient following a dose of 6 mgm. of mecholyl chloride intramuscularly.

THE EFFECT OF ORALLY AND INTRAVENOUSLY ADMINISTERED AMINO ACID MIXTURES ON VOLUNTARY FOOD CONSUMPTION IN NORMAL MEN

By CHARLEY J. SMYTH, ANDREW G. LASICHAK, AND STANLEY LEVEY

(From the Department of Medicine of Wayne University College of Medicine, Detroit and the Wayne County General Hospital and Infirmary, Eloise, Michigan)

(Received for publication November 26, 1946)

Intravenous and oral protein alimentation using hydrolysates of casein for treatment and prevention of protein deficiency states is receiving increasing recognition. Emphasis has been centered around nitrogen metabolism in such surgical conditions as shock (1), burns (2), blood loss (3, 4), wound healing (5, 6, 7), convalescence (8, 9), and postoperative infections (10, 11). Numerous investigations (12 to 15) have shown that positive nitrogen balance can be maintained for short periods of time in patients receiving intravenous amino acid mixtures as the only source of protein. Another of the major indications for parenteral nitrogen feedings is in patients with debilitating diseases who are unable or unwilling to take adequate food by mouth. In such cases the aim is to supplement the oral nitrogen intake by the use of intravenous protein hydrolysates to provide for the restoration of depleted protein reserves and the daily protein requirements.

During the course of previous investigations in this hospital it was observed that individuals who received intravenous injections of an acid hydrolysate of casein ("Parenamine") failed to eat the normal amount of food at the subsequent meal and many complained of loss of appetite. Reports of the occurrence of nausea, vomiting and anorexia associated with the administration of protein hydrolysates are common (12, 16–23). The symptoms of intolerance to these preparations occur most frequently upon rapid injection and constitute one of the disadvantages to their practical use.

Since nausea, vomiting, and anorexia following the infusion of protein digests might result in a decrease in food intake, the advantages offered by intravenous alimentation could thus be offset by a decrease in the consumption of food. The present investigation was undertaken to determine to what extent the administration of solutions of amino acid mixtures would influence the voluntary food intake in normal individuals. Studies were also carried out on the relationship of the rate of injection of amino acid mixtures to the occurrence of anorexia, nausea, and vomiting.

EXPERIMENTAL

Eight normal healthy adult males and 1 patient with portal cirrhosis were chosen for this study. They were permitted to be ambulatory except for the time required to complete the infusions. Each subject was offered a standard diet which supplied 3,544 calories. It contained approximately 135 grams of protein, 180 grams fat and 347 grams carbohydrate. Each item of uneaten food was weighed and the amount consumed was calculated as the difference between the weight of food offered and the weight of that returned. The items in the diet were varied to permit some choice. From the weight of the food consumed it was possible to calculate by the use of standard reference tables (24) the total calories and the amount of fat, carbohydrate, and protein consumed each day.

The general plan of the study was to keep the subject on the diet for a few days, then give amino acid preparations either orally or intravenously along with the diet, and note any effect on the food consumption. The days during which added protein was given will be referred to in this report as the *experimental period;* it lasted from 3 to 7 successive days when the supplemental protein was given orally and from 3 to 6 successive days, usually 3, when it was given intravenously. The subjects were under continuous observation for from 21 to 35 days. Each individual was studied for at least 2 experimental periods each of which was preceded and followed by control periods of not less than 3 days. Three amino acid preparations were used and they will be designated mixture I, II, and III.[1]

[1] Mixture I is an enzymic digest of casein and pork pancreas and is marketed under the trade name "Amigen," Mead Johnson and Co. Mixture II is an acid hydrolysate of casein to which tryptophane is added. It is marketed as "Parenamine" and was supplied through the courtesy of Frederick Stearns and Co. Mixture III is a synthetic amino acid mixture containing the ten essential amino acids to which glycine is added. The amounts used were suggested by Madden, S. C., and Clay, W. A. (J. Exper. Med., 1945, 82, 65) and referred to by them as mixture "VUJ." It was supplied through the courtesy of Merck and Co.

The sequence of amino acid mixtures used during the successive experimental periods was varied, as shown in Figures 1A, 1B and 2. Two subjects received only one of the mixtures, 7 subjects received 2 mixtures, and 2 of the subjects also received a 10 per cent glucose solution and physiological saline solution interspersed with the solutions of amino acid mixtures in order to obtain information on the effect that these solutions had on the food consumption (Figure 1B). In 4 subjects the effect of using casein hydrolysates by the oral route was investigated for 5 experimental periods and in these studies only mixture I was used.

The amount of mixtures given on each experimental day was equivalent to 100 grams of protein.[2] The volume of the solution administered daily was 1,440 ml. given in three 480-ml. infusions following each meal. Care was taken to arrange infusions so that they would not interfere with meals. The final concentration of amino acid mixture I and II was 8.3 per cent and of mixture III, 8 per cent. The speed of the infusions was purposely varied so that the 480 ml. of fluid was delivered in from 60 to 180 minutes. The rate of protein administration, therefore, varied from 13 grams to 40 grams per hour (Table II).

RESULTS

The results of the influence of oral and intravenous protein supplemental feedings on the amount of food voluntarily consumed during all of the control and experimental periods are summarized on Table I and Figures 1A, 1B, and 2. It can be seen that during the control period when the only source of food was the basal diet, the daily caloric intake remained relatively constant in all subjects. It is also evident that when amino acid Mixture I was given by mouth as the supplemental feeding (Figure 1A) there was little effect on the amount of food eaten. These changes, expressed as calories consumed per day, are interpreted as not being significant. Five subjects received amino acid Mixture I parenterally, and, of these, 4 had little or no depression of the caloric intake. The one patient in whom a depression of appetite occurred (Case No. 2, Figure 1A), had an intake of 67 per cent of the basic control diet. In sharp contrast are the results which occurred in all 7 subjects who received amino acid Mixture II by the intravenous route. There was a constant reduction in the food voluntarily consumed; the average fall was to 61 per cent of the normal consumption with variations ranging from 37.8 per cent to 87 per cent (Table II). This reduction occurred in each of 2 experimental periods in 1 subject (Patient 9, Figure 2) when he was given this preparation. The same results followed the giving of this solution irrespective of whether its use preceded or followed the other 2 mixtures.

Amino acid Mixture III was administered to 3 men (Patients 6, 7, and 8, Figure 2) and no measurable change of food consumption occurred during or following the preparation. Ten per cent glucose and physiological saline infusions were

[2] The total nitrogen of each amino acid mixture, based on the data supplied by the manufacturer, was multiplied by 6.25 to give the equivalent of the number of grams of protein.

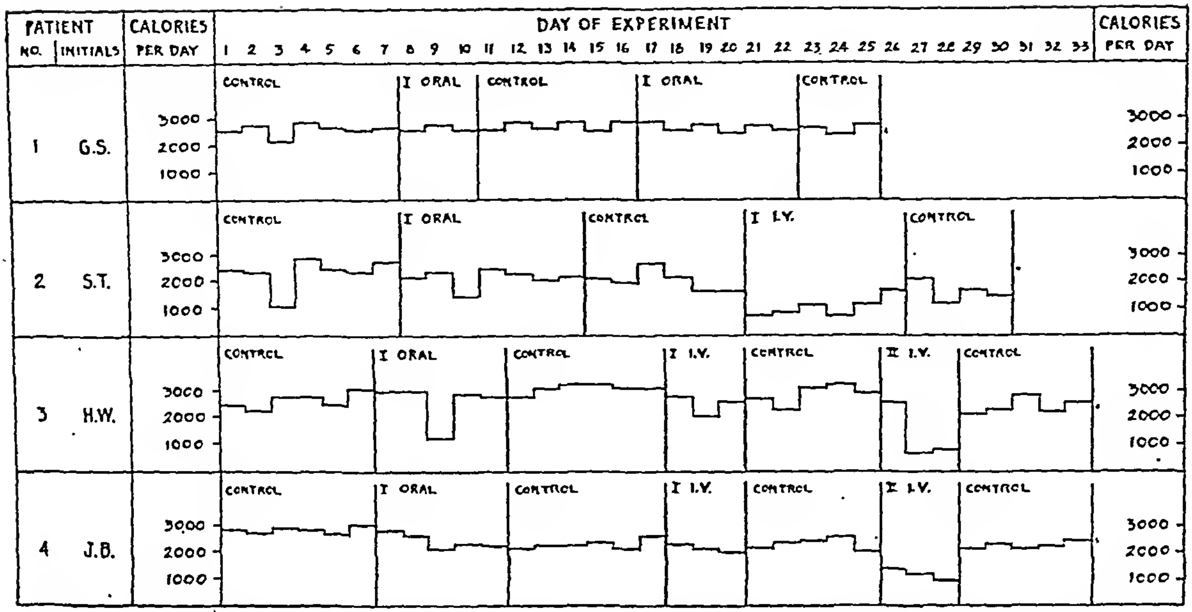

FIG. 1A. EFFECT OF AMINO ACID MIXTURE I ADMINISTERED ORALLY AND INTRAVENOUSLY AND AMINO ACID MIXTURE II ADMINISTERED INTRAVENOUSLY UPON THE VOLUNTARY FOOD INTAKE

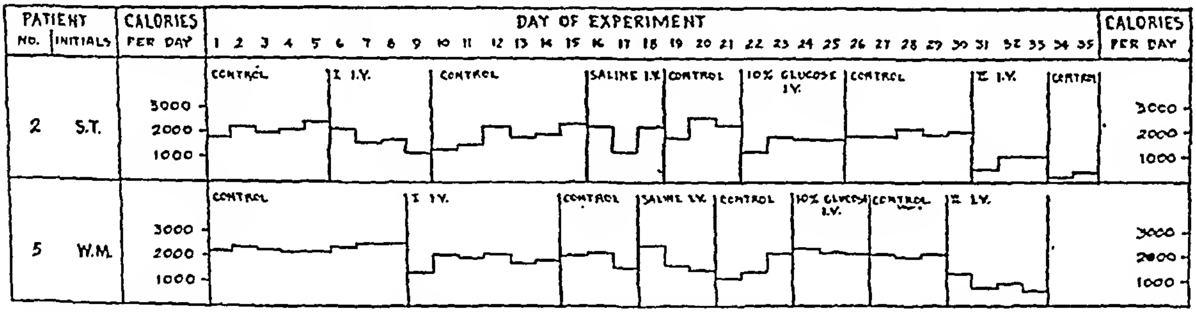

FIG. 1B. EFFECT OF THE INTRAVENOUS ADMINISTRATION OF AMINO ACID MIXTURES I AND II UPON THE VOLUNTARY FOOD INTAKE, COMPARED WITH THE INTRAVENOUS ADMINISTRATION OF PHYSIOLOGICAL SALINE AND TEN PER CENT GLUCOSE SOLUTION

given to 2 individuals and the results are shown in Figure 1B. These 2 commonly employed solutions produced little effect upon the appetite of these men.

In many experimental periods, notably with patients Nos. 2, 4, 5, 6, and 7, there occurred a stepwise depression of food consumption with each additional day during the infusion of supplementary protein. In some instances this progressive depression extended into the first or even the second day of the following control period. This tendency toward a progressive loss of appetite on the last days of the experimental periods and a lag or overlap into the subsequent control period was particularly notable with the use of Mixture II; it occurred to a lesser degree with Mixture I, and was not observed with Mixture III.

It was observed that an important factor which influenced the consumption of food in these subjects was the reactions occurring with or soon after the subject received the amino acid mixture. In the case of amino acid Mixture III no reactions occurred, but Mixture II produced nausea and vomiting in many of the subjects. Another important complaint of the persons receiving the latter preparation was a burning sensation in the arm while receiving the mixture. The burning extended up the arm along the vein to the axilla and was occasionally followed by thrombophlebitis. The thrombosis and pain in the arms made pro-

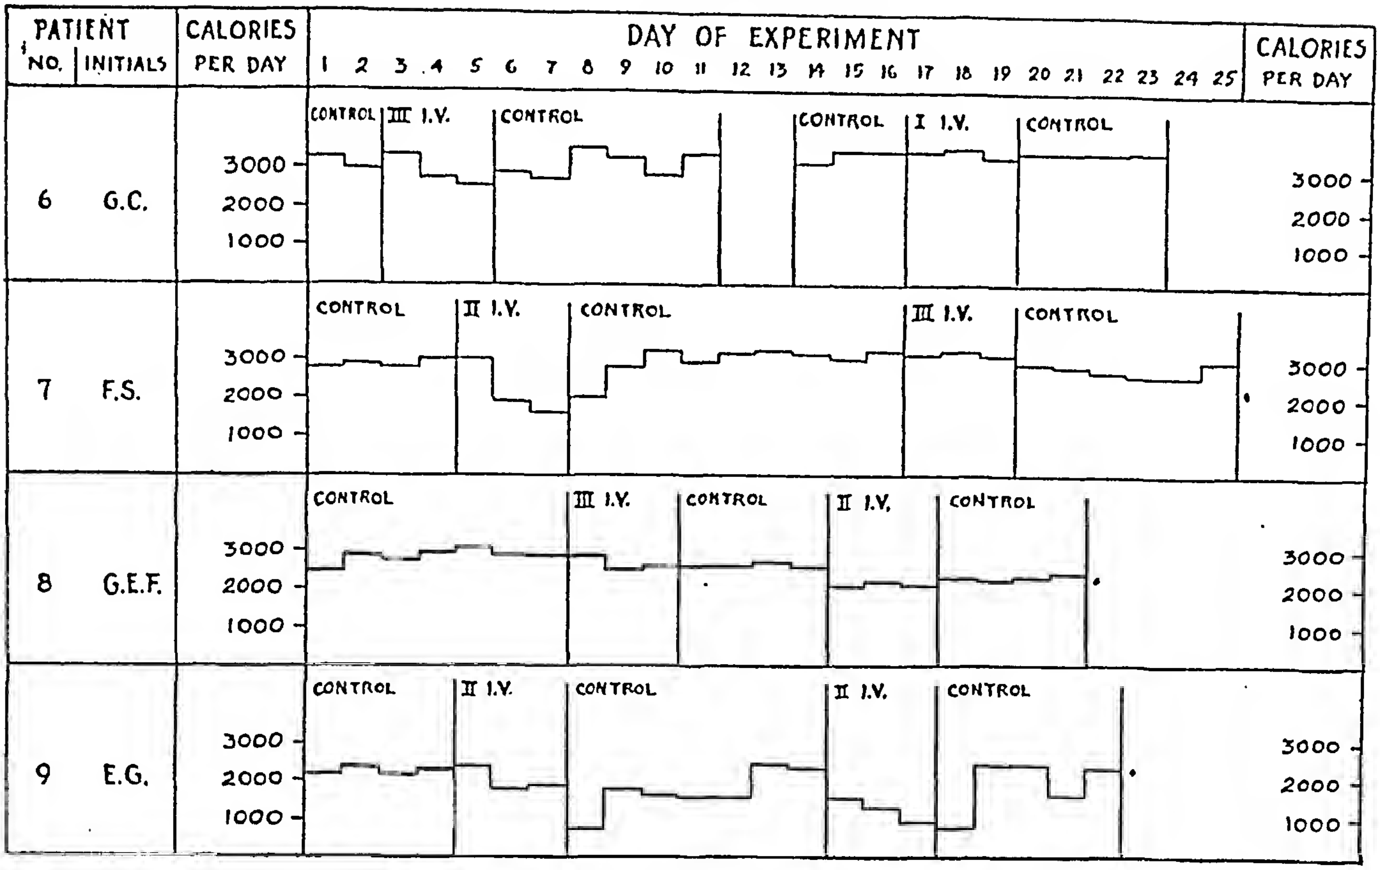

FIG. 2. EFFECT OF INTRAVENOUS ADMINISTRATION OF AMINO ACID MIXTURES I, II, AND III UPON THE VOLUNTARY FOOD INTAKE

longed administration of this mixture difficult. The depression of appetite as reflected in the decreased food intake was not directly related to the presence or absence of the venous thrombosis because the depression occurred in subjects in whom no vein lesions developed, but the associated pain probably contributed to the poor appetite to some extent. Some of the men complained that after receiving any of these preparations they had an unpleasant taste that was similar to the smell of the casein digest. This peculiar taste was reported by a number of patients and remained for a few days after the administration of the amino acids stopped.

* Information incomplete.

The results of the studies of the relationship of rate of infusion to the food consumption during intravenous protein feedings are summarized in Table II. Some of the peculiarities involved in the rate of administration of these products can be seen in the data derived from patient H. W. (No. 3). Preparation I was given at an average rate equivalent to 40 grams per hour with no ill effects, while Preparation II caused a marked depression in food consumption when given at an average rate of 26 grams of protein per hour. Patient J. B. (No. 4) received both Mixtures I and II at almost identical rates. In this case the drop in calories consumed per day occurred only with the latter mixture. An unusual effect is presented by patient E. G. (No. 9) who received Mixture II on 2 different experimental periods of 3 days each. The rate was 30 grams per hour during the first period and only slight step-wise depression of the total food consumed resulted. At the second experimental period the rate of infusion was approximately ½ that of the first period (14.5 grams per hour) and on this occasion this same mixture caused a pronounced fall in the amount of food eaten. Mixture III did not cause any change in the appetite as judged by the amount of food consumed, and the rate of its infusion was comparable to or faster than those used with the other mixtures.

In these cases where there was some reduction in the voluntary intake after the giving of amino acid digests, the question of selective reduction of any one of the major foodstuffs was investigated. The amount of fat, carbohydrate, and protein eaten by each subject was calculated and expressed as the ratio of Protein:Fat:Carbohydrate. Table III is a summary of some of these ratios. There appears to be no constant decrease in consumption of any given class of foodstuffs after amino acid therapy. Variations in the ratios appear, but no trend is evident. In other words, when these individuals cut down on eating they did not tend to avoid selectively the high protein foods and to eat only foods high in carbohydrates or fats.

DISCUSSION

Co Tui (9) has pointed out that one of the major drawbacks to the clinical use of casein hydrolysates for intravenous protein feedings is the difficulty in giving enough to supply the nitrogen and caloric needs. This is particularly true if it is desired to give large amounts of protein building materials. Elman (25), in presenting a régime for intravenous alimentation of patients suf-

* Figures in the table are fat: carbohydrate ratio, protein = 1.

fering from severe protein deficiency, advised the giving of both amino acids and glucose. The sum of the volumes of solutions given per 24-hour period amounted to 3,000 ml., and the total caloric intake was only 1,200 calories, an amount which usually would not be sufficient for a normal subject to maintain his weight. In this investigation the daily dose of the equivalent of 100 grams of protein was arbitrarily chosen because it was considered an amount adequate to provide the generally recommended allowance of 1 gram of protein per kilogram of body weight and a margin to replace depleted protein reserves.

A practical consideration in giving intravenous protein supplements is to employ a method that will not interfere with the patient's daily food intake. In this study 3 injections were given daily, and the individual infusions were completed in not more than 3 hours. Longer infusions were considered inadvisable from the standpoint of comfort to the patient and because the presence of the needle in the vein was a factor which mechanically interfered with the eating of the regular meals. The rates used with Mixture I and II exceeded those usually recommended. Mixture III was frequently given at rates twice those used with the casein digests. The data regarding the rate of infusion in the present study do not permit any final conclusions.

One of the requirements for an acceptable intravenous preparation is that it must be injectable in adequate amounts without producing nausea, vomiting, or other unpleasant reactions. The relationship of reactions which occurred during or following the infusions to the depression of the appetite is a matter of great practical importance. The one constant finding was that, of the 3 mixtures used, the greatest impairment in the appetite occurred during those experimental periods when Mixture II was given. However, it is noteworthy that none of the subjects given Mixture III had any side-effects, and in this same group no significant reduction in the consumption of food was observed. When these same patients received Mixture II impairment of the appetite occurred.

At the present time there is no satisfactory explanation for the occurrence of nausea and vomiting. Albanese (26) questioned if these toxic effects were due to unnatural isomers of certain amino acids which cannot be utilized by the human body. Hopps (27) suggests that the presence of some histamine-like substances, peptones or tyramine as agents may explain the frequently observed reactions of flushing, sensation of warmth, and nausea; but he gives no experimental data to support these ideas. Madden and associates (22) have shown that both glutamic and aspartic acids when added to a mixture of pure amino acids will cause violent vomiting in dogs. The effect of these 2 amino acids upon the voluntary food consumption and as a factor causing emesis in humans is being investigated and will be reported in a separate communication. Hoffman, Kozoll, and Osgood (28) have presented evidence that the height of the amino acid nitrogen content of the blood is probably the factor responsible for producing nausea. They found that if the rate is sufficiently rapid to get a blood amino acid nitrogen value of 10 mgm. per cent or greater, nausea will result. These studies were carried out using Mixture II. Hecht (21), using Mixture II, has suggested that perhaps the rapidity of the rise of the amino acid blood levels and not the actual levels themselves were responsible for the side effects.

The progressive step-wise reduction in the amount of food voluntarily consumed during the succeeding days of the experimental periods occurred with such regularity, particularly with Mixture II, that it must be considered more than a chance occurrence. The overlap into the subsequent first and second days of the control period and the gradual recovery were the usual findings in these cases. At present there is no explanation for this occurrence.

These studies raise the question as to whether the advantages of giving large doses of amino acid mixtures intravenously are offset by increased urinary nitrogen "wastage" which would be expected to accompany the rapid rates of infusion. In the search for a more acceptable preparation for intravenous use, this important point will require investigation.

SUMMARY

The effect of the oral and intravenous administration of mixtures of amino acids on the volun-

tary food consumption in normal human subjects was studied. Three preparations were used: an enzymic hydrolysate of casein (I), an acid hydrolysate of casein (II), and a mixture of the 10 essential amino acids plus glycine (III). The enzymic digest had little effect on the appetite whether it was given orally or intravenously. The acid hydrolysate of casein consistently produced a marked depression in the voluntary food consumption during and following its intravenous administration. The mixture of the essential amino acids had no depressing effect on the appetite. This product was the best tolerated of the 3 tested and could be given at exceedingly rapid rates without any ill effects. When there was reduction in the amount of food eaten, it consisted of a general lack of interest in food rather than a selective rejection of a certain class of foodstuff.

MINIMUM DOSAGE OF THIOUREA, GIVEN TOGETHER WITH IODINE MEDICATION, NECESSARY FOR THE PRODUCTION AND MAINTENANCE OF A REMISSION IN HYPERTHYROIDISM [1]

By A. W. WINKLER, E. B. MAN, and T. S. DANOWSKI

(From the Departments of Internal Medicine and Psychiatry, Yale University School of Medicine)

(Received for publication November 27, 1946)

It has been shown that thiourea in amounts smaller than those recommended for thiouracil can produce a satisfactory remission in hyperthyroidism (1). The thyroid-depressant effect is enhanced if thiourea is used in combination with strong solution of iodine (2, 3, 4). The administration of these two substances together results in a more rapid and more profound drop in the concentration of serum precipitable iodine than that observed with thiourea alone. Symptoms and signs of thyroid overactivity disappear along with or soon after the fall in serum precipitable iodine. Continued administration of thiourea, however, in the dosage initially used to produce a remission (280 to 210 mgm. daily) ultimately results in hypothyroidism in a number of patients. Ingestion of desiccated thyroid is followed by disappearance of the hypothyroidism and the serum precipitable iodine concentration returns to normal.

These facts suggest that the dosage initially employed was unnecessarily large. The present study arose from an attempt to avoid hypothyroidism by the use of the minimum effective dose of thiourea. To determine the magnitude of this, the effects of small doses of thiourea, 0.075 to 0.015 gram daily, together with iodine solution in inducing and maintaining a remission in hyperthyroidism have been studied. Results obtained with iodine medication alone, and those with amounts of thiourea greater than 0.075 gram are included for purposes of comparison.

MATERIALS AND METHODS

Data are presented on 4 groups of hyperthyroid subjects, some with diffuse goiter and some with adenomata. With but few exceptions the patients were not hospitalized. The diagnosis of thyroid overactivity was based primarily upon the presence of a concentration of serum precipitable iodine of 8.0 gamma per cent or more (5, 6). This was usually but not invariably accompanied by an increase in the basal metabolic rate above plus 20 per cent. In all patients the clinical history and findings were compatible with the diagnosis of hyperthyroidism. No toxic reactions were observed in any of the patients during treatment with thiourea.

RESULTS

A. Production of a remission in hyperthyroidism. The effects of 2 treatment régimes on the course of active hyperthyroidism, measured by changes in the serum precipitable iodine, have been studied in 89 patients.

(1) TREATMENT WITH IODINE AND THIOUREA. Fifty hyperthyroid patients were treated with thiourea together with strong solution of iodine. Of these patients, 9 received 0.280 gram of thiourea daily in a single dose; 12 were treated with a total of 0.210 gram daily taken in 3 equal doses 8 hours apart; 17 other patients were started on either 0.070 gram in a single dose, or on 0.075 gram divided into 3 equal doses of 0.025 gram each; the remaining 12 patients took 0.005 gram of thiourea 3 times daily for a total daily dose of 0.015 gram (Figure 1A, B, C, and D). Each patient in this group of 50 also received 5 drops of strong solution of iodine 3 times daily.

It is evident from the figure that equally satisfactory results were obtained with either 0.280 gram or 0.210 gram of thiourea daily in addition to iodine solution. At the end of 10 to 12 weeks of treatment or less, all but one patient in each of these 2 groups had developed concentrations of serum precipitable iodine of 8.0 gamma per cent or less (Figure 1A and B). The use of a smaller amount of thiourea, 0.07 gram daily, proved to be somewhat less effective. At the end of a similar period of treatment, 10 out of 13 patients had responded (Figure 1C). A daily intake of only 0.015 gram of thiourea, on the other hand, failed

[1] Aided by a grant from the Fluid Research Fund, Yale University School of Medicine.

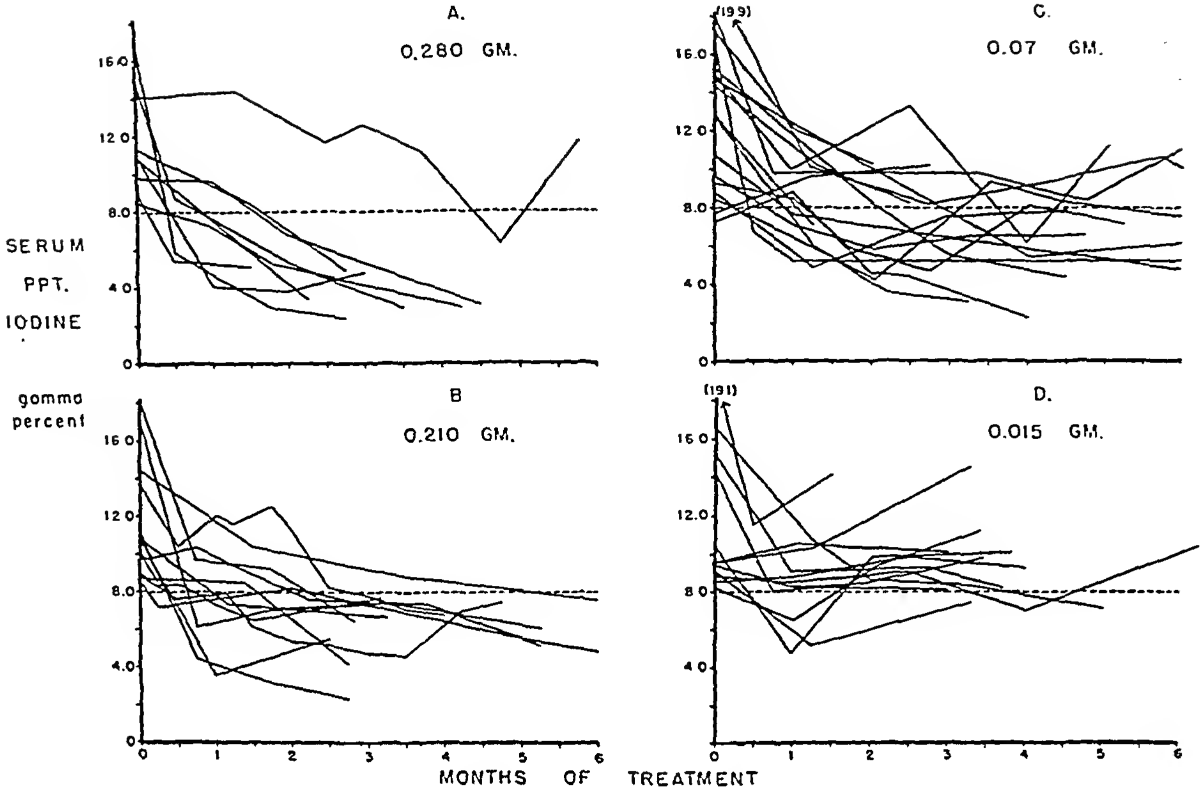

FIG. 1. TREATMENT OF HYPERTHYROIDISM WITH IODINE SOLUTION TOGETHER WITH THIOUREA

The return of the serum precipitable iodine to normal concentrations together with amelioration of the hyperthyroidism occurred almost as often in patients maintained on 0.07 gram of thiourea daily as it did in those on 0.280 or 0.210 gram. With doses as low as 0.015 gram daily, however, no thiourea effect is apparent; the occasional response observed is to be attributed to the iodine solution.

with but 1 exception to bring and keep the hyperthyroidism under control (Figure 1D). Moreover, in contrast to the findings in the preceding 3 groups, hypothyroid levels of serum precipitable iodine (4.0 gamma per cent or lower) did not develop in any of these patients.

The response to these various doses of thiourea is also reflected in the values of the serum precipitable iodine at selected points during the course of treatment. The averaged values of the serum precipitable iodine, for example, were quite comparable prior to treatment in the 4 groups. They were 11.7 ± 2.6, 11.8 ± 2.9, 12.8 ± 3.8, and 11.7 ± 3.6 gamma per cent in groups A, B, C, and D respectively. After 10 to 12 weeks of treatment, the average value of the serum precipitable iodine in patients in group A had declined to 5.7 ± 2.9 gamma per cent. The decrease was progressively less marked in groups B and C receiving smaller amounts of thiourea, since the average value in the former during the 10- to 12-week period was 6.5 ± 2.0 gamma per cent, and in the latter 6.9 ± 2.3. In group D, however, the average level of precipitable iodine during a comparable period was 9.5 ± 1.5 gamma per cent. The serum precipitable iodine therefore declined significantly in groups A, B, and C but not in group D. The differences in extent of decline among the first 3 groups are probably not significant.

(2) TREATMENT WITH IODINE ALONE. Thirty-nine patients were treated with strong solution of iodine alone, in a total daily dose of 15 drops. To simplify, graphic presentation results obtained with this therapy have been subdivided into 4 categories based upon changes in the concentration of the serum precipitable iodine (Figure 2A, B, C, and D). The serum precipitable iodine declined to and remained at euthyroid levels, 4.0 to 8.0 gamma per cent, in only 9 of the 39 patients (Figure 2A). In 6 other patients the serum precipitable iodine

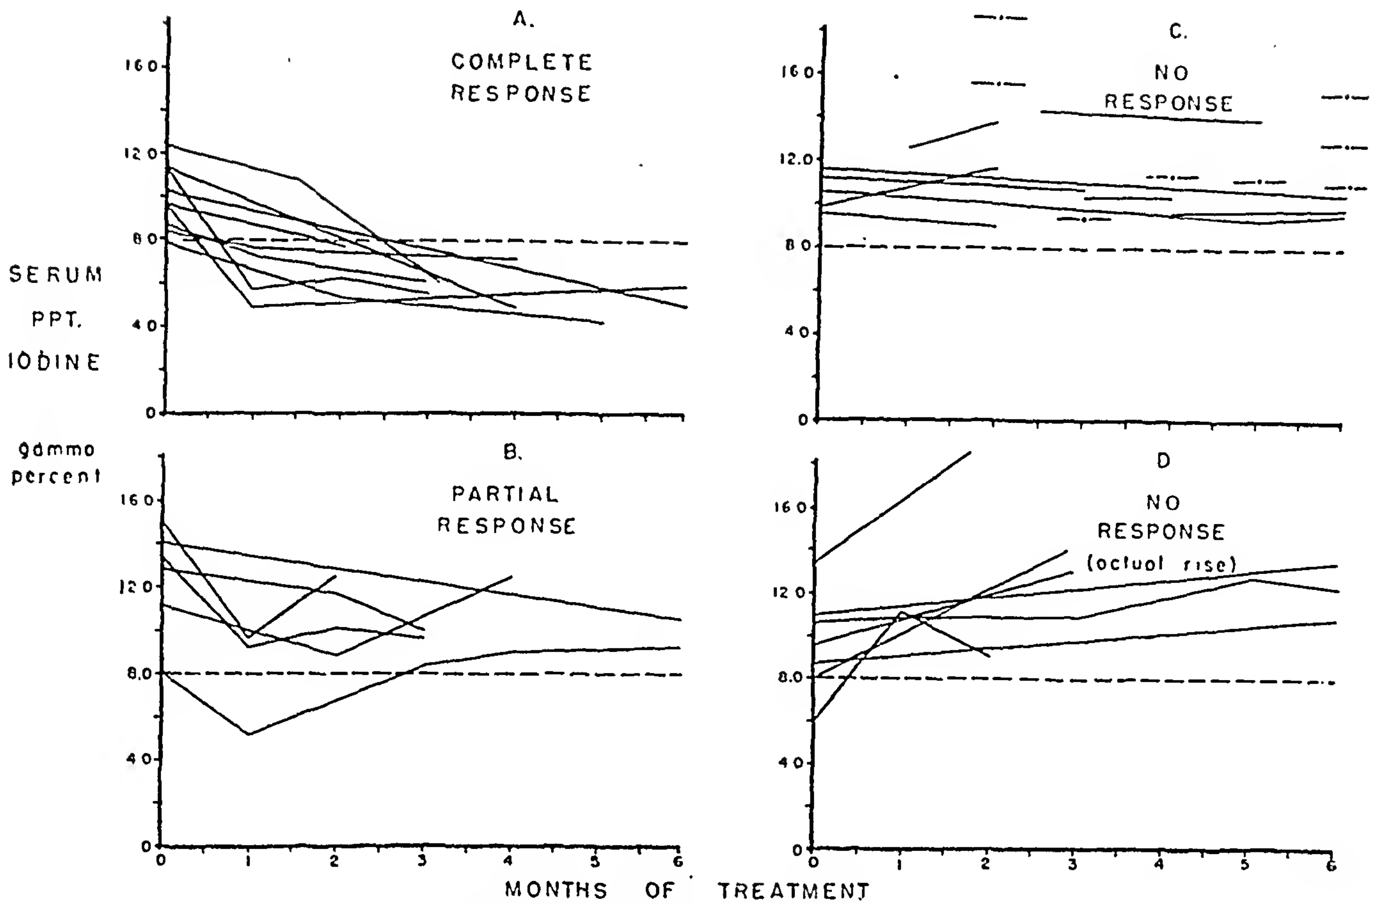

FIG. 2. PROLONGED TREATMENT OF HYPERTHYROIDISM WITH IODINE SOLUTION ONLY

Clinical improvement and euthyroid concentrations of serum precipitable iodine appeared and persisted in 9 of the 39 patients. In the remaining 30 patients the serum precipitable iodine, save for a temporary initial decrease in some instances, remained elevated and thyroid overactivity continued.

fell 2.0 gamma per cent or more, but in only 1 did the concentration become normal. This patient and several others showed a subsequent rise to the pretreatment levels (Figure 2B). In the majority of patients, 17 in number, the serum precipitable iodine either failed to change at least 2.0 gamma per cent or was still distinctly elevated despite prolonged treatment with iodine solution (Figure 2C). In the 7 remaining patients, the serum precipitable iodine actually increased during iodine treatment (Figure 2D).

In those few patients in whom the concentration of serum precipitable iodine fell to normal levels the hyperthyroidism largely disappeared. Some of the others also showed a measure of clinical improvement. This did not always correlate in either magnitude or direction with the change in the serum precipitable iodine. In the majority of patients, however, the clinical symptoms and signs of thyroid overactivity continued unabated or actually increased during treatment with the iodine solution. None of the patients developed hypothyroid concentrations of iodine.

B. Maintenance on reduced amounts of thiourea and on iodine solution. The effectiveness of 0.07, 0.05, 0.035, 0.025, and 0.015–0.010 gram doses of thiourea and 15 drops of iodine solution daily in maintaining the remission obtained by larger amounts of thiourea has been studied in 15 patients. Following the appearance of a stable euthyroid state the daily intake of the drug was reduced. In some of the patients the maintenance dose was decreased more than once. The strong solution of iodine, however, was continued throughout the entire treatment period in all 15 patients without alteration in dosage. Variations in the concentration of serum precipitable iodine following reduction in the dose of thiourea are presented in Table I together with other pertinent data.

The remission was maintained despite a reduction in the daily intake of thiourea to 0.07 gram

in 11 patients in whom the initial response had been induced by 0.280, 0.210, or 0.140 gram. Further decrease in the maintenance dose of thiourea to 0.050, 0.035, or 0.025 gram resulted in a recurrence of hyperthyroidism in only 1 out of 11 trials (Patient E. B.). Attempts to control thyroid overactivity with 0.015 to 0.010 gram of thiourea daily failed, however, in 5 out of 8 patients.

In the 4 patients in whom the serum precipitable iodine decreased to 4.0 gamma per cent or lower, the level was raised to euthyroid values in 2 (Patients F. W. and P. G.) and toward normal in the other 2 (Patients K. S. and S. L.) by reducing the daily intake of thiourea. Maintenance of a remission for prolonged periods of time is quite feasible, therefore, on 0.07 to 0.025 gram of thio-

* At end of period.

urea with only rare exacerbation of hyperthyroidism. Reductions to these amounts also prevent or correct myxedema. Amounts of thiourea as low as .015 gram, however, appear to be quite as ineffective in maintaining a remission as they were found to be in producing the initial response.

C. Effect of withdrawal of thiourea. In 10 patients, thiourea has been discontinued after administration in various amounts for 5 to 24 months, together with strong iodine solution. In 3 of these, the iodine solution was stopped along with the thiourea. In the remaining 7, it was continued as the sole medication. All 10 patients in this group were free of hyperthyroid symptoms and

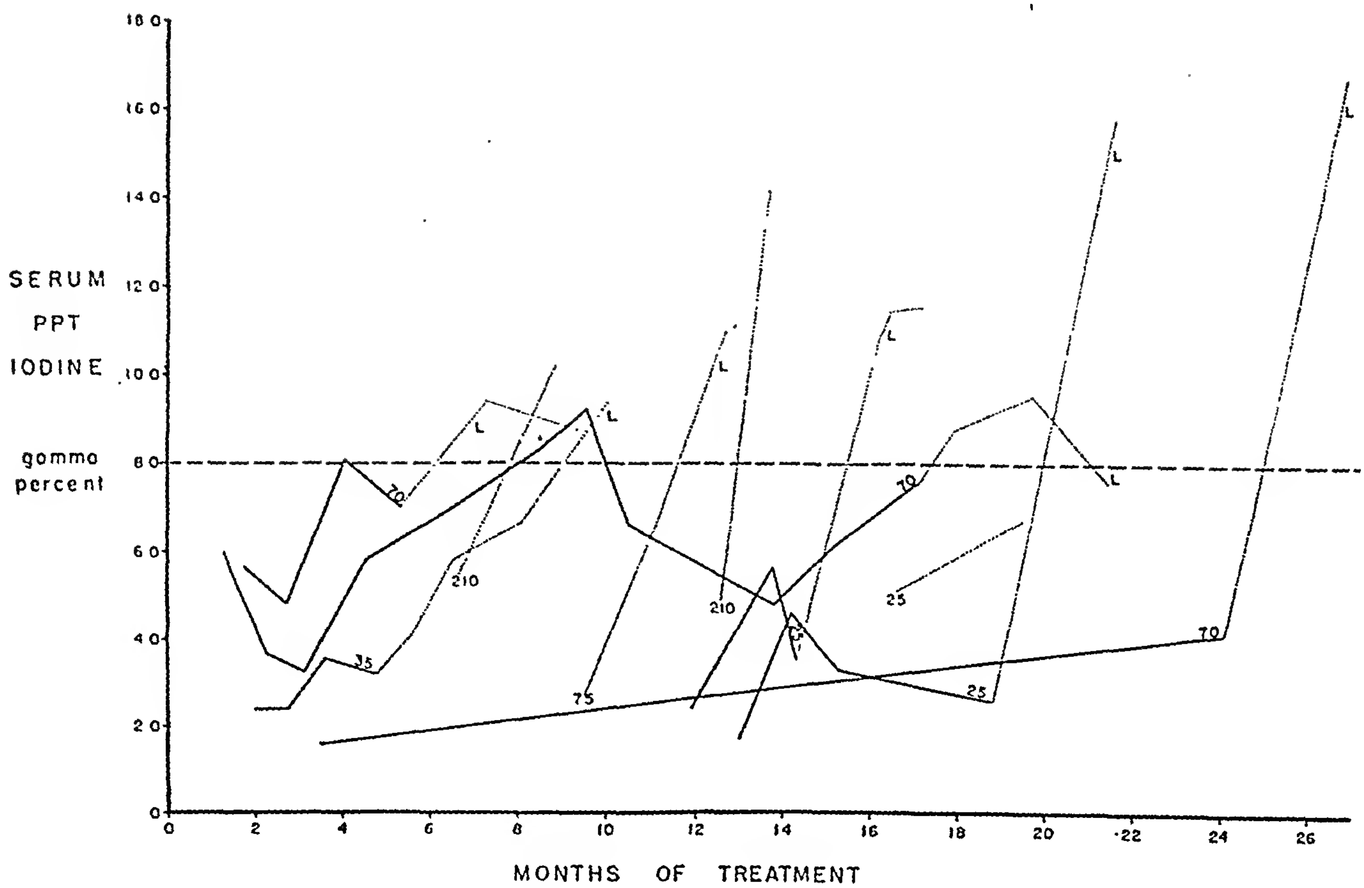

FIG. 3. EFFECT OF WITHDRAWAL OF THIOUREA

In patients in remission on thiourea plus iodine, hyperthyroidism usually recurs if thiourea medication is omitted, even after months of treatment, and even if iodine medication (all lines marked "L") is continued. The numbers refer to the daily dosage of thiourea prior to withdrawal of this medication. Dotted lines indicate changes in serum precipitable iodine following cessation of thiourea therapy.

had been repeatedly found to have euthyroid concentrations of serum precipitable iodine prior to the withdrawal of thiourea. The effect of this change in the therapeutic régime on the concentration of serum precipitable iodine is shown in Figure 3.

Hyperthyroidism recurred in 8 of the 10 patients within 6 to 12 weeks after withdrawal of the drug. This high incidence of recurrence appears to be independent of whether the iodine solution was continued or discontinued at that time.

DISCUSSION

It is evident that in most patients it is not necessary to provide a daily intake of thiourea greater than 0.07 gram given with strong iodine solution in order to produce a rapid and complete remission in hyperthyroidism. Since a response to 0.015 gram of thiourea together with iodine solution is obtained in only a very small proportion of subjects, the minimum effective dose of thiourea, given in conjunction with iodine, must lie between 15 and 75 mgm. daily in most patients. Variations in individual response make more exact estimation difficult. Two advantages may be derived from the use of smaller doses of thiourea such as 70 mgm. rather than 210 or 280 mgm. First, it is possible that the number of toxic reactions may be minimized. Although in the studies reported in this paper no untoward reactions were encountered, drug fever developed in 2 patients in a previous series (2). Second, the smaller the dose employed, the less is the probability of the development of hypothyroidism. We have, therefore, adopted the following regular plan of treatment. Ambulatory patients are usually started on 70 mgm. a day, along with strong solution of iodine, 5 drops 3 times a day. If they do not respond within 4 to 8 weeks, the dose is increased. Hospitalized patients with cardiac or other complica-

tions, on the other hand, are from the start treated with the larger amounts in addition to iodine solution. Comparison between patients receiving the entire dose once a day and those in whom it was divided and spaced in 3 parts shows no significant difference in the response of the hyperthyroidism. Divided doses are preferable, however, in those patients subject to gastrointestinal reactions.

If 210 mgm. daily are employed initially, it is desirable to reduce the maintenance dose of thiourea to 70 mgm. daily or less once remission has occurred (Table I). In this way hypothyroidism and myxedema can usually be avoided entirely. The dose should not be reduced below 25 mgm. daily since 15 mgm. and smaller amounts are generally ineffective. The large proportion of recurrence which follows the cessation of thiourea therapy (Figure 3) effectually disposes of the possibility that the hyperthyroidism has been cured.

In a previous paper (2), the additive effects of iodine and thiourea in the larger doses, 280 or 210 mgm. daily, were demonstrated. Too few observations on the effects of 70 mgm. daily doses of thiourea without iodine are as yet available to establish that this same additive effect is present at these low levels of dosage. The possibility, on the other hand, that the beneficial effects of this combined form of therapy are to be ascribed chiefly to the iodine solution given can be easily discarded. From Figure 2 it is evident that iodine solution by itself only rarely produces a sustained remission in hyperthyroidism, and from Figure 3 it is clear that iodine alone cannot sustain a remission produced by thiourea. These results confirm the general impression that continued treatment of hyperthyroidism with iodine medication alone is generally unsatisfactory.

The physiological effect of these small amounts of thiourea point to a particular sensitivity of the thyroid gland to this drug, since, at least in the normal dog, there is no tendency for the thyroid gland to destroy or concentrate thiourea in measurable amounts (7). Thiourea does not accumulate in the body to any extent and is distributed through most of the body fluids in about the same concentration as that found in serum water (7). The concentration of thiourea in serum after a daily dose of 25 mgm. is too low to measure by present analytical methods, but the general range may be estimated from the volume of distribution of thiourea (about 0.8 times the body weight) and its renal clearance (50 to 60 ml. per minute) (8). This calculation indicates that the concentration ranges from 5 to 50 gamma per cent of thiourea in body fluids including, presumably, the available water of the thyroid gland. These are to be compared with concentrations of inorganic iodine in the water of the thyroid gland of the magnitude of 10 mgm. per cent, or 10,000 gamma per cent (9). It seems improbable that relatively few molecules of thiourea can combine with and render unavailable, as has been suggested (10, 11), this great excess of inorganic iodine. The thiourea effect appears to be mediated, rather, through a block at a crucial link in the chain of reactions through which all of the iodide which is converted to organic iodine must pass. The studies reported in this paper indicate that this block in the conversion of inorganic iodine to diiodotyrosine and thyroxine can be produced by almost infinitesimal traces of thiourea.

The fact that iodine medication does not interfere with the action of thiourea, even when the latter is present in relatively trifling amounts, and the fact that their actions are additive, prove that these substances act at quite different points. There is good evidence that iodine has two separate actions on the hyperthyroid gland; the first inhibits the effect of thyrotropic hormone, the second favors the accumulation of iodine within the gland, as a result of an excess of inorganic iodine (9). Thiouracil and related drugs interfere with neither action (12 to 15). Since they certainly prevent the synthesis of thyroxine and diodotyrosine from inorganic iodine (13), it is reasonable to suggest that they may act by poisoning the enzyme system responsible for this synthesis. The lack of interference in the action of thiourea by iodine in large excess is most readily explained in this way. The experiments of Astwood (10) in which he demonstrated a greater goitrogenic potency of thiouracil in animals maintained on a low iodine diet than in those on a high iodine diet do not prove that there is a direct interference between iodine and thiouracil. The high iodine diet more probably acts by inhibiting thyrotropic hormone action and so delaying the development of goiter.

SUMMARY AND CONCLUSIONS

1. Doses of thiourea as small as 0.07 gram daily, in conjunction with iodine solution, produce a remission in hyperthyroidism with considerable regularity.

2. The remission in hyperthyroidism can usually be maintained by the use of 0.05 to 0.025 gram of thiourea daily in addition to iodine solution.

3. A daily intake of 0.015 gram of thiourea together with iodine solution does not induce a remission, or maintain it, following the use of larger amounts.

4. Withdrawal of thiourea, even when the maintenance dose is as low as 0.025 gram, is frequently followed by exacerbation of a previously controlled hyperthyroidism.

5. Control of hyperthyroidism with iodine solution alone is only rarely possible, with or without previous thiourea treatment.

6. Prolonged, and perhaps indefinite, maintenance on thiourea and iodine is necessary to prevent recrudescence of hyperthyroidism.

VASODILATOR FIBERS IN THE HUMAN SKIN

By STANLEY J. SARNOFF AND FIORINDO A. SIMEONE

(From the Department of Surgery of the Harvard Medical School at the Massachusetts General Hospital)

(Received for publication December 9, 1946)

Reports on vasodilator fibers in the human skin have not been in general agreement concerning either their existence or their relative functional significance (1–6). In a recent review on sympathetic surgery (7), the interruption of vasodilator fibers was cited as a possible cause for the limited benefit that occurs after sympathectomy for certain types of peripheral vascular disease. It seemed worthwhile, therefore, to reexamine the available evidence and approach the problem of vasodilator activity from points of view other than those previously described.

Lewis and Pickering (4) suggested that heating the body produces maximal vasodilatation in the skin of the extremities by inhibiting vasoconstrictor impulses and also by stimulating additional active dilatation by vasodilator impulses. If this is true, local nerve block performed during pronounced heating of the body or of the other extremities should interrupt these vasodilator impulses, exclude active vasodilatation, and produce a slight but definite fall of skin temperature. The magnitude of the reduction should be proportional to the postulated activity of the vasodilator mechanism at the time of the block.

METHOD

Patients on the surgical wards of the Massachusetts General Hospital were studied. Before beginning the experiment, the patient was placed in the cold room and covered only by a loin cloth. Skin temperatures were determined by means of 8 iron-constantan thermocouples which led to an electronic, nongalvanometric, continuous balance potentiometer.[1] This recorder registered in rotation every 30 seconds so that each thermocouple registered every 4 minutes.

When skin temperatures were determined on the hand, the palmar surface of the distal phalanx of the second and fifth digits were used. The plantar surface of the distal phalanges of the toes and a point on the lateral aspect of the dorsum of the foot were used in obtaining skin temperatures of the lower extremity. The shielded wire proximal to the naked thermocouple was taped to the appropriate site at least 2.5 cm. away from the point of actual determination so that there was no interference with heat loss at the point of determination.

Rectal temperatures, when obtained, were recorded by means of a resistance bulb and potentiometer recording on a circular chart readable to 0.02° centigrade.[2] The values at 5-minute intervals were charted. Procaine or metycaine hydrochloride was used for the local blocks. The ulnar nerve was blocked at the elbow. Ankle block was achieved by combining the conventional posterior tibial block with complete ring block at the ankle. The spinal block and the ring block of the toe were performed in the conventional fashion. Care was taken to make certain that epinephrine was not added to the anesthetic agent. In those patients in whom a sympathectomy had been done, the blocks were always performed on the intact side.

Indirect vasodilatation in the hands was induced by placing the legs in warm water at 43–44° C. up to the knees (8, 9). Vasodilatation in the feet was induced by placing the arms in warm water up to the elbows. In 1 experiment, number 4, an air envelope, through which the arms and head protruded, covered the patient, and warm air at 45° C. was blown into it. In 4 cases rectal temperature was recorded. In all cases, after placing the legs or arms in warm water, the degree of perspiration was noted.

In order to control the factor of evaporation, latex rubber was sealed over the area under observation with collodion in 2 experiments, numbers 7 and 8. In this way the loss of heat occurred from a dry surface both before and after the block.

RESULTS

Figure 1 is the chart of experiment 2 and is representative of experiments 2 to 8. The patient was brought into the cool room in which the temperature was maintained at 19.7° C. He was covered only by a loin cloth. The control temperature plateau prior to heating was obtained and at 10:30 a.m. the arms were placed up to the elbows in water at 43–44° C. Sweating began at 10:40 a.m. and soon became profuse. This was continued until a second plateau was reached and at 11:44 a.m. a complete left ankle block, including the posterior tibial nerve, was performed. Just prior to the block a towel was placed over the left foot: the artificial rise in skin temperature thus induced is indicated by broken lines in Figure 1. The

Arms immersed in warm bath at 10:30 a.m. Towel covering left foot produced artificial rise in skin temperature indicated by dotted lines. Ten minutes after start of ankle block, anesthesia was complete and the skin temperature of the left foot and great toe rose above the pre-block level.

towel was removed immediately and anesthesia began to set in at 11:50. This was followed by a sustained rise in skin temperature that exceeded the pre-block level by 2.1° C. on the great toe and 1.4° C. on the dorsum of the foot. A full block was still in effect at the end of the experiment.

Had active vasodilator impulses been responsible for the height of skin temperature engendered by the heating of the indifferent extremities, blocking the local nerve supply should have resulted in a fall in skin temperature. A rise actually occurred. Reflex activity in the sympathectomized extremity was apparently absent.

Table I summarizes the results. Experiment 1 was essentially a reproduction of one type of procedure upon which Lewis and Pickering based their conclusions; and, although our data are similar to theirs, we believe, as do Warren *et al*, that another interpretation is tenable. This view is supported by the results of experiments 2 to 8. Experiment 2 has already been described. In experiments 2 to 8 no evidence could be found that active vasodilators took part in the reflex vasodilatation resulting from heating the extremity or the body. Local nerve block in these experiments was followed by a rise in skin temperature instead of a fall in 5 of the 7 experiments, and in the remaining 2 the nerve block resulted in no appreciable change. In none did a fall in the skin temperature occur.

Experiments 7 and 8 represent attempts to control the factor of evaporation in order to be certain that the rise in skin temperature following the local nerve block was not due to the cessation of sweating. In these experiments the area from which the skin temperature was determined was covered with latex rubber and sealed with collodion so that heat loss occurred from a dry surface both before and after the nerve block.

Figure 2 is the chart of experiment 8. The left fifth finger was covered with a finger cot at 1 and indirect vasodilatation was induced by placing the legs in warm water at 2. Just prior to the block the patient became quite apprehensive, and

a slight fall in skin temperature occurred. After the block, however, the unblocked area (the left second finger) resumed its previous level, while the blocked area exceeded its pre-block level by 1.2° C., even though the factor of evaporation was controlled throughout.

Figure 3 is the chart of experiment 7. Indirect vasodilatation was begun at 1. The dorsum of the foot was covered by latex rubber and sealed at the arrow. Spinal anesthesia was induced at 2. The arms were removed from the warm bath at 3. Despite the fact that the arterial pressure fell and

Despite a 1.4° C. fall in body temperature and a lower systolic arterial pressure, the skin temperature of the right foot maintained its previous level. (See text.)

there was a 1.4° C. fall in body temperature, the skin temperature of the blocked area did not fall, but maintained its pre-block level. In this experiment, as in experiment 8, the factor of evaporation was controlled by making certain that heat loss from the area occurred from a dry surface both before and after the block.

In experiments 2 to 8 inclusive (illustrated by Figures 1 to 3), "maximal vasodilatation" was first induced by heating the indifferent extremities with warm water or by heating the body with warm air. Heating was intense enough (*a*) to produce profuse sweating in every instance and (*b*) to elevate rectal temperature 0.3° to 2.3° C. in the 4 experiments in which it was determined. If vasodilator nerves share in the control of blood flow to the skin of the digits, there is every reason to believe that the stimulus used in these experiments was adequate to bring them into action. Subsequent local nerve block resulted in complete anesthesia in the appropriate area and a fall in skin temperature did not occur in any case. It is reasonable to conclude from these results that the vasodilatation produced by pronounced body warming does not include any measurable component that can be attributed to vasodilator impulses.

DISCUSSION

It is well to point out that small changes in skin temperature at the higher ranges (33° to 36° C.) reflect relatively major alterations in blood flow. Wright and Phelps (10) have found that a rise of 1° C. in this range may represent a change in the corresponding blood flow determination from 3 ml. per 100 ml. of tissue per minute to a value of 10 ml. per 100 ml. of tissue per minute.

In recent years, support for the theory that vasodilator fibers exist in the skin of the extremities comes mainly from 4 groups of investigators. Lewis and Pickering (4) performed experiments in which normal subjects and sympathectomized patients with Raynaud's disease were studied. They showed that in an individual who had undergone a dorsal sympathectomy, the temperature of the fingers of the intact hand rose to higher levels after indirect vasodilatation than did those of the sympathectomized side. They concluded from this that it was the presence of vasodilator fibers on the undisturbed side that was responsible for the higher level of skin temperature attained. Experiments were also done in which an ulnar nerve block was performed on a patient with Raynaud's disease while the patient was in a cold room. Indirect vasodilatation was then induced, and it was observed that the skin temperature of the anesthetized area did not rise while that of other areas did rise. Similar observations were made on both the lower and upper extremities (1, 2).

Grant and Holling (3) subjected patients to body heating and studied its effect on blood flow in the forearm. They concluded that the increase in flow depended upon the integrity of the sympathetic nerves and that vasodilatation was brought about both by inhibition of vasoconstrictor tone and by active vasodilator impulses. In their observations, a forearm was flushed and warmed directly and then kept so by indirect heating. Local nerve block then caused the anesthetized area to pale, cool, and cease sweating. However, as pointed out by Warren, *et al* (6), the authors are unable to account for the difference between the effect of sympathectomy which increases forearm flow and the effect of local nerve block which, they concluded, under certain conditions, diminishes it. It should also be added that these investigators added epinephrine to the procaine with which the local nerve blocks were performed. Similar experiments were performed by Doupe *et al* (11).

Warren *et al* (6) also point out that when body heating produces indirect vasodilatation which is greater in the intact than in the sympathectomized extremity, this cannot be used as evidence for the presence of vasodilator fibers, for it has been repeatedly demonstrated that the peripheral vascular bed of a sympathectomized extremity acquires an appreciable tone and that this tone is not affected by efforts at homeostasis mediated through the central nervous system. We have in fact observed several individuals in whom a unilateral sympathectomy had been performed and in whom a "paradoxical response" was observed, that is, when indirect vasodilatation was induced, the temperature of the sympathectomized extremity fell several degrees while that of the intact side responded in the usual fashion. This phenomenon, produced experimentally, is accompanied by a slight lowering of the arterial pressure.

Warren *et al* (6) have demonstrated that complete procainization of the sympathetic supply to the upper extremity causes an increase in blood

flow that is equivalent to the maximal increase produced by immersing the hand in water at 43° C. plus indirect heating. The authors concluded that these data make it unnecessary to assume the presence of active vasodilator fibers to the skin.

In the various investigations which purport to demonstrate the functional activity of vasodilator fibers, the lack of a rise in skin temperature following local or paravertebral block plus indirect heating was construed as being due to a lack of vasodilator activity in the anesthetized area. These experiments were made on patients suffering from vasospastic disease. Yet we know that where diminished peripheral flow is due to arteriolar constriction alone, block of the nerve supply to that area is followed by a local rise in skin temperature.

In this connection it is profitable to examine the chart of patient number 7 (Figure 3). At point 1, the arms were placed in warm water and the skin temperature on the dorsum of the right foot rose while that of the left third toe did not. Had a procaine block of the left third toe been performed prior to 1, this curve would resemble that type of chart upon which the main body of evidence in favor of vasodilator fibers in the human skin is founded. That the block was not performed indicates that other factors may contribute to this type of result. Support is given this view by the fact that this result has not been obtained in the normal human, but only in the patient with well established peripheral vascular disease. It is of additional interest to note that 8 days after a left lumbar sympathectomy, the skin temperature of the left third toe was 30.4° C. after the patient had been exposed for 1 hour in the cold room.

It cannot be denied that, prior to the block, when the skin temperature is high due to indirect heating, there may remain a certain amount of vasoconstrictor plus vasodilator tone, if such exists. In this case, the release of the residual vasoconstrictor tone may overbalance the release of vasodilator tone resulting in a net rise in skin temperature. It is for this reason that we have not found it possible to devise a conclusive experiment which would demonstrate that vasodilator fibers to the human skin do not exist. It was believed, however, that the above experiments do strongly suggest 2 facts: first, that previous investigations have not established the functional activity of vasodilator fibers in the hand or foot; second, that, if they do exist, their functional significance is very limited.

It is not the purpose of this report to consider the controversy as to whether or not active vasodilator impulses travel in posterior root fibers. After careful study, Westbrook and Tower (2) concluded, "The concept that nerve fibers emerge from the spinal cord into the posterior roots in adult mammals including man is without foundation in anatomical fact or physiological necessity and therefore may be dispensed with." Whether this point of view becomes generally recognized as correct is not important to the issue involved in this study. The nerve blocks performed in these experiments were either subarachnoid or peripheral somatic and therefore should block all impulses going to the area under examination whether they travel via the somatic or autonomic pathways.

Additional evidence indicating that active vasodilator fibers traveling in somatic nerves are of little or no importance in elevating the skin temperature consequent to indirect vasodilatation may be seen in Figure 1. The right lumbar sympathectomy had interrupted the sympathetic pathways supplying this patient's right lower limb. The absence of any reflex change in that extremity is evidence that the remaining nerves supplying that extremity were inactive in this regard. The same considerations apply to experiments 1, 3, and 6. Curves of this type are commonly seen in the literature on peripheral vascular disease (2, 4, 5). Further evidence supporting this view may be found in the work of Dole and Morison (13).

These considerations have clinical as well as physiological implications. Grimson, in a recent, extensive review on the limitations of sympathectomy as a therapeutic procedure (7), cites the possibility that the removal of vasodilator fibers may account for the lack of benefit in some instances. We believe that in the normal human, as well as in the patient with well established Raynaud's or Buerger's disease, vasodilator fibers are of only slight significance at most. This factor, therefore, should not be allowed to enter into the consideration of whether sympathectomy should

be performed in any given case, insofar as the circulation to the skin of the hands and feet is concerned.

SUMMARY

Experiments have been performed to test the theory which holds that vasodilatation in human skin in response to the heating of the indifferent extremities is due in part to vasodilator impulses. It was found that at the height of the elevation of skin temperature due to reflex vasodilatation, block of the nerve supply to that area did not cause a fall in skin temperature. In most cases an elevation occurred. These observations were made upon patients with a normal peripheral vascular bed as well as in patients with Raynaud's and Buerger's disease.

It may be concluded that if active vasodilator fibers exist in the skin of the digits their functional significance is very limited. The indirect vasodilatation produced by heating the indifferent extremities is, therefore, due to the central inhibition of vasoconstrictor impulses. Evidence was cited to indicate that these considerations apply to both somatic and autonomic pathways.

THE EFFECT OF VARYING PULMONARY PRESSURE ON THE ARTERIAL PRESSURES IN MAN AND ANESTHETIZED CATS [1]

By RAYMOND J. DERN AND WALLACE O. FENN

(*From the Department of Physiology of the School of Medicine and Dentistry of the University of Rochester, Rochester, N. Y.*)

(Received for publication December 14, 1946)

Numerous observations of the effects of pressure breathing on the arterial blood pressure of anesthetized animals are available in the literature (1–7). In all cases an increase in the pulmonary pressure results in a fall of the arterial pressure (mean pressure as measured on a mercury manometer), with an occasional secondary compensatory rise.

With negative pulmonary pressures the effects are less regular, according to Schaefer and Bain (2), but usually the arterial pressure rises (7). Bruns (8) showed an increased stroke volume in a plethysmographic record of a rabbit heart during negative pressure breathing and Böger, Cobet, and Stepp (9) found an increased cardiac output of 15 to 162 per cent, and an increased oxygen consumption (37 per cent) with a negative pulmonary pressure of 5 cm. H_2O in a rabbit. Since these experiments were done on anesthetized animals it is difficult to apply them directly to the human problem.

Most measurements previously made on men are confined to brief periods of increased positive pressure such as may be obtained by the Valsalva experiments (5, 6, 10–14). It has been generally found that with such an increase of intrapulmonary pressure the systemic arterial pressure rises briefly and then falls. This is followed by a secondary rise above the initial level. The secondary rise does not occur if the intrapulmonary pressure is too high. The heart rate usually accelerates. According to Bürger (13), only 3 out of 145 cases showed a slowing of the heart. Barach *et al* (15) recently reported a series of experiments on men breathing air at a constant pressure of 20 cm. H_2O in which he found a rise in arterial blood pressure equal approximately to the applied pulmonary pressure.

The effects of negative pressures in man were studied by Kuhn (16, 17) who used a mask (Saugmaske) with a restricted inlet orifice and a large outlet. Because of the increased amount of blood in the lungs this was regarded as a useful type of therapy for tuberculosis. Evidence was also offered however to show that the volume of the pulse was increased. Later, Bruns (8, 18) concluded, mostly on the basis of similar evidence, that negative pulmonary pressure increases the cardiac output. He recommended negative pressure breathing for patients with poor venous return and certain types of heart disease. Subsequent investigators have paid little attention to this subject and the treatment has not been further investigated possibly because of the danger of dilating the heart or rupturing a vein in the thorax. One such case of dilated heart was recorded by Stigler (19) as a result of negative pressure breathing (man under water breathing surface air through a tube). The evidence concerning the physiological effects of this procedure in man is still fragmentary.

The experiments reported below were designed primarily to elucidate the problems of positive pressure breathing of possible military importance, but for the sake of completeness they were extended to cover negative pressures as well. The respiratory effects of these same procedures on our subjects were studied simultaneously and the results have been reported elsewhere (20).

METHODS

For the animal experiments, cats were anesthetized with dial. Mean arterial pressures were obtained by a carotid

[1] This work was done under contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and the University of Rochester. The data included in this paper were obtained by the cooperative effort of a large group including Doctors Hermann Rahn, L. H. Chadwick, Arthur B. Otis, Lorin J. Mullins, R. E. Gosselin, and others who kindly served as subjects. Some of the other data from the same experiment have been published elsewhere (Rahn, Otis, *et al*, 1946 and Otis, Rahn, *et al*, 1946).

artery cannula connected to a recording mercury manometer. Simultaneous right auricular pressures were recorded by means of a sound inserted to the level of the heart through the jugular vein, activating a recording tambour. Peripheral venous pressures were measured on a saline manometer connected to a femoral vein cannula. The tracheal cannula was attached to a very short sidearm on a large rubber hose. One end of the hose was connected to a compressed air line for positive pressures or to a vacuum pump for negative pressure. In either technique air was passed through the hose rapidly enough to avoid rebreathing. Pressures were regulated by a pinch clamp on the end of the hose opposite to the pump. Intratracheal pressures were measured on a water manometer connected to a sidearm in the cannula. This system permitted the pulmonary pressure to be set at any value up to 40 cm. H_2O, positive or negative, and the variation in pressure during the respiratory cycle was not over ± 3 cm. H_2O. The animal board was constructed so that the animal could be tilted either head or feet down (45 degrees) without altering the position of the heart relative to the recording instruments.

In the experiments on humans, systolic and diastolic pressures were read partly by the usual auscultatory method but more often by the use of the Tycos recording sphygmomanometer. Heart rates were counted from the carotid pulse over a 30-second interval. Measurements were made, with the subjects in the supine and in the sitting positions. In the lying position, the subjects were in a Drinker respirator and the equivalent of a positive pulmonary pressure was obtained by a continuous negative pressure in the respirator. For the sitting position we used a "body box" with the head protruding through a rubber collar in the top, or a helmet with the bottom closed by a similar collar. When the subject was in the body box or the Drinker respirator the blood pressure in the arm was recorded outside the box. In this case the pressure as read was the pressure in relation to the pulmonary or atmospheric pressure as zero, not the pressure as related to that surrounding the arm. For the sake of uniformity, therefore, we added the differential pulmonary pressure to our readings. In the charts all the pressures are those which would be read in the arm in the usual way if the positive pressure had been applied to the head only by means of a helmet. The usual procedure was to increase or decrease the pulmonary pressure in steps of 8 mm. Hg, holding the pressure at each stage for from 5 to 8 minutes.

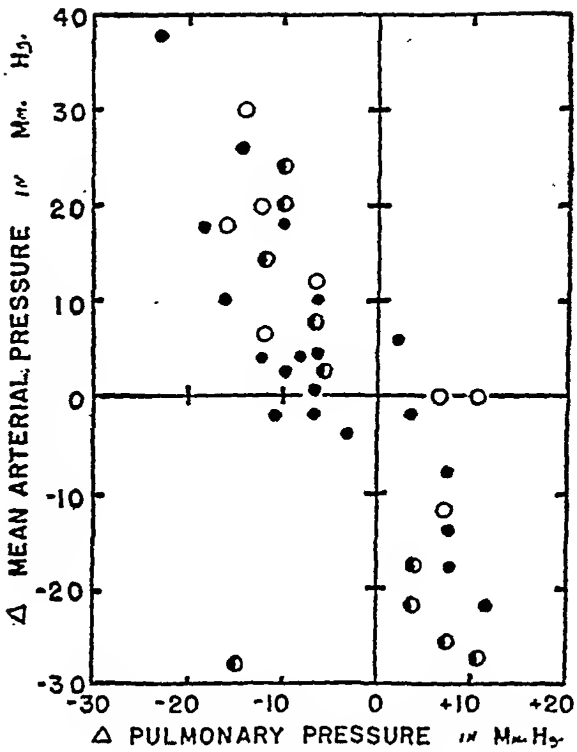

FIG. 1. THE CHANGE IN THE MEAN ARTERIAL PRESSURE OF THE CAT WHEN THE INTRAPULMONARY PRESSURE IS ALTERED

Ordinates: The change in mean arterial pressure in millimeters of mercury.

Abscissae: The change in intrapulmonary pressure in millimeters of mercury.

Meaning of symbols: Open circles: Cat in head-down position. Half closed circles: Cat in feet-down position. Solid circles: Cat in horizontal position.

RESULTS

(1) *Cat experiments.* The data of 4 cat experiments are given in Figure 1. Abscissae represent the applied intrapulmonary pressure in mm. Hg; and the ordinates, the change in mean arterial pressure. Each determination with negative pressures was made over an interval of from 1 to 5 minutes. The determinations with positive pressures are open to question since each application was brief due to threatened respiratory embarrassment and adequate time was probably not allowed for the compensatory rise found by others (2). With one exception negative pressures gave a rise in arterial pressure. With positive pressures, there is a tendency for the feet-up position to protect against a fall in arterial pressure and for the feet-down position to render the animal more susceptible to this effect. If true, this is presumably due to the effect of these positions on the venous return. The effect of negative pressures appears to be independent of the position of the animal. During the course of an experiment there was a slow but steady decline in arterial pressure. It was observed that negative pressures produced a greater rise in blood pressure if the arterial pressure was initially low, in general tending to restore the arterial pressure to normal. Shortly before

Hg, and heart rate in beats per minute for one subject in the sitting position in response to changes in intrapulmonary pressures. Abscissae: The change in intrapulmonary pressure in mm. Hg.

death, however, negative pressure failed to alter the arterial pressure.

Our venous pressure data in the cat will not be presented in detail because they confirm, in general, those of Holt (21). In both cases the auricular pressure falls by an amount equal to the decrease in pulmonary pressure.[2] With increased pulmonary pressures in the dog, Holt found a rise in auricular pressure almost equal to the rise in applied pressure, but in our experiments on cats the rise was only about ½ that of the pulmonary pressure. Holt (22) and Otis *et al* (23) in their studies on man report a 50 per cent rise. The failure to obtain a greater rise has been explained by the absorption of part of the applied pulmonary pressure by the elasticity of lung tissue.

(2) *Experiments on man.* Typical results on one individual, P. B., in the sitting position are shown in Figures 2 through 5. The changes in systolic pressure are plotted against the changes in the pulmonary pressure. It is evident that the systolic pressure rose with positive and fell with negative pulmonary pressures. A change in the blood pressure equal to the change in the pulmonary pressure is indicated by the straight diagonal

[2] This equality of pressures appears to indicate that the lung is more distensible when the volume and pressure are low than in the normal breathing range.

lines passing through the origin. Since all (but one) of the points are below this line during positive pressure breathing it is evident that the systolic pressure does not follow completely the change in pulmonary pressure. However, the intrathoracic pressure does not rise quite so much as the pulmonary pressure because of the elasticity of the lungs; so it is probable that in this case the systolic pressure is closely following the intrathoracic pressure. The changes in the heart rate of P. B. (Figure 4) were variable. On some days it increased and on other days it decreased under apparently comparable conditions. Similar variations were occasionally observed in other subjects.

In Figures 6 and 7 are shown curves for systolic pressures in other individuals in the sitting and the

Numbers on the graph identify the different subjects.

supine positions respectively. The numbers on the curves refer to the numbers of the subjects. Different subjects were used however for the two series so that similar numbers in the two series do not refer to the same subjects. All the subjects were members of the staff or medical students, and all were in normal health. The corresponding diastolic pressures in these same experiments are shown in Figures 8 and 9. The numbers of the subjects in Figures 6 and 8 correspond, as do those in Figures 7 and 9. The general result obtained in all these experiments is very evident. Positive pressures increase and negative pressures decrease both systolic and diastolic pressures. An occasional exception occurs.

The curves in Figures 6 to 9 were drawn to give a reasonable fit to the scatter of points obtained with each individual as indicated for P. B. in Figures 2 to 5. To avoid confusion the individual points are not given. Details of the curves often represent only single points and are of no significance. At the highest pressures of 28 mm. Hg the systolic pressures seem unduly high in many cases. We did not usually leave the subjects very long at this pressure and the high reading may be only an initial effect due to the excitement. When the pulmonary pressure reaches a point where the venous filling pressure is no longer able to compensate, the arterial pressure would of course be low. In subject No. 3 in the sitting position (Fig-

Figures 10 and 12 are for the supine position; Figures 11 and 13 are for the sitting position. Ordinates: Figures 10 and 11, the change in heart rate in beats per minute. Figures 12 and 13, the change in pulse pressure in mm. Hg. Abscissae: The change in applied pulmonary pressure in mm. Hg. Each curve is for a single subject identified by the number on the graph.

ures 7 and 9) we actually found an arterial pressure too low to give any readable deflection in the record. This occurred just before the subject had to be relieved of the pressure because of a threatened collapse. It was generally observed that the subject's blood pressure reached an equilibrium for a given pulmonary pressure within 1 minute after its application. It was also noted that in those subjects who nearly collapsed the blood pressure was maintained at its normal level until a minute or two before the onset of severe distress

A comparison of Figures 6 and 7 shows that with positive pressures the systolic blood pressure rises to a higher level in the sitting than in the supine position for an equal increment of pulmonary pressure. However, the average diastolic pressures for both positions follow roughly the intrathoracic pressure although the variation is large. This results in a decrease in the average pulse pressure in the supine position but no change in the sitting position. The various explanations suggested for these facts may be omitted here as purely speculative.

Changes in heart rate in the sitting and the supine positions are shown in Figures 10 and 11 respectively. The numbers represent subjects as before. Numbers in Figures 10 and 12 correspond to those in Figures 6 and 8. In these figures the graphs are drawn through the actual points or the average points (where 2 or more observations were available). Such average points are indicated by dots on the curves. Detailed variations are of no significance, but it may be noted that, in the sitting position especially, there is a rather pronounced tendency in some subjects toward a decreased heart rate at the higher pressures. When the subject became alarmed at these high pressures or was about to collapse the rate might have gone high. (See curves for subject No. 3 in Figure 11.) Low heart rates have usually been attributed to increased intracerebral pressure and the absence of an acceleration due to excitement and effort or to a less sensitive carotid sinus which would not respond to a decreased pulse pressure. The incidence of low heart rates with increased pressure is much higher in our series than that reported by Bürger (13). Most individuals gave the same characteristic response on successive days, either a rise or a fall, but some gave an increase one day and decrease the next without apparent cause.

In the sitting position, at least, there is no consistent change in pulse pressure as can be seen from the average curves for 8 subjects shown in Figure 13. In the supine position however there appears to be a slight decrease of 10 or 15 per cent at the extreme pressure of 30 mm. Hg (Figure 12). This is consistent with the observation of a slightly decreased cardiac output (24).

DISCUSSION

Since our results with human subjects show that the arterial pressure follows approximately the intrapleural pressure (whether positive or negative) it may be argued either (1) that the explanation is purely mechanical, *i.e.* the arterial pressure is higher simply because the initial pressure in the ventricle was higher before systole began, or (2) that the blood pressure level is regulated reflexly by afferents arising from structures such as those around the aorta, which are exposed to the variations in intrapleural pressure. Such structures would respond in such a way as to maintain a constant difference between arterial and intrapleural pressure. Central structures within the brain itself would presumably behave in the same way since the pressure of the cerebrospinal fluid varies closely with the intrapleural pressure (Hamilton, Woodbury and Harper, 25). In our experiments with either helmet or body box the carotid sinus was exposed exteriorly to a pressure equal to the pulmonary pressure. If this organ were solely responsible for the regulation of the level of the arterial pressure, it would have kept the level of the blood pressure constant relative to the pulmonary pressure. Actually, the blood pressure is more nearly constant relative to intrathoracic pressure which increases somewhat more than half as much as the pulmonary pressure. Furthermore, Barach *et al* (15) have shown that when pressure is applied by mask, the arterial pressure remains constant relative to the pulmonary pressure. With their technique, the carotid sinus is not affected by the applied pulmonary pressure but is exposed through the skin to atmospheric pressure at all times. Its presumed effect would therefore be to control the arterial pressure at a level which is constant relative to atmospheric pressure. Since, in both techniques, the expected carotid sinus effect is apparently absent, it may be concluded that the carotid sinus is in-

sensitive to a rise in arterial pressure of at least 15 mm. Hg or to a fall of at least 10 mm. Hg, or that it is dominated by other receptors.

The ability of an individual to maintain pulmonary pressure has been used as a test of right ventricular fitness (6, 10, 11, 13, 26) on the theory that pressure increases the resistance of the pulmonary circuit. This is borne out by the work of Heinbecker (27) who perfused lungs in an artificial thorax. When they were inflated by negative pressure in the thorax, the flow increased but when they were inflated by positive intrapulmonary pressure the flow was decreased. No heart was included in this circuit so that inflow and outflow pressures were constant, and the result can clearly be attributed to the enlargement or diminution in the size of the vessels due to the respective increase or decrease in mean pressure surrounding them. When the heart is included in the circuit the situation is more complex because the heart is also exposed to the intrathoracic pressure. The immediate effect of pressure changes on the flow depends upon the capacity of the lungs (28, 29) which varies greatly with pressure, but in general the decrease in pulmonary resistance with negative pressure inflation is confirmed (30). In these experiments, however, the venous pressure remained constant while in the body this is not the case and the flow through the pulmonary circuit depends more upon the filling of the heart than upon the pulmonary resistance. This is especially true when the intrapulmonary pressure is maintained higher or lower than normal more or less indefinitely so that the capacity of the lung vessels can reach a steady state value.

The filling of the heart depends of course upon the venous pressure which in man appears to follow the intrapleural pressure with remarkable promptness and fidelity (23). With positive pressure the venous return is therefore well maintained although there is evidence of a slight decrease in cardiac output (15, 24). This is indicated indirectly also by the rise of arterial pressure in man with increased intrapulmonary pressure. In the anesthetized cats, however, where the arterial pressure fell, the inflow into the heart must have diminished as it does in anesthetized dogs (31). Conversely in the cats a rise of arterial pressure was observed with negative pressure breathing indicating that the venous return was improved. In man the absence of such an increase in arterial pressure suggests that the normal venous pressure was adequate to fill the heart to its limit so that further increases of the pressure gradient had no further effect. The fall in arterial pressure which we have observed in man with negative pulmonary pressures lends no support to the idea that this procedure increases cardiac output and would therefore be beneficial, but it does not contradict this possibility. Since we have observed a diminished pulse volume during positive pressure breathing it seems probable that an increase in pulse volume occurs in negative pressure breathing as has previously been reported (17, 8, 32). Böger *et al* (9) found the heart rate decreased in anesthetized rabbits but Bruns (18) found it mostly increased in man. It is possible, therefore, that with negative pressure breathing there is a slight increase in the cardiac output just as, with positive pressure, there is, if anything, a slight decrease (15, 24). Such an increase would be particularly likely to occur in any condition in which the venous return was initially defective. Further work on the effects of negative pulmonary pressures is needed to verify this interpretation of our results.

SUMMARY

1. The response of the systolic and diastolic pressures and heart rate of man, and of the mean arterial, right auricular, and femoral venous pressures of the anesthetized cat, to increased and decreased intrapulmonary pressure was studied. Body position was also varied.

2. In the cat, mean arterial pressures rise in response to a decreased pulmonary pressure, independently of the position of the animal. With increased pulmonary pressure only the primary fall of arterial pressure was studied, and this was much less in the head down than in the feet down position. Holt's (21) venous pressure observations were confirmed.

3. In man, in both supine and sitting positions, increased intrapulmonary pressure gave an increase in both systolic and diastolic pressures, and decreased intrapulmonary pressure gave a fall in both.

4. Pulse pressures in many were variable ($\pm$ 10 mm. Hg) and tended to give a consistent decrease only with positive intrapulmonary pressure in the supine position.

5. Heart rates were variable (±10 beats per minute).

6. If increased intrapulmonary pressure produced circulatory failure, arterial pressures and heart rates were maintained until within a minute or two of the onset of severe symptoms.

7. The effect of pressure breathing on blood pressure regulatory receptors is discussed.

STUDIES ON GANGRENE FOLLOWING COLD INJURY: VI. CAPILLARY BLOOD FLOW AFTER COLD INJURY, THE EFFECTS OF RAPID WARMING, AND SYMPATHETIC BLOCK[1]

By J. M. CRISMON and F. A. FUHRMAN

(From the Department of Physiology, School of Medicine, Stanford University, California)

(Received for publication December 16, 1946)

Indirect evidence, based upon measurements of skin temperature and observations of skin color in the feet and ears of rabbits subjected to severe cold injury, indicates that complete arrest of blood flow does not occur until more than 50 hours after injury (1). Tests of the local circulation in cold-injured regions with intravenously injected fluorescein show that the exchange of this dye between blood and interstitial fluid is impaired during the interval when the minute volume blood flow is greater than that in comparable uninjured regions (2, 3). Early arrest of blood flow in regions injured by cold has been variously ascribed to "conglutination" of red-cells (4), to capillary stasis (5), and to intravascular clotting (2). While all of the above phenomena may be observed in frostbitten tissues, none has provided an explanation of the nature of local changes in blood flow adequate to account for the maintenance of high peripheral tissue temperature at a time following cold injury when exchanges of oxygen, nutrients, and metabolites appear to be impaired.

This report presents the results of microscopic study of blood flow in the small vessels of the ears of rabbits during the first hour after freezing. Blood flow was also studied in the ears of animals which were treated by rapid thawing of the ear in warm water and by procaine block of the stellate ganglion on the injured side.

METHODS

Cold injury was produced by immersing the distal one-half to one-third of the ear for 60 seconds in a mixture of water, ethylene glycol, and alcohol cooled to $-55°$ C. with solid carbon dioxide. Details of this method for the production of controlled cold injury and the characteristic effects on the tissues are given elsewhere (6).

Both normal and frostbitten ears of a uniform strain of New Zealand white rabbits were observed through a binocular dissecting microscope having 9X oculars and 4.8X objectives. The light sources was a 100-watt Spencer microscope lamp from which the light was conducted to the ear by means of a polished rod of ¾-inch methyl methacrylate (Lucite) 2 feet long. The rod was tapered to a cone having a rounded tip 7 mm. in diameter. The distal 8 inches of rod were bent into a curve which presented the brilliantly illuminated tip at a right angle to the original path of light. With the rod in an adjustable clamp, its flattened end in contact with the blue glass of the microscope lamp, the ear was placed under the objectives of the microscope in direct contact with the methacrylate rod. Liquid petrolatum was applied to the shaved ear in order to clear the keratinized epithelium. Photographic recording of the changes observed proved to be unsatisfactory because of the thickness of tissue and the changing optical plane.

OBSERVATIONS

Blood flow in the capillaries of the normal ear. Movement of blood could not be seen in the larger vessels. In the smaller arterioles and venules, rapid flow was easily made out. Numerous channels affording relatively direct communication between arterioles and venules were seen. These channels were usually of smaller diameter than either their supplying arterioles or the receiving venules, and many of them were small enough to force the corpuscles to traverse them in single file. Reversal of flow was not observed in these vessels, and the flow was uniformly rapid. The relatively few true capillaries which were open at any one time could be identified as richly anastomosing branches containing corpuscles either singly or in small clumps interrupted by clear areas. Often the location of true capillaries could be identified only when an occasional corpuscle was seen to wander off through an area apparently free of vessels and then finally to enter a collecting capillary and venule.

Hyperemia induced by the application of heat caused opening of vessels of all types, and many

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Stanford University.

regions, which had been entirely free of visible channels, were seen to be richly supplied with capillaries.

Blood flow in the capillaries of the ear after frostbite. Observations of blood flow were made on the normal and the frostbitten regions of ears of 15 rabbits. The changes which were observed in the local circulation were consistently reproducible in terms of their time relations and nature. The following description applies to the sequence of changes observed in the blood flow within the frostbitten area after the distal half of the ear had been immersed in the freezing mixture at − 55° C. for 1 minute and then allowed to thaw in air at room temperature without additional treatment. Blood flow began in the largest channels of the frostbitten portion of the ear within 3 minutes and before the ear was completely thawed. Flow in those channels was rapid and at that early stage only a limited number of capillaries in the immediate vicinity of large vessels became filled with blood. At the completion of thawing, the ears became markedly hyperemic. Progressive opening of capillaries was observed, and brisk blood flow could be detected for a few minutes after the capillaries became visible, but over a period of about 10 minutes slowing and final cessation of flow occurred. The capillaries contained packed red blood cells interrupted by clear regions along the length of the vessel. Within the interval, 10 to 20 minutes after frostbite, these vessels became completely filled with cells, their course was grossly distorted, and the walls were roughened and irregular.

The period of onset of stasis was accompanied by increasing edema. A homogeneous brownish substance began to accumulate in the areas adjacent to the capillaries and was found in largest amounts near the larger blood vessels in which flow persisted longest. Although no actual movement of blood could be observed, sluggish flow could be demonstrated by observing the refilling of vessels after they had been emptied of blood by pressure upon an overlying coverglass. Such persistence of flow was demonstrated in the larger arterioles and venules and also in some small, relatively straight vessels. The latter were bright pink in color and had smooth walls; their diameter was slightly smaller than that of the distended capillaries which contained packed red cells.

Vessels in the area proximal to the frostbitten region were widely dilated for the first 20 to 50 minutes after thawing. Usually within 2 hours these vessels became markedly reduced in diameter. The central artery and its branches were more noticeably affected than the veins, and there appeared to be a region of especially marked narrowing of the artery at the junction of the normal with the injured area. At the same time it was noticed that the large vessels within the frostbitten part of the ear remained widely dilated.

Study of the circulation after frostbite with the aid of intravenous injections of India ink. Intravenous injections of particulate carbon in the form of India ink were used to assist in the visualization of blood vessels in both normal and frostbitten ears. The ink was administered in doses of 5 ml. of 50 per cent India ink in saline both immediately before frostbite and at various intervals from 2.5 minutes to 49 minutes after the ear was removed from the freezing mixture. The circulation in the ears of 10 animals was observed after the injection of carbon.

By the selection of the appropriate time interval for the injection of carbon in relation to the time of frostbite it was possible to demonstrate the following: (*a*) carbon particles present in the circulating blood either just before frostbite or within 6 minutes afterward entered the capillaries of the frostbitten region; (*b*) varying amounts of carbon became trapped in the capillaries of both the normal and the frostbitten parts of the ear; (*c*) carbon trapped in capillaries of the normal part of the ear was removed by the increased blood flow when hyperemia was induced by heat, but particles caught in the dilated capillaries of the frostbitten region during the period of stasis could not be removed by this means; (*d*) up to 6 minutes after frostbite, more carbon was trapped in the capillaries of the frostbitten region when carbon injections were made late in this 6-minute interval than after pre-frostbite injection or very early post-frostbite injection of ink; (*e*) when the injection of ink was delayed as long as 20 minutes after frostbite, only occasional particles of carbon could be seen in the vessels of the frostbitten region,—when these did appear, they were seen only in the relatively large channels and not in the true capillaries.

Thus, the interval during which the entrance

and trapping of carbon particles could occur was brief and was terminated by stasis. The channels which did remain open contained flowing blood, were relatively large in diameter, and hence probably permitted any carbon which entered them to be carried on through.

The junction of the normal part of the ear with the frostbitten region exhibited some differences from both regions distal and proximal to it. When India ink was injected after stasis had become complete in the true capillaries, *i.e.*, more than 20 minutes after frostbite, carbon accumulated and became trapped at the junction when none or very little could be found in either the frostbitten region or the normal part of the ear. This observation suggests that the stasis which occurred here was relatively late in appearing, since it was not sufficiently advanced to prevent the entrance of carbon particles but later did progress to the point where large amounts of ink were trapped.

While no positive explanation of the above observation is justified on the basis of our present information, it is suggested that the tissues of the junction may have been less severely injured by reason of their failure to reach temperatures as low as those in the more distal portion of the ear. Since swelling progressed from the injured region toward the base of the ear, distortion and occlusion of capillaries may account for late appearance of stasis in the region of the junction even though the direct injury by cold was not severe enough alone to induce stasis.

Local blood flow in frostbitten ears after rapid thawing in warm water. Frostbite produced in the ears of rabbits by immersing the part in the freezing mixture at − 55° C. for 1 minute resulted invariably in the development of gangrene and the ultimate loss of all of the ear up to the line of immersion, if the ears were allowed to thaw (in air at 25° C.) without treatment. In confirmation of the work of Ariev (7), we have found that the same exposure to cold followed by immediate warming of the ear in water at + 42° C. for 2 minutes prevents the development of gangrene and loss of the injured tissue (8). In spite of the favorable end result of rapid thawing, the tissues underwent a series of changes which were grossly similar to the pregangrenous changes in the frozen, untreated ears. The stages of hyperemia, swelling and later exudation of serous fluid from the surface of the injured part of the ears were, if anything, more marked than in the untreated ears, but in spite of these alarming manifestations, only the surface epithelium was lost.

Observations were carried out in the manner described previously, and injections of India ink were used to test for the appearance of stasis. The ears of 3 animals were studied after subjecting both ears to frostbite (1 minute at − 55° C.) and thawing one of them rapidly in warm water. The injections of ink were made at 20 to 25 minutes after frostbite and were thus administered during the period when capillary stasis is complete in similarly injured, untreated ears.

Before the intravenous injection of carbon, the changes of blood flow observed in the rapidly warmed ear were not strikingly different from those in the contralateral, frostbitten but untreated ear. Refilling of vessels emptied by external pressure persisted longer in the treated ear and larger amounts of brown extravascular material appeared. When particulate carbon was introduced into the blood stream, it was seen to enter the treated ear more readily than the untreated one in 2 out of 3 rabbits studied. In the third, the amounts of carbon were about the same in both ears (not more than 3 to 4 particles per field). For 1 or 2 hours after the injection of ink, the particles were either observed to move spontaneously in the vessels of the treated ear or could be made to move by mechanical manipulation. In one experiment, hyperemia was induced in the treated ear by infiltrating the tissues about the base of the ear with 1 per cent procaine 77 minutes after the injection of ink. The increased blood flow removed some of the carbon which previously had been trapped. Hyperemia induced by this means or by warming was shown to be ineffective in removing trapped carbon from frostbitten ears which had not been treated by rapid thawing.

The observations showed that rapid thawing of frostbitten ears had the effect of delaying complete stasis in the true capillaries. When stasis did develop, it coincided in time with the period of maximal swelling (approximately 2 hours after injury) and with the reduced blood flow brought about by the constriction of arterial supply in the uninjured portion of the ear. Thus, when perfusion pressure within the capillaries was dimin-

ished, and distortion of the tissues by the presence of large amounts of extravascular fluid occurred, cessation of flow in the true capillaries was an accompanying feature. However, flow of blood in the true capillaries could be made to proceed by changing the pressure relationships within those vessels either by increasing the flow of blood through the injured tissue or by mechanical pressure applied externally and released.

The local circulation in frostbitten ears following procaine block of the stellate ganglion. In order to determine whether the effects observed after rapid warming of frostbitten ears were the result of the changes in blood supply alone or whether some other effect of rapid warming was responsible for the delay of capillary stasis, 6 rabbits were subjected to frostbite of the distal half of both ears in the same manner as those described in the previous sections, and as soon as possible after the ears were removed from the freezing mixture, 1 to 2 ml. of 2 per cent procaine with epinephrine 1:30,000 were injected into the region of the stellate ganglion on one side. All of the animals in this group demonstrated satisfactory paralysis of the vasomotor supply of the ear as judged from the presence of the more readily palpable pulse in the central artery and skin temperatures 4° to 6° C. higher on the blocked side.

When carbon was injected into the blood stream within 5 minutes after frostbite, large amounts of it were observed in the capillaries of the frostbitten, untreated ear, but relatively little of it was found in the ear subjected to vasomotor paralysis. Stasis in the untreated ear resulted in the immobilization of large amounts of carbon, but in the capillaries of the ear on the side blocked by procaine, blood flow and movement of carbon particles persisted for more than 2 hours. Two hours and 10 minutes after the injection of India ink some stasis was noted in capillaries close to the surface; these vessels could not be emptied by external pressure, but in spite of this late stasis there was no trapping of carbon except at the junction of normal and frostbitten and normal tissue. In this case failure of trapping may have been due to removal of carbon from the circulation before stasis developed. When the injection of carbon was delayed until 22 minutes after frostbite, the usual exclusion of carbon particles from the capillaries of the injured but untreated ear was observed. In the ear which was treated by the production of vasomotor paralysis, the capillaries were seen to contain moving carbon particles, but within an additional 30 minutes stasis occurred with immobilization of carbon granules. In this animal the duration of increased blood flow was rather brief, and both ears were cool and about the same temperature by the time that stasis was observed in the treated ear. The vessels did not refill after being emptied by external pressure.

These observations indicate that the increased blood flow which followed stellate ganglion block was associated with a delay of stasis in the true capillaries of frostbitten ears. While stasis was not postponed for a period as long as that following rapid thawing of the ear in warm water, it was qualitatively similar. This suggests that at least a part of the improvement in capillary blood flow noted after rapid thawing may be the result of increased intravascular pressure. However, that rapid thawing produced other changes in the response of the tissues was evident from the difference in final result: preservation of the frostbitten region after rapid thawing as compared with merely the delay for 24 hours of the wet and dry stages of gangrene and loss of the injured portions of the ear, which was the uniform experience after the use of procaine block.

Lymph flow and the spread of colloidal dye in frostbitten skin. Glenn, Gilbert and Drinker (9) reported an augmented lymph flow for at least 2 hours following severe hot water burns of the foot in dogs. Massive swelling was a constant feature of the response to injury in their experiments. The high rate of lymph flow points to a dynamic rather than a static alteration of fluid distribution in the injured tissues. In view of the many similarities between the vascular disturbance in burns and frostbite (10) the demonstration of augmented lymph flow in the frostbitten extremities of rabbits might throw some light on the nature of fluid exchanges following severe injury by cold. It has been pointed out that the edematous tissues after frostbite are to some extent organized (1), in that only limited quantities of edema fluid flow from the incised swelling. Organization of this fluid either in the form of a fibrin clot or in a gel stabilized by hyaluronic acid (11) might offer some mechanical barrier to free movement of fluid and plasma protein in the extravascular compart-

ment and also hinder the movement of fluid into capillaries even though adequate filtration gradients existed.

A small number of experiments designed to demonstrate lymph flow by the use of the dye Patent Blue V as employed by McMaster (12) and the state of the interstitial fluid by the spread of T–1824 by the method of McMaster and Parsons (13) were carried out on the frostbitten and normal ears of rabbits. Two rabbits were used for the studies with Patent Blue V. One ear of each animal was frostbitten by immersion in the freezing mixture for 1 minute at − 55° C. The contralateral ear of each animal was used for control observations. Patent Blue V (0.01 ml. of an 11 per cent solution in water) was injected intradermally through a G–26 hypodermic needle. In one animal, the dye was introduced into both ears midway between the central artery and the marginal vein 4.5 hours after frostbite. In the frostbitten ear diffuse, blue streamers were seen to extend proximally within 5 seconds. After 10 seconds, a poorly defined blue band extended from the point of injection to the marginal vein. These bands blended into the neighboring skin areas with no clear, fine lines. The color became diffuse and faded completely within a few minutes. In the normal ear of the same animal, narrow, sharply defined blue lines radiated from the point of injection. Within 60 seconds after injection, a small blue streamer reached the marginal vein; and, after 4 to 5 minutes, fine blue lines extended proximally along the central artery.

A second rabbit was subjected to the same degree of injury as the first, but the dye was injected 30 minutes after frostbite. Rapid and diffuse spread of dye in the frostbitten ear toward the central artery and laterally toward the marginal vein was observed. Two hours after injection of dye, diffuse, blue streamers extended proximally along the central artery and near the marginal vein. After 5.5 hours all dye had disappeared from the frostbitten ear. In the normal ear, fine lines extended proximally along the central artery, but these moved at a much slower rate than those in the frostbitten ear. After 2 hours no streamers were seen. A large amount of dye remained at the original site of injection at the end of 5.5 hours.

These observations indicate that lymph flow in the frostbitten ears of rabbits persisted after injury and that it was more rapid than that observed in normal ears.

The spread of T–1824 in normal and frostbitten skin of rabbits' ears was studied after injection of 0.01 ml. of dye (1 per cent T–1824 in isotonic sodium chloride solution) intradermally into both ears after one of them had been frostbitten in the usual manner. The size of the spot of dye was measured at intervals over periods of 17 to 21 hours. Seven rabbits were studied in the manner described. The results in all 7 animals were essentially similar. Spread of dye occurred in both normal and frostbitten ears but was more extensive in the frostbitten ears than in the normal ones. A single example will suffice to indicate the relative magnitude and qualitative aspects of changes observed. The size of the spot of dye immediately after injection was 4 × 4 mm. in each ear. At 170 minutes after injection of dye the spot had increased to 6 × 11 mm. in the normal ear while that in the frostbitten ear was 15 × 60 mm. After 21 hours the dimensions were 11 × 13 mm. in the normal ear while no dye was detectable in the frostbitten ear at this time.

The results of similar measurements on an animal in which the frostbitten ear was thawed rapidly in warm water (3 minutes at + 42° C.) did not differ strikingly from those obtained on untreated, frostbitten ears. A series of 5 animals studied after marked edema had been induced in one ear by wetting it with xylene showed differences between the edematous and the normal ears which were similar to those observed when edema was produced by frostbite.

As judged from the observations made with intradermally injected dye in frostbitten ears, there appears to be no evidence of physical organization of the edema in such a way as to impede the spread of colloidally dispersed material within it.

COMMENT

Direct observations of blood flow changes in the minute vessels of normal and frostbitten ears of rabbits, both with and without intravascular India ink injections, are in substantial agreement with those reported by Tittel (14) and by Rotnes and Kreyberg (15). The following points are brought out:

(*1*) Cold injury leads to stasis in the true capillaries in proportion to the severity of injury as it is determined by time of exposure and temperature.

(*2*) Following a standard cold injury of 1 minute immersion of the distal half of the ear in the freezing mixture at − 55° C.:

(*a*) Blood flows into all vessels of the ear in the early period after thawing.

(*b*) Stasis appears first in the true capillaries, begins with the return of blood flow, and is complete in the true capillaries within 10 minutes after the first reappearance of blood in the injured region.

(*c*) Stasis is accompanied by loss of fluid from the true capillaries into the surrounding tissues and by dense packing of erythrocytes within the capillaries.

(*d*) Carbon particles (India ink), injected into the blood stream before stasis is complete, become trapped in the true capillaries during the development of stasis, but if the injection of carbon is delayed until after stasis is complete, none of it enters and none is trapped.

(*e*) Blood flow in the cold-injured region, after stasis has closed the true capillaries, occurs in arteriovenous anastomoses and in arteriolar-venular capillaries, described as "thoroughfare channels" by Chambers and Zweifach (16).

It is evident from the above summary that during the hyperemic phase after injury the total cross sectional area of the vascular bed between the arterioles and venules within the frostbitten region becomes sharply reduced to include only a-v anastomoses and arteriolar-venular capillaries. This response to injury by cold has been noted by other investigators (17 to 22). An important consequence of such a local redistribution of blood flow in the presence of a total increase in minute volume flow, as indicated by the changes of skin temperature, would be a marked rise in effective filtration pressure. Thus, in spite of the fact that the true capillaries may lose large amounts of fluid up to the time that stasis is complete, the later loss of fluid into the extravascular compartment must occur mainly as the result of the high filtration pressure within the "thoroughfare channels." The measurement of changes in volume and subcutaneous tissue pressure in frostbitten feet of rabbits (23) showed that maximum volume is reached in about 2 hours after injury and that the pressure of fluid in the interstitial compartment reaches its maximum of 25 to 30 cm. of water at about the same time. In the period between thawing and the attainment of maximum swelling a new filtration equilibrium is established at high levels of capillary pressure, interstitial fluid pressure, and rate of fluid exchange. That fluid continues to be lost from the blood in the injured regions at rates which overwhelm the local routes of removal is illustrated by 2 observations: (*a*) the movement of edema fluid in the subcutaneous tissues far into the uninjured regions from the area injured by cold (23); and (*b*) the rapid lymph flow from the injured region as demonstrated with the aid of dyes.

The "flux" of plasma ultrafiltrate in normal tissues has been described by Zweifach (24) as filtration from the plasma in the capillaries with high internal pressure (the arteriolar-venular capillaries) and the re-entry of plasma ultrafiltrate into the blood stream by seepage into true capillaries, especially in the region close to their junction with an a-v capillary as it enters a collecting venule. In frostbitten ears of rabbits, the closure of true capillaries and the rapid inflow of blood during the hyperemic stage favor the vigorous formation of plasma ultrafiltrate and perhaps even the loss of some protein through the walls of a-v capillaries; but the stasis, effective in diverting inflowing blood into "thoroughfare channels" at high pressure, at the same time renders the true capillaries useless as routes of re-entry of fluid into the blood stream. In addition to closure by primary stasis, obstruction of some capillaries may be accomplished as a result of the spatial distortion and kinking which occur during swelling.

The effect of closure of true capillaries upon exchanges between the blood and the extravascular compartment is that of sharply limiting the available surface across which diffusion may take place and at the same time increasing the rate of filtration. Danielli and Stock (25) and Zweifach (24) have pointed out the separate nature of exchanges by diffusion and exchanges which occur largely by filtration. Resting tissues characteristically depend upon the flux of plasma ultrafiltrate; minute volume blood flow is relatively small and only a few true capillaries are open at a time. Active tissues depend upon a considerable increase in the area

available for diffusion as well as upon increased filtration. Thus, in active tissues the minute volume blood flow is large, many true capillaries are open, and an appreciable volume of filtrate is formed. In frostbitten tissues an anomalous and probably harmful situation exists: blood flow and local temperature are high at a time when the total area available for diffusion exchange is reduced. In spite of the high temperatures, which might be expected to increase the metabolism of tissues in the injured region, measurements of arterio-venous oxygen differences in the blood perfusing these tissues indicate that the rate of oxygen consumption is extremely low (23).

SUMMARY

1. Paralysis of vasomotor activity, both tonic contraction and phasic responses, was produced in the injured regions when the distal halves of rabbits' ears were exposed to $-55°$ C. for 1 minute in a liquid freezing mixture. Vasomotor activity was preserved in vessels proximal to the line of immersion.

2. After thawing of the frozen ears in air at 25° C., blood flow was re-established and all vessels became markedly dilated. Stasis began in the true capillaries with the return of blood flow and was complete in 10 minutes.

3. Particulate carbon, injected intravenously, became trapped in the true capillaries when injection was made within the first 10 minutes but failed to enter true capillaries when injection was delayed for longer intervals after injury.

4. Blood flow persisted in arterio-venous anastomoses and in arteriolar-venular capillaries for about 24 hours but declined virtually to zero over the ensuing 24 to 30 hours.

5. Rapid thawing of frozen ears in warm water (1 to 3 minutes at $+42°$ C.) delayed the development of stasis in the true capillaries until maximal swelling was reached at about 2 hours after injury.

6. Procaine block of the stellate ganglion augmented the hyperemia after injury and delayed the onset of stasis for 50 to 60 minutes.

7. Persistence of rapid lymph flow and rapid formation of interstitial fluid in frostbitten ears up to 21 hours after injury was demonstrated with the aid of intradermal injections of the dyes, Patent Blue V and T-1824.

STUDIES ON GANGRENE FOLLOWING COLD INJURY. VII. TREATMENT OF COLD-INJURY BY MEANS OF IMMEDIATE RAPID WARMING[1]

By F. A. FUHRMAN and J. M. CRISMON

(*From the Department of Physiology, School of Medicine, Stanford University, California*)

(Received for publication December 16, 1946)

It has long been considered that the immediate application of warmth to frostbitten extremities should be avoided. In 1939 the Russian investigator, Ariev (1), reviewed the experimental and clinical observations upon which the accepted procedure of slow, gradual warming is based. He concluded, on the basis of his experimental results (cited below), that rapid warming in cases of cold injury should be subjected to clinical trial. Two human cases were reported in which no ill effects were observed to follow rapid warming of the feet and legs.

The older literature, cited by Sonnenburg and Tschmarke (2), Ariev (1), and Harkins (3), contains many observations which have been interpreted to indicate the danger of rapid warming of frostbitten parts. These observations are, however, uncontrolled and in many cases open to doubt. Perhaps the outstanding example is Barron Larrey's description of cold injury among the soldiers of Napoleon's army during the retreat from Moscow in the winter of 1812–1813 (4):

> "Unfortunate was the fate of him, who, with his animal functions nearly annihilated, and his external sensibility almost destroyed by the cold, should suddenly enter too warm a room, or approach too nearly a large bivouac fire. The projecting parts of the body, grown insensible, or being frozen, and remote from the centre of circulation, were attacked with gangrene, which manifested itself at the same moment, and was developed with such rapidity, that its progress was perceptible by the eye, or else the individual was suddenly suffocated by a sort of turgescence, apparently invading the pulmonary and cerebral systems. He perished, as if in a state of asphyxia."

An experimental approach to the problem of slow *versus* rapid warming of frozen extremities was made in 1937 by Harkins and Harmon (5). Hind limbs of dogs were frozen with solid CO_2 and one leg was thawed at 42° C. for comparison with the other thawed at 2° to 12° C. One frostbitten ear of rabbits was thawed at 38° C. and the other at 2° C. In neither case was any essential difference reported between the rapidly and slowly thawed extremities, although the frostbitten legs were observed only for 18 hours. They reported that "if anything, the ears that were thawed in ice water showed a trace more gangrene."

Ariev (1) has reported the results of several series of experiments which were designed to compare the effect of slow and rapid warming of frozen ears and feet of rabbits. After freezing both ears of rabbits with ethyl chloride, one ear was warmed with hot compresses wet in water at 40° to 45° C. The frostbitten part of the slowly-warmed ear was ultimately lost in 5 animals while the rapidly-warmed ear showed only fibrosis in the distal part. Both feet of rabbits were frozen with ethyl chloride to the tibio-tarsal joint. One foot was then rapidly thawed by means of the application of compresses wet with water at 35° to 40° C. while the other was thawed in air. In the rapidly warmed foot, gangrene "only touched the most distal parts of the toes," while in the opposite foot "total gangrene spread over the entire region subjected to freezing."

The experiments reported here were carried out in order to determine the effectiveness of immediate rapid warming in preventing the occurrence of gangrene following controlled cold injury. The effect of rapid warming on local blood flow in frostbitten ears and feet following thawing has been examined by means of fluorescein and by measurement of skin temperature.

METHODS

The method used for the production of controlled cold injury has been described previously (6). In this series of experiments, rabbit ears were immersed at − 55° C. for 1, 1½ or 2 minutes; rabbit feet were immersed at − 55°

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Stanford University.

C. for 3 minutes and at − 15° C. for 60 minutes. The rapid warming was accomplished by immersion of the foot or ear, immediately after removal from the cold liquid, in a water bath at + 42° C. Ears were warmed for periods ranging from 15 to 120 seconds; feet were warmed for 2 minutes or 5 minutes. During immersion in the warm water the foot or ear was kept in constant motion to facilitate thawing.

The effectiveness of immediate rapid warming was evaluated on the basis of the extent of ultimate tissue loss, the time required for the development of wet and dry gangrene, and the extent of induration and scarring of the ear or foot several weeks after injury.

RESULTS

1. *Immediate rapid warming of rabbit ears following controlled cold injury.* The extent of tissue loss following frostbite of rabbit ears without treatment and with treatment in the form of immediate rapid warming is given in Table I. The entire distal part of the ear as far as the line to which it was immersed becomes gangrenous and is eventually lost when the ear is thawed in air at room temperature (untreated). After 60-second immersion at − 55° C. the procedure of immediate rapid warming resulted in saving the entire frostbitten part of the ear in 4 out of 6 animals, and in the retention of about 90 per cent of the injured region in 1 animal. With frostbite of longer duration (90- and 120-second immersion at − 55° C.) the procedure of rapid warming resulted in saving the entire area in 1 out of 4 animals and incomplete loss in 1 animal.

TABLE I

Tissue loss following severe cold injury in untreated animals and in animals treated by immediate rapid warming of ears

All ears frostbitten by immersion in liquid at − 55° C.

*Untreated control series**

Duration of exposure	Number animals	Extent of tissue loss
seconds		
60	11	Complete to level of immersion
90	24	Complete to level of immersion
120	2	Complete to level of immersion

120	+42	45	Complete to level of immersion

* These animals are the same as those included in paper I of this series (6).

In the treatment of frostbite of rabbit ears by immediate rapid warming, thawing of the frozen ear occurs 10 to 15 seconds after it is placed in warm water. Following removal from the warm bath the ear is intensely hyperemic and usually tends to be somewhat cyanotic. Edema is evident upon removal from the warm bath and exceeds that observed in untreated frostbitten ears during the first 24 hours. Blisters are frequently seen. Exudation of protein-containing fluid from the surface of the ear occurs after 24 to 48 hours and results in the accumulation of a crust of protein which covers the entire frostbitten part of the ear. The crust begins to crack and fall from the ear after 10 to 15 days, revealing a pink surface covered by a thin layer of epithelium. The ear beneath contains a large amount of fibrous tissue which shrinks during the next few weeks. After several weeks the ear is shrunken and thickened, but shows no loss of tissue as the results of injury. The appearance of frostbitten ears treated by means of rapid warming is shown in Figure 1. The course of events following frostbite of a rabbit ear, with and without rapid warming, is outlined in Table II. The times required for development of wet and dry gangrene were quite uniform in the animals treated by rapid warming and in controls.

2. *Immediate rapid warming of rabbit feet following controlled cold injury.* The extent of tissue loss following frostbite of rabbit feet without treatment and with treatment in the form of immediate rapid warming is given in Table III. In general, rabbit feet frostbitten for 3 minutes at − 55° C. and permitted to thaw in air at room temperature (untreated) develop gangrene over the entire injured area and are usually lost to the level of immersion (Table III; Figure 2B and 2C). Following untreated frostbite produced by immersion of rabbit feet for 60 minutes at − 15° C., gangrene develops over the whole of the injured

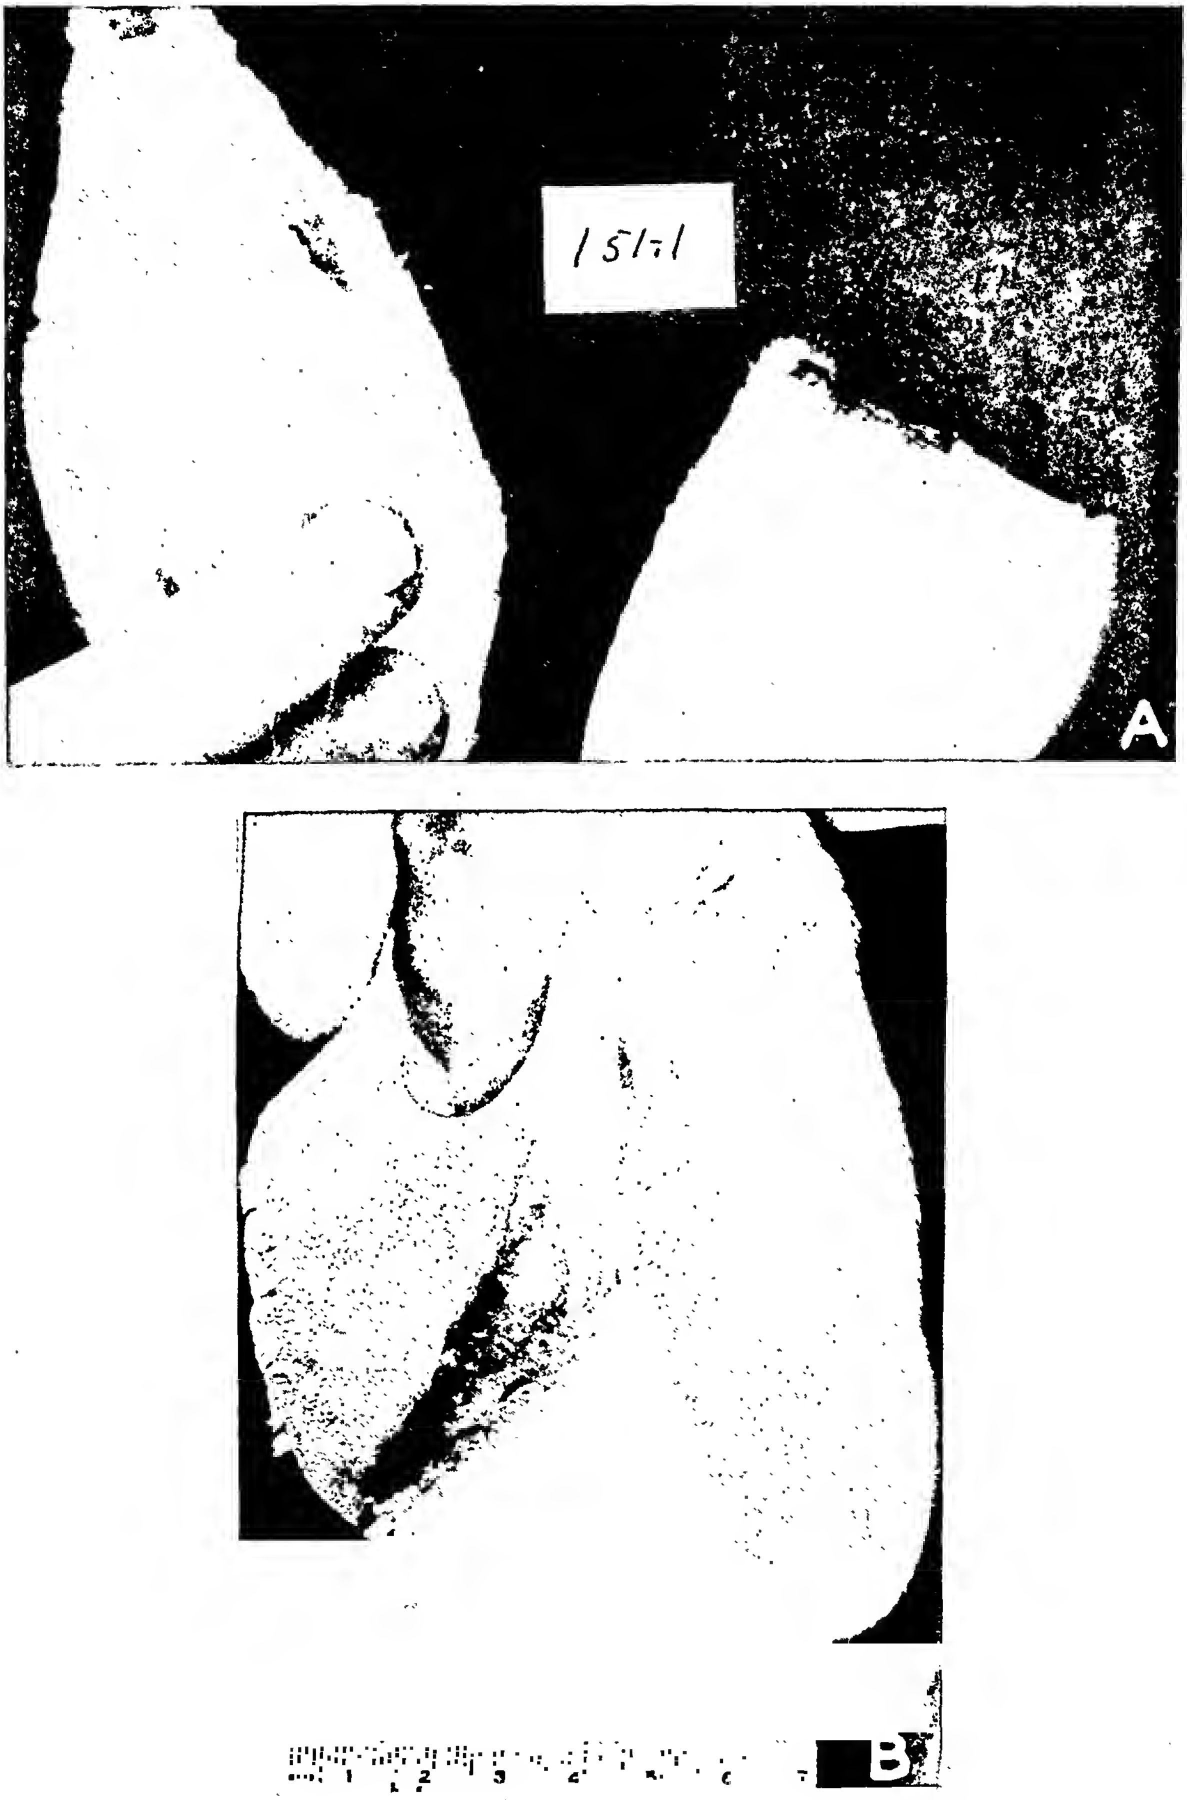

Fig. 1.

TABLE II

Effect of immediate rapid warming on the course of events following frostbite of rabbit ears

Time course of changes following severe cold injury of both ears of one rabbit. One ear treated by immediate rapid warming, while the other permitted to thaw at room temperature in air. Both ears injured by immersion for 60 seconds at −55° C. Right ear warmed in water at +42° C.

Days after injury	Right ear immediate rapid warming	Left ear untreated; thawed in air
1	Edematous. Warm. No blistering	Edematous. Cool. Moderate cyanosis. Large blister
2	Edematous. Warm	Edematous. Cool
3	Edematous. Warm	Weeping. Cool
5	Slight weeping. Warm	Weeping. Cool. Cyanotic. Wet gangrene on tip
6	Warm. Slight weeping. Encrusted with protein	Cold. Wet gangrene, but beginning to dry on tip
8	Encrusted with protein. Warm	Dry to level of frostbite
15	Crust peeling off. Frostbitten portion of ear intact	Spontaneous amputation at level to which immersed

area, and either the entire foot is lost to the level of immersion or a slender tongue of tissue on the plantar surface of the foot is retained.

Treatment of frostbite, following exposure at −55° C. for 3 minutes, by means of immediate rapid warming results in the survival of all of the injured region except the toes (Table III; Figure 2D). Rapid warming following exposure at −15° C. for 60 minutes reduces the extent of tissue loss so that the toes or parts of the toes only are lost (Table III; Figure 2E and 2F).

The course of events in rapidly warmed feet is similar to that in rapidly warmed ears. Thawing occurs after about 1 minute in the warm bath. Following removal from the warm water bath the foot usually appears cyanotic and very hyperemic. The edema is somewhat greater than in untreated feet. Exudation begins after about 2 days. Wet gangrene develops on the toes after 4 to 5 days, and drying follows within 1 to 2 days. The toes shrink, become mummified, and eventually separate.

TABLE III

Tissue loss of untreated frostbitten rabbit feet and of frostbitten rabbit feet treated by means of immediate rapid warming

One hind foot of rabbit immersed in cold liquid, at the indicated temperature, to the level of the tuberosity at the base of the fifth metatarsal

*Untreated control series**

† Numbers in parentheses indicate number of animals.

rate. In some cases wet gangrene may develop on the dorsal surface of the foot, but this soon dries into a crust 1 to 2 mm. thick. This eschar separates after 10 to 14 days, leaving a pink, granulating surface which is soon covered by epithelium. The foot remains warm at all times in contrast to the fall in temperature which occurs in untreated feet after about 48 hours (7). In final appearance the foot is thickened, with moderate scarring especially on the dorsal surface (Figure 2, compare normal A with D, E, F).

FIG. 1. TREATMENT OF EXPERIMENTAL FROSTBITE BY MEANS OF IMMEDIATE RAPID WARMING.

A. Both ears exposed at −55° C. for 1 minute. The ear on the left was warmed for 2 minutes at 42° C. immediately after injury. The ear on the right received no treatment and was permitted to thaw in air at room temperature. Photographed 16 days after frostbite.

B. The ear on the left was exposed at −54° C. for 1 minute and then immediately warmed in water at 42° C. for 2 minutes. The ear on the right is normal. Photographed 21 days after injury.

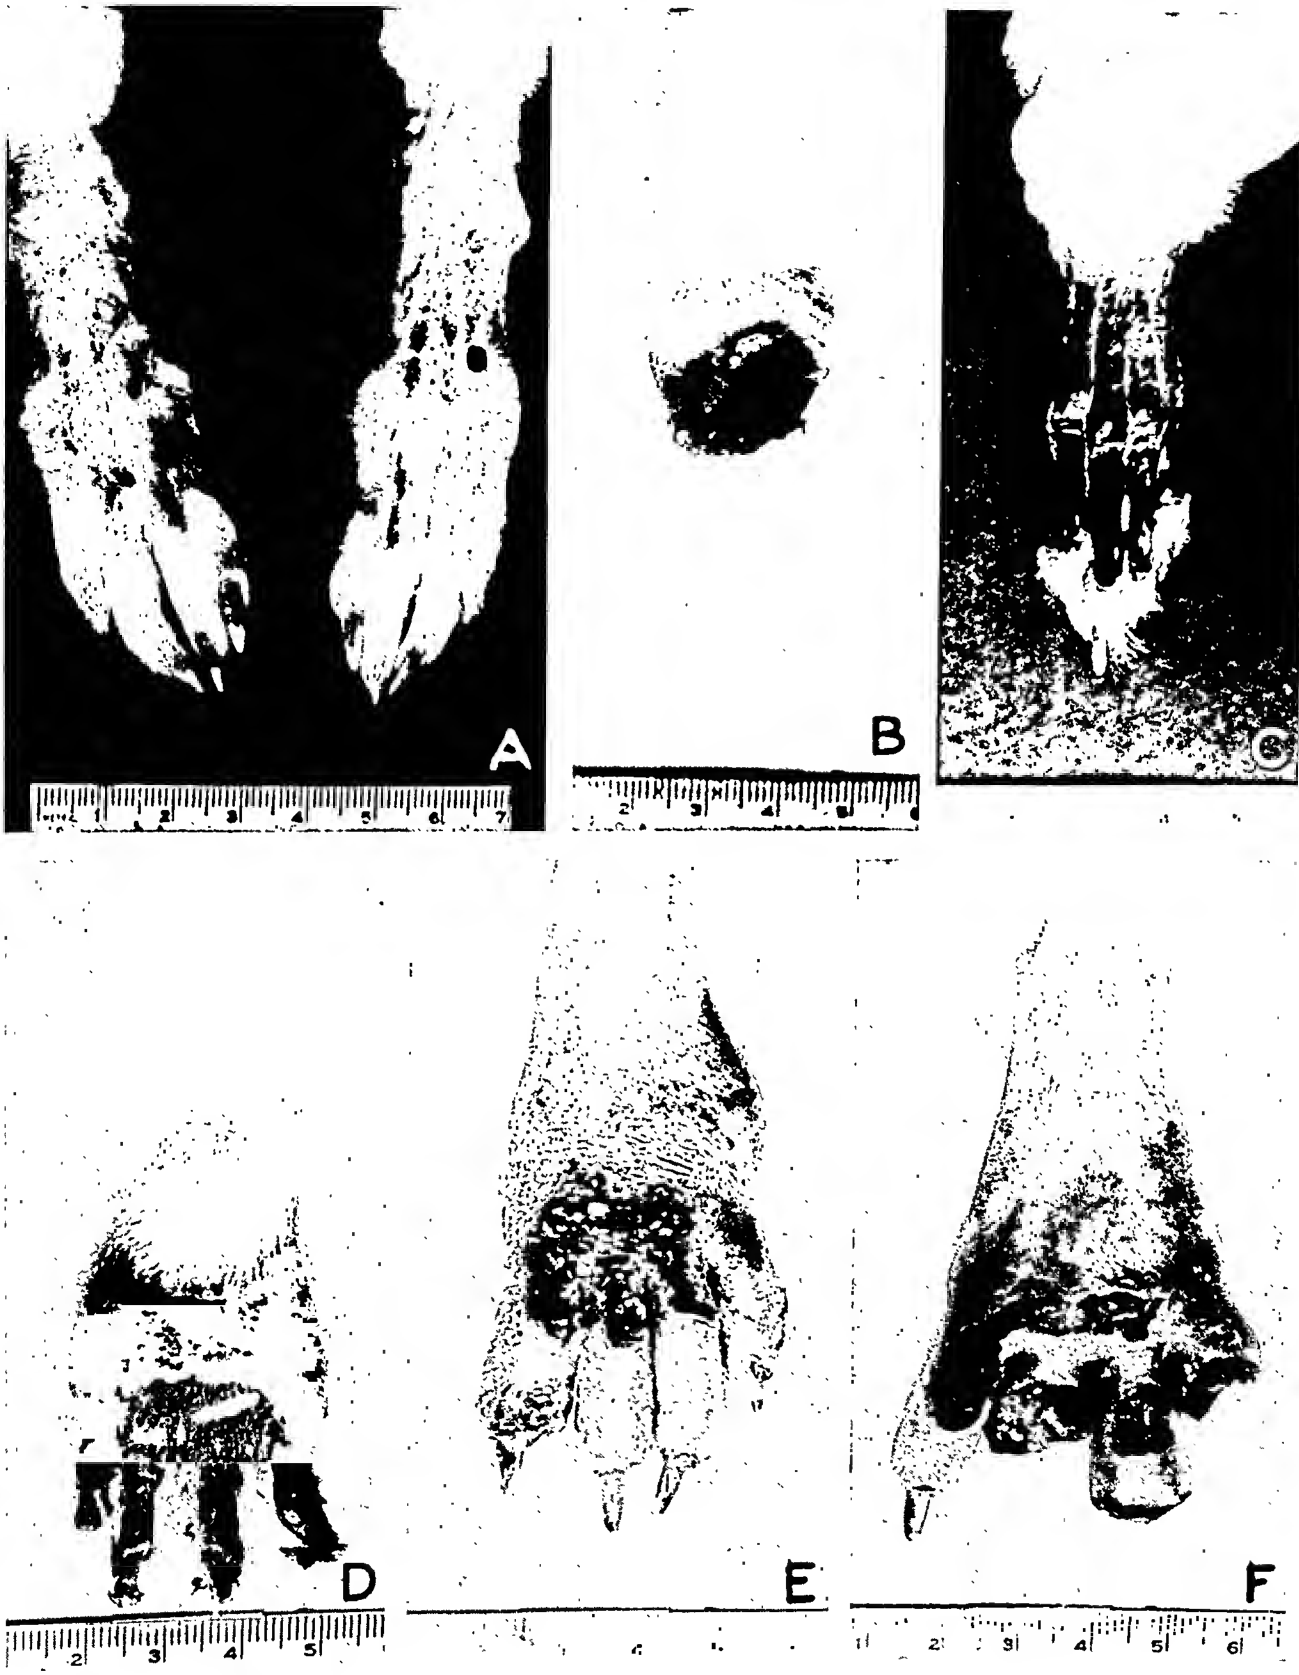

FIG. 2. TREATMENT OF FROSTBITE OF FEET BY MEANS OF RAPID WARMING

A. Normal rabbit feet clipped in preparation for frostbite.
B. Untreated frostbite 16 days after injury. Foot immersed at −55° C. for 3 minutes. Spontaneous amputation at the level of immersion occurred 14 days after frostbite.
C. Untreated frostbite 27 days after injury. Foot immersed at −55° C. for 3 minutes. Foot mummified to level of immersion but not separated.

After immediate rapid warming of feet exposed for 60 minutes at − 15° C., induration is more severe than in those feet frostbitten at − 55° C. for 3 minutes. Partial resolution of the induration occurs over a period of about 3 weeks, but sufficient periarticular fibrosis remains to cause spreading of the foot to 1.5 to 2 times its normal width. The fibrosis is particularly marked about the metatarsal-phalangeal joints (Figure 2E and 2F).

3. *Local status of the circulation in frostbitten ears and feet following immediate rapid warming.* Investigation of ears and feet of rabbits subjected to immediate rapid warming following cold injury has shown that certain important differences can be established between these rapidly warmed extremities and those which did not undergo treatment. Reference should be made to the previous papers in this series, cited below, for the details of the methods used.

a. Skin temperature. Skin temperature measurements of rabbit ears, which were immediately warmed for 2 minutes at + 42° C. following 60-second exposure at − 55° C., were made during the first few hours after injury and at intervals up to 5 days. Immersion of the frozen ear in warm water results in a rise in skin temperature to between 25° and 30° C. A further rise in temperature occurs during the next 30 minutes so that the maximum temperature does not differ markedly from that of untreated frostbitten ears at this time (7). During the first 5 to 6 hours after injury the skin temperature of the injured part of the rapidly warmed ears falls several degrees. The most striking differences in temperature between rapidly warmed ears and those thawed in air (control animals) are observed after 24 hours (Table IV). By this time the decline in temperature of the frostbitten untreated ear has become marked, while the frostbitten, rapidly warmed ear is at approximately the same temperature as the normal ears. Forty-eight hours after injury the temperature of the untreated frostbitten ear has fallen to that of the environment; the skin temperature of the rapidly warmed ears remains at 35° to 37° C. Skin temperature measurements of the ears of 3 untreated animals and 3 animals in which the frostbitten ears were rapidly warmed are given in Table IV. It is quite clear that blood flow through the frostbitten, rapidly warmed ears is maintained at a high level at all times during the period following injury.

TABLE IV

Effect of immediate rapid warming upon the skin temperature of frostbitten ears

b. Demonstrations with fluorescein of local circulation in frostbitten ears treated by rapid warming. The adequacy of the local circulation in untreated frostbitten ears and in frostbitten ears treated by immediate rapid warming has been examined by measuring the intensity of fluorescence under ultraviolet illumination in the injured region after the intravenous injection of fluorescein (8).

In 6 animals the distal half of the ear was frostbitten at − 55° C. for 60 to 90 seconds and im-

D. Frostbite treated by rapid warming. Photographed 26 days after immersion at − 55° C. for 3 minutes. Treated by immediate rapid warming in water at 42° C. for 5 minutes.
E. Frostbite treated by rapid warming. Photographed 16 days after immersion at − [illegible] C. for 60 minutes. Treated by immediate rapid warming in water at 42° C. for 5 minutes.

mediately warmed in water at + 42° C. Sodium fluorescein, 75 mgm. per kgm., was then given intravenously. In some cases, a second injection of fluorescein was made after 24 or 72 hours. The fluorescence of the rapidly warmed ear was compared with that of the ear of another animal subjected to the same type of cold injury but permitted to thaw in air at + 23° C. The results in all animals were similar. When the fluorescein was given immediately after injury the entry into the rapidly warmed ear was more rapid than in the untreated ear and the maximum fluorescence was greater in the rapidly warmed ear. The differences became more marked when fluorescein was given at successively longer intervals after injury. Figure 3 shows the difference between a rapidly warmed ear (No. 18) and an ear thawed in air (No. 19) 18 hours after frostbite and 40 minutes after the administration of fluorescein. In the untreated ear, fluorescence is apparent only around the central artery and near the tip, in the region of large vessels. In the rapidly warmed ear fluorescence is fairly uniform.

Fluorescein injected 72 hours after injury usually fails entirely to enter the frostbitten untreated ear, while the rapidly warmed ear glows brightly.

In one animal both ears were frostbitten for 60 seconds at −55° C.; one ear was then rapidly warmed in water at + 42° C. Fluorescein was given immediately, and again after 48 hours. The curves showing the intensity of fluorescence as a function of time in both ears are given in Figure 4. After both injections, the fluorescence was more intense in the warmed ear. Forty-eight hours

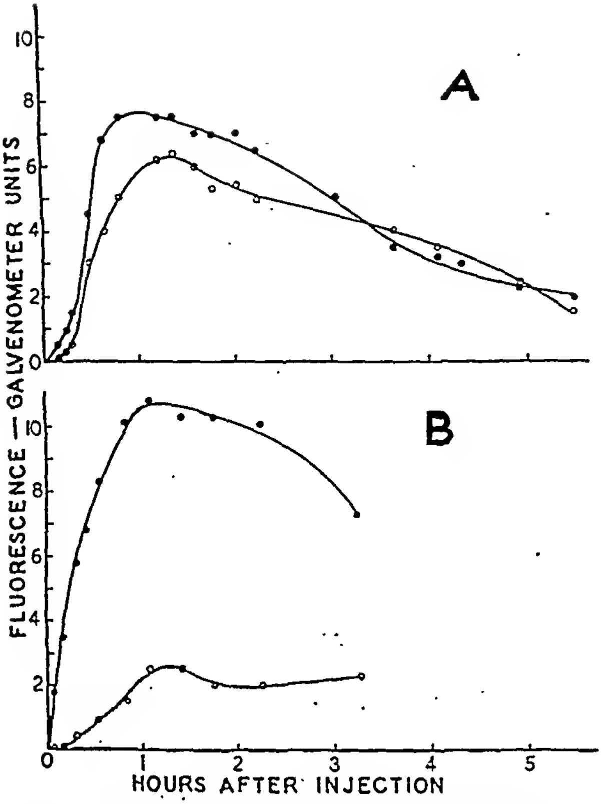

FIG. 4. EFFECT OF IMMEDIATE RAPID WARMING ON THE FLUORESCENCE OF FROSTBITTEN RABBIT EARS AFTER INTRAVENOUS ADMINISTRATION OF FLUORESCEIN

The results of a single experiment in which both ears of a rabbit were frostbitten by immersion at $-55°$ C. for 1 minute. Sodium fluorescein (75 mgm. per kgm.) given intravenously immediately after frostbite (A) and again 48 hours after frostbite (B).

O—O Ear thawed in air (control).

●—● Ear treated by immediate rapid warming by immersion in water at $+42°$ C. for 2 minutes.

after injury the maximum fluorescence of the rapidly warmed ear was 4.4 times that of the untreated ear.

The more rapid entry of fluorescein into rapidly warmed ears than into untreated frostbitten ears indicates that circumstances are present in the treated ears which permit the rapid establishment of equilibrium between the plasma and interstitial fluid in the ears. It is probable that this difference is a measure of the greater area through which fluorescein is able to diffuse into the rapidly warmed ear than the area through which it can pass in the untreated ear.

c. EFFECT OF RAPID WARMING UPON THE DEVELOPMENT OF STASIS AS DETERMINED WITH CARBON INJECTION. These data have been presented in detail previously as part of the description of local circulation following severe cold injury (9). Rapid warming of frostbitten ears had the effect of delaying the onset of complete stasis as determined by injection of carbon particles and direct observation of the trapping of carbon in the minute vessels of the ear. When stasis did develop in the rapidly warmed ears it coincided in time with the period of maximal swelling.

4. *Comparison of immediate rapid warming and cooling following severe cold injury.* Cooling of injured extremities has been recommended following cold injury of the trench foot or immersion foot type (10). In the treatment of frostbite, cooling in the form of cold baths (10° C.) and even rubbing with snow have often been recommended (11). From a theoretical point of view the maintenance of a low tissue temperature, and consequently of a low metabolic rate of the tissues, is desirable under circumstances in which blood flow is reduced.

In 2 animals the effect of cooling on the course of events following frostbite was studied for comparison with the results obtained by immediate warming. Both animals were frostbitten by immersion of one foot at $-54°$ C. for 3 minutes. The foot was then permitted to thaw in air at room temperature and was then cooled. The foot of one animal was suspended on a cradle inside a copper coil 3 inches in diameter, through which liquid at about $+5°$ C. was circulated. Air temperature inside the coil was maintained at 15° C. for 4 hours. The foot of the second animal was encased in rubber drainage tubing and cooled in cracked ice for 7 hours. In both animals the foot was lost to the level to which it had been immersed in the freezing mixture. The course of events leading to loss of the foot was similar to that in untreated animals.

DISCUSSION

Since any direct injury to the tissues resulting from the action of low temperature *per se* has already occurred by the time treatment can be instituted, any therapeutic measure, to be effective, must be directed toward prevention of the occurrence of the secondary changes which follow exposure to cold. S. S. Girgolav (12), director of a

bureau established in Leningrad under the Commissariat of Public Health, expresses a similar point of view in summarizing the Russian investigations: "From a clinical and pathologic standpoint, tissue necrosis in the body does not result immediately from the effect of cold, but appears as a secondary complication. . . . The course of necrosis is determined primarily by interference with or eventual complete stoppage in blood circulation."

The treatment of experimental frostbite by immediate rapid warming is an effective means of preventing the occurrence of the secondary changes following injury. The beneficial effects are probably not the result of shortening the length of time during which the part remains frozen. Thawing in water at + 36° C., rather than at + 42° C., was not effective in saving tissue even though the foot thawed within 2½ minutes after removal from the freezing bath. At 42° C. thawing requires approximately 2 minutes. In one experiment a foot frozen for 3 minutes at − 53° C. was then maintained in the frozen state at − 2° C. for 30 minutes. It was then thawed rapidly in water at + 42° C. for 5 minutes. The resulting tissue loss—toes only—was comparable to that obtained by rapid warming immediately after removal from the − 55° C. bath.

In confirmation of the work of Ariev (1) the immediate rapid warming of frostbitten feet and ears by immersion in water at + 42° C. has been shown to result in less extensive gangrene and smaller tissue loss than in untreated animals. Those ears and feet which were treated by this method underwent stages of hyperemia, massive edema, and exudation of serous fluid equal to, or exceeding, those of untreated animals. In spite of these changes, the extent of tissue loss was reduced after rapid warming. Evidence has been obtained to indicate that this beneficial effect of rapid warming is brought about by maintenance of blood flow through capillaries. The high skin temperatures of frostbitten parts treated by rapid warming are indicative of high rates of blood flow through the tissues. The accelerated rate of entrance of fluorescein from the blood stream into the interstitial fluid of frostbitten ears following rapid warming was observed in contrast to the slow entrance of the dye in frozen untreated ears. Since evidence has been presented which indicates a direct relationship between rate of penetration and available diffusion area (8), the above observation may be interpreted to indicate the preservation of a larger number of functional capillaries, and hence larger diffusion area, in the rapidly warmed ear. Delay of capillary stasis following rapid warming of frostbitten ears has been observed with the microscope in transilluminated ears, and persistence of blood flow has been verified with the aid of injected carbon.

In a recent publication of the Red Army on cold injury Ariev (13) states: "The fundamental goal of treatment in the pre-reactive period is elevation of tissue temperature, that is, warming of the cold-injured extremity, leaving aside the question of the advisability of rapid warming as under war conditions it does not have a great practical importance." Girgolav (12) also concurs in this view: "It has been definitely ascertained through a number of experimental investigations on different animals, that the more rapidly the chilled animal or any of its parts, such as the ear or extremity, is warmed, the more effective is recovery. From numerous experiments of this type, it has been clearly demonstrated that warming is the most satisfactory procedure."[2] If immediate rapid warming is as effective a measure in the prevention of gangrene following cold injury in man as it appears to be in experimental animals it would be highly desirable to develop methods for the institution of this treatment in the field. In spite of Ariev's statement (13) that conditions for warming are seldom available at evacuation stations at the front and that therefore the question of rapid or slow warming is devoid of practical interest, it seems possible that equipment for rapid warming could be developed if circumstances warrant its use.

Although immediate rapid warming of frostbitten feet and ears results in far less tissue loss

[2] Although this paper by Girgolav is titled "Modern Data on Frostbite" it is apparent that he is also concerned with hypothermia. For example he speaks of "frozen animals" treated by rapid warming and describes the minimum body temperatures tolerated. Part of this confusion has undoubtedly arisen as the result of translation. In view of the results obtained by Ariev (1) with rapid warming of rabbit ears which were frozen beyond doubt, it appears probable that Girgolav intends, in the quotation cited above, to include both frostbite and hypothermia. Treatment of hypothermia by means of rapid warming is considered by Sheinis (14) and by Alexander (15).

than in untreated extremities, the ear or foot which is retained is always thickened by the presence of dense fibrous connective tissue. Later, contraction of the scar is particularly evident in ears, which become shortened, narrower, and somewhat distorted in appearance (Figure 1). With the aim of reducing the extent of this fibrosis which may lead to loss of function, rapid warming should be supplemented by measures designed to control edema. The application of pressure dressings or of closed plaster or plastic casts to feet are satisfactory methods of accomplishing control of the edema following experimental frostbite. These methods of treatment will be described in detail in another paper (16).

SUMMARY

Controlled cold injury of rabbit feet and ears, produced by liquid immersion, was treated by immediate rapid warming of the injured part. The rapid warming consisted of immersion of the ear or foot in water at + 42° C. for 2 and 5 minutes respectively, immediately after withdrawal from the freezing mixture. In the majority of cases this treatment resulted in complete preservation of the frostbitten ear after immersion at − 55° C. for 1 minute, a severity of injury invariably leading to gangrene and loss of the injured part in untreated animals. Gangrene was in most cases prevented, or very greatly reduced in extent, and the amount of tissue loss was greatly reduced by rapid warming of rabbit feet injured by immersion at − 55° C. for 3 minutes or at − 15° C. for 60 minutes. Evidence is presented to indicate that the beneficial effect of rapid warming is brought about by alteration in the pattern of local blood flow in the frostbitten part.

Several weeks after injury the treated ears were shrunken and somewhat thickened and the treated feet showed evidence of periarticular fibrosis sufficient to cause spreading of the feet and toes. It is suggested that rapid warming should be supplemented by measures designed to control edema.

STUDIES ON GANGRENE FOLLOWING COLD INJURY. VIII. THE USE OF CASTS AND PRESSURE DRESSINGS IN THE TREATMENT OF SEVERE FROSTBITE[1]

By J. M. CRISMON and F. A. FUHRMAN

(From the Department of Physiology, School of Medicine, Stanford University, California)

(Received for publication December 16, 1946)

It has been reported in a previous communication (1) that increased leakage of fluid from capillaries is an invariable consequence of cold injury in rabbits' ears and feet. Although stasis in the true capillaries was observed to occur in ears about 10 minutes after injury, it could be delayed by several procedures (2). The delayed appearance of stasis in the treated ears, as well as the invariable late occurrence of stasis at the junction between the normal and frostbitten regions of an ear, suggest that distortion of the tissues, resulting from the massive edema, may close true capillaries and produce stasis. The effect of capillary closure in limiting the exchanges between the blood stream and the cells is an important one.

The similarity between the vascular lesion in frostbite and in burns is obvious and has been pointed out previously by others (3). Glenn (4) has recently reviewed the development of the treatment of burns by means of external pressure and by means of non-elastic, non-distensible dressings. Whether the good results of these forms of treatment depend upon "the control of capillary leakage" as suggested by Glenn or whether the benefit may derive from prevention of the mechanical distortion produced by swelling has not been determined. However, measures which aim at the control of either of these consequences of heat injury find equal justification for their use in the treatment of frostbite.

Two different types of dressings are available for the mechanical control of fluid loss following injury:

(*a*) Closed plaster casts were used by Glenn, Gilbert, and Drinker (5) for the treatment of experimental burns. The rationale of this procedure has been described by Glenn (4): "As plasma escapes from the dilated hyperpermeable capillaries, the extravascular tissue fluid pressure quickly builds up against the rigid encasement to exactly equal the pressure attempting to push fluid out of the capillaries." Such dressings should be skin-tight, non-elastic and non-distensible. In order to be maximally effective they should be applied before swelling of the injured part has taken place, and they must be applied in such a way that the distal part of the limb is encased in the dressing.

(*b*) External pressure to control fluid loss, as used by Allen and Koch (6) and others, is applied in the form of a pressure dressing of elastic material. A layer of padding separates the tissue from the elastic bandage and serves to equalize the pressures within the dressing. This form of dressing offers no obvious advantages over rigid casts for immediate treatment of frostbite in the period before swelling has begun.

METHODS

Standard cold injury. Injury was produced by immersing the hind feet of rabbits in a mixture of water, ethylene glycol, and alcohol cooled by the addition of solid carbon dioxide. The times of exposure and the temperatures used included those from 15 to 60 minutes at − 15° C. and 2 and 3 minutes at − 55° C. Details of standardization of cold injury produced by this means are given in the first paper of this series (7).

Closed plaster and plastic dressings. Closed plaster casts were prepared by impregnation of 1-inch gauze strips with dental "flasking" plaster. These were wetted and applied over a thin layer of gauze.

In order to prepare a light weight, non-distensible dressing which would serve a purpose similar to that of closed plaster casts, dressings were made from solutions of plastic materials applied to gauze. Most of the closed plastic dressings were made of a solution of polyvinyl butyral in isopropyl alcohol and castor oil ("Sealskin").[2] Some were formed with acetone solutions of 40 per cent isobutyl methacrylate or methacrylate interpolymer.[3] Those made of "Sealskin" proved to be most satisfactory;

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Stanford University.

[2] "Sealskin—viscous," Clay-Adams & Co., N. Y.

[3] Kindly supplied by E. I. duPont de Nemours, Ammonia Dept., Wilmington, Del.

examples are shown in Figure 1. The dried cast was very light in weight, non-distensible, and non-elastic, but to some extent permeable to air. Those made from the methacrylates were more rigid, less permeable to air, and tended to shrink slightly after application.

In most cases closed plaster and plastic dressings were applied to the feet of rabbits after thawing had taken place, but before swelling was noticeable. Upon measurement of foot volume immediately before application of the cast it was usually found to have increased about 1 ml. In a few animals the casts were applied before thawing was complete. The results did not differ from those first described. All feet had been freed of hair by close clipping before injury. The alcohol-ethylene glycol-water solution (7) in which the frostbite was produced was removed from the foot by gentle wiping. Tincture of merthiolate was usually used as a surface antiseptic, although this was sometimes omitted. Next a thin layer of K-Y jelly or of petrolatum was applied. Each toe was separated from the next by means of gauze, cotton, paper wadding, or lamb's wool. A thin layer of the padding was also uniformly distributed around the foot. Over this was applied 1 layer of seamless tubular gauze, then 2 to 3 layers of 1-inch gauze followed by 2 layers of seamless tubular gauze. The plastic solution was applied with a wooden tongue depressor in 2 coats; 1 over the gauze strips and 1 over the final layer of tubular gauze. The feet were then dried for 20 to 30 minutes in the air stream from a fan. The plastic dressing covered the entire foot and extended as far proximally as possible without impairing ankle flexion.

Pressure dressings. Pressure dressings were always applied after swelling was well started or after it had reached a maximum. They were constructed of approximately 2.5 yards (stretched length) of 1-inch wide elastic bandage. Both "Ace" and "Adaptic" bandages were used; standard 2-inch widths were cut lengthwise before use. Padding material was applied in a thicker layer than was used under closed plastic dressings. Of the 30 pressure dressings used, 24 were padded with lamb's wool, 4 with cotton and 1 each with paper wadding or gauze. Care was taken to begin tight application of the bandage distally and work as far toward the ankle as full flexion of this joint would permit.

RESULTS OBTAINED BY THE USE OF CLOSED PLASTER AND PLASTIC DRESSINGS AND THEIR COMBINATION WITH WARMING AND COOLING

For convenience of comparison of results following various types of treatment with appropriate untreated controls, the following classification of tissue loss in the order of increasing severity was used (Table I):

I. Partial loss of the toes.
II. Complete loss of the toes.
III. Loss of all tissue distal to a line 1.5 cm. from the level of frostbite.
IV. Loss of all tissue distal to a line 1.0 cm. from the level of frostbite.
V. Loss of all tissue distal to a line 0.5 cm. from the level of frostbite.
VI. Loss of all tissue except a narrow extension of the plantar pad.
VII. Loss of all tissue to the level of frostbite.

Table I indicates in the first column the type of treatment, the time of exposure, and temperature of the freezing mixture used to produce injury.

Closed plaster and plastic dressings. Closed plaster casts were applied to rabbits' feet following 3-minute exposure at $-52°$ C. to $-55°$ C.; closed plastic dressings were applied following 3-minute exposure at $-53°$ C. to $-56°$ C., 2-minute exposure at $-54°$ C., and 60-minute exposure at $-15°$ C. The results as shown in Table I indicate the number of times each degree of tissue loss was encountered in untreated controls and treated animals. The efficacy of this form of treatment may be seen from comparison with data on similar untreated injuries. It is apparent that the most striking results were obtained when the treatment was applied to frostbite of 3-minute duration at $-55°$ C. (a severe injury, which usually resulted in complete loss of the foot to the level of frostbite). Of 7 animals, frostbitten for 3 minutes at $-55°$ C. and treated by means of plaster or plastic casts padded only with gauze, 6 animals lost only toes or parts of toes. A typical result of this treatment is shown in Figure 1. It is apparent that too early removal of casts is disastrous; those animals frostbitten 60 minutes at $-15°$ C. with casts removed after 2 and 3 days (see examples marked * in Table I) lost the entire injured region.

Rapid warming followed by closed plastic dressings. The feet of 6 animals were exposed at $-53°$ C. to $-55°$ C. for 3 minutes, then rapidly warmed in water for 5 minutes at $+42°$ C. and encased immediately in closed plastic (Sealskin) dressings padded with a minimum amount of lamb's wool. While without treatment none of the 17 animals subjected to this degree of injury retained more than 1.5 cm. of the injured part of the foot, all 6 treated by rapid warming plus plastic dressings lost only the toes or parts of the toes (Table I).

Pressure dressing applied 3½ hours after injury and left in place for 4 days. The level of immersion in the freezing mixture is indicated in D and E by the transverse inked line.

TABLE II

Treatment of frostbite by closed plastic dressings plus cooling

Feet exposed at −54° C. to −56° C. for 3 minutes. Closed plastic dressing applied after thawing. Cooling began immediately after dressing dried (about 15 minutes).

Animal number	Cooling	Days dressing left in place	Result
84*	Cooled to +5° to +15° C. for 6 hours	5	Lost to level of frostbite
87	Packed in ice 8 hours	5	Lost to level of frostbite
88*	Cooled to +1° to +5° C. for 7 hours	6	Lost toes
98*	Cooled to +10° C. 7 hours	5	Lost toes
103	Cooled in ice 7 hours	6	Lost to level of frostbite except 3 cm. tongue of tissue on plantar surface
104	Cooled in ice 7 hours	6	Lost toes

* Thermocouples placed inside dressing.

foot could be maintained at 5° to 10° C. during the cooling period. Three of these animals lost only the toes, while 3 lost an amount of tissue similar to that in untreated animals.

Rapid warming followed by closed plastic dressings and cooling. In 5 animals the treatments used above were combined. Immediately after injury (by exposure of the foot for 3 minutes at − 55° C.), the foot was warmed 5 minutes in water at + 42° C., encased in a plastic (Sealskin) dressing, and then cooled with ice during the next 5 to 6.5 hours (Tables I and III). This procedure did not seem to produce results superior to those obtained by closed dressings alone or by rapid warming followed by closed plastic dressings.

TABLE III

Treatment of frostbite by immediate rapid warming plus closed plastic dressings plus cooling

Feet exposed at −53° C. to −55° C. for 3 minutes, warmed in water at +42° C. for 5 minutes. Closed plastic dressing applied immediately after warming; cooling began immediately after dressing dried (about 15 minutes).

Cooling	Days dressing left in place	Result
Cooled at +5 to +12° C. for 5 hours	7	Lost distal and middle phalanges of all toes
Cooled in ice 6.5 hours	7	Lost to 1 cm. distal to level of frostbite
Cooled in ice 6 hours	7	Lost toes
Cooled in ice 6 hours	6	Lost to 1 cm. distal to level of frostbite
Cooled in ice 6 hours	6	Lost to level of frostbite

TEMPERATURE MEASUREMENTS OF FOOT ENCASED IN PLASTIC DRESSINGS

Method. In 11 animals thermocouples were placed on the toes or on the dorsum of the foot, or both, before application of the plastic dressings. The thermocouple leads were brought out through the proximal end of the dressing and were wrapped around the animal's leg, as shown in Figure 1, so as not to interfere with its movement in the cage when temperatures were not being measured. Temperature measurements were made with a Leeds and Northrup Potentiometer Indicator using iron-constantan thermocouples attached to copper discs 7 mm. in diameter.

In 6 of the animals the thermocouples were primarily for the purpose of measuring the temperature inside the dressings during cooling of the feet following injury. Measurements of the temperatures were, however, continued for the period during which the dressing was left in place.

In the remaining animals, temperature measurements were made during the first several hours after application of the dressing and at intervals during the ensuing 5 to 7 days. It was found that the temperature of the foot inside the dressing gave an accurate indication of the blood supply to the injured part. In those feet or parts of feet which were subsequently lost, the temperature (measured by the thermocouples within the dressing) either failed to rise above about 26° C. to 29° C. or fell to this level after 24 to 48 hours. Figure 2 shows temperature measurements of the toes and dorsal surface of the feet of 2 animals during the period that the dressings were in place. In both instances the feet were exposed for 3 minutes at − 55° C. Plastic (Sealskin) dressings were applied immediately after thawing occurred. In No. 32, padding was used between the toes and around the foot in such a manner that uneven pressure was avoided. The temperature of both the toes and dorsum increased rapidly and remained high throughout the period of measurement. Tissue loss was confined to 1 toe. In No. 30, no padding of any kind was used between the toes and it was afterward found that excessive pressure occurred around the base of the metatarsals. In this animal the temperature within the dressing increased more slowly, never exceeded 30° C., and fell again after 24 hours. Loss of the entire injured area with the exception of a narrow segment on the plantar surface occurred.

The incorporation of thermocouples for frequent measurement of skin temperature within closed dressings employed in human surgery might offer a convenient and accurate means of determining the state of blood flow to the part when it is not possible to determine this by direct observation.

RESULTS OBTAINED BY THE USE OF ELASTIC PRESSURE DRESSINGS AND BY PRESSURE DRESSINGS IN COMBINATION WITH MULTIPLE INCISION OR RAPID WARMING

These dressings were, in every case, applied after swelling had reached its maximum. They offer the advantage, over closed plaster or plastic dressings, of not requiring immediate application.

Elastic pressure dressings. Elastic pressure dressings, without other treatment, were applied to the feet of rabbits injured by exposure for 3 minutes at − 55° C., for 2 minutes at − 54° C., and for 50 minutes at − 15° C. (Table I). The results should be compared with those obtained in untreated cold injury of similar duration. It is evident that the amount of tissue loss was reduced in most animals. Following 3-minute exposure at − 55° C., 4 out of 7 animals lost only the toes. With the 2 less severe degrees of cold injury, parts of the toes were saved in all except 1 animal.

Rapid warming followed by elastic pressure dressings. Rabbits' feet exposed for 3 minutes at − 53° C. to − 55° C. or for 60 minutes at − 15° C. were immediately warmed in water at + 42° C. for 5 minutes, then permitted to swell for 40 to 180 minutes before application of elastic pressure dressings. In all 8 animals the results were uniformly good (Table I). Following 3-minute exposure at − 55° C., parts of the toes were saved in 2 animals.

Multiple incision followed by elastic pressure dressings. The method of multiple incision, introduced by Noesske (8), was applied to frostbite by Wittek (9) and Bundschuh (10). Although their results may be questioned on the grounds of inadequate numbers of control cases, the removal of fluid and the establishment of free drainage before application of pressure dressings may seem to be desirable. Seven animals were treated in this manner following 3-minute exposure at − 55°

C. (Table I). In the first 6 animals, 3 incisions were made through the skin of the dorsal surface parallel to the long axis of the foot. In the seventh animal similar incisions were made on the toes. In order to encourage free drainage the incisions were packed with a small amount of 5 per cent sulfathiazole cream before application of the pressure dressings. Although the animal in which the toes were incised lost only the toes, the results are not superior to those obtained by means of pressure dressings alone. The added danger of infection probably constitutes sufficient grounds for avoiding this method of treatment in clinical practice.

TREATMENT OF COLD INJURY BY PULSATING EXTERNAL PRESSURE

Pressure pulses transmitted through tissues from arteries and arterioles have been shown to be one of the important dynamic agencies in the maintenance of lymph flow (11). To the extent that edema following severe injury by cold (1, 2) may be responsible for some of the changes leading to gangrene, the acceleration of lymph drainage of edematous areas should be helpful in reversing the processes which lead to the development of gangrene. Even in circumstances where gangrene does not occur, the swelling has been shown to lead to induration and later formation of collagenous scars in the subcutaneous tissues (12). Past experience has shown that most cases of accidental injury by cold, especially in military operations, do not receive treatment until a considerable time after exposure, and edema is then usually well advanced. The literature has been reviewed in the first paper of this series (7).

The experiments below were undertaken to study the effects of external application of pulsating pressure upon the course and ultimate results of severe injury by cold in the feet of rabbits.

Methods

Fifteen rabbits were used in the study. Thirteen of the animals were subjected to a degree of injury by cold which had been shown to produce extensive gangrene (Table I); 3 minutes at $-50°$ C. to $-56°$ C. The remaining 2 animals received injury to the feet which usually resulted in some gangrene and loss of the toes: 2 minutes at the same temperatures used above.

Treatment was begun at varying times after injury. In all cases swelling was allowed to progress practically to its maximum. The times of application of treatment are indicated in Table IV.

External pulsating pressures were applied to the injured feet by enclosing them in a heavy glass cylinder having an internal diameter of 2 inches. The cylinder was filled with water and connected to the source of pressure with heavy-walled pressure tubing. Various methods were used to maintain a closed system with the foot inside the cylinder. The first method involved the use of a heavy rubber diaphragm, having a hole 2 cm. in diameter in its center. A short cuff of thin-walled latex drain tubing was cemented to the edges of the hole and extended at right angles to the plane of the diaphragm. The hole through the diaphragm and the lumen of the cuff were distended by stretching, and the foot was introduced in such a way that the diaphragm enclosed the leg just above the ankle joint and the cuff extended distally along the foot. The free margins of the diaphragm were then secured in the manner of a gasket to the end of the glass cylinder and held in place by a ring plate and bolts. Because of some fear that the closure about the rabbit's legs might occlude venous blood flow or lymph drainage, the tight latex rubber cuff was replaced by a looser one extending proximally from the diaphragm: this was secured about the part of the leg proximal to the diaphragm by a collar of sponge rubber. The first 4 animals listed in Table IV were secured in the apparatus for pulsation by the first method of closure described. The next 3 animals were secured by means of the closure with a sponge rubber collar. The remaining 5 animals were given pulsation treatment under conditions which effectively prevented occlusion of blood flow or lymph drainage by the use of a dipped latex bag with a reinforced collar at the open end. The bag was introduced into the glass cylinder and the open end everted over the open end of the cylinder. This formed a closed system having a flexible portion invaginated to receive the foot.

Two types of apparatus were used as sources of pulsating pressure. Apparatus "A" (Table IV) consisted of a perfusion pump, artificial peripheral resistance, and air chamber. Propulsion of fluid by the pump was effected by the compression and forward movement of fluid in a segment of rubber tubing by 4 brass rollers mounted on the periphery of a rotating drum. Mean pressure level was determined by the compression pressure in a standard artificial peripheral resistance of the Starling type. The frequency of pulsations was determined by the rate of rotation of the drum and the size of the pressure pulses by the degree of compression of the rubber tubing by the rollers.

Apparatus "B" consisted of a pump constructed from a 5-ml. syringe mounted on a universal joint. The plunger of the syringe was moved by the arm of a crank driven through reduction gears. An adjustable air chamber constructed from a 50-ml. syringe provided for variable damping of the pulse waves. Frequency of pulsations was altered by changing the drive to the reduction gears, and the volume of the pulse was adjusted by manipulation of the stroke of the syringe plunger.

TABLE IV

Treatment of frostbite by means of pulsating external pressure

Animal no.	Time elapsed before treat.	Pressure	Rate	Duration of pulsation	Result
	hours	*mm. Hg*	*puls. per min.*	*hours*	
Feet exposed at −50° C. to −55° C. for 3 minutes					
9	24	+110/+90	208	7	Lost to level of frostbite
11	3	+111/+91	208	3	Lost to 1 cm. distal to level of frostbite
13	2	+90/+64	208	2.5	
	22	+90/+64	208	8	Lost to level of frostbite
35	3	+41/+34	208	3	Lost to 1/2 cm. distal to level of frostbite
54	4	+42/+38	208	2.5	Lost toes
63	3	+45/+35	208	2.5	Lost to level of frostbite
87	2	+30/−10	60	3	Lost to level of frostbite

The type of apparatus used for the treatment of the various animals is indicated in Table IV.

Results

The pertinent data from these experiments are presented in Table IV. The pulsation rates and the magnitudes of the pulse waves in the first 7 animals were selected to reproduce rather closely the pulsations to be expected in the small arteries of the extremities. The frequencies and magnitudes of pulse waves in the last 6 animals were employed to avoid possible interference with blood flow which might have been encountered with the use of higher pressures and also in order to reproduce influences upon lymph flow which resembled those resulting from muscular activity.

None of the feet treated by external pulsating pressure was found to decrease in volume during the period of treatment. In the interval from 15 to 21 hours after the foot was removed from the pressure cylinder, there was usually some additional swelling amounting to 1 to 3 ml. The time course of decreasing foot volume was usually a little more rapid than that of the untreated controls, but the difference was neither marked nor uniform.

The final result of the injury did not differ from that in untreated animals. Exposures of 3-minute duration to the freezing mixture at − 50° C. to − 56° C. produced gangrene and loss of the foot to within a few millimeters of the line of immersion, and 2-minute exposures to these temperatures was followed by loss of the toes. The time interval between the exposure to cold and the loss of tissue was the same as that in the controls.

STATISTICAL SUMMARY OF RESULTS

Analysis of the results was carried out by the "exact" method of Fisher (13) for 4-fold tables. The criterion of comparison of control animals with treated animals depended upon the distribution of degrees of tissue loss in the controls. None

of the control animals fell into class I or II (partial loss of toes or complete loss of toes). Therefore, the treated animals were compared with the controls on the basis of the number of animals in each series which fell into tissue loss classification I and II as distinguished from those falling into classes III to VII. Thus, for purposes of statistical analysis, no result was regarded as favorable unless the loss of tissue was restricted to the toes or parts of toes. Only the data from animals injured by exposure for 3 minutes at − 50° C. to − 56° C. were included in the statistical analysis. The values of P in Table V indicate for each type of treatment the probability of encountering the indicated reduction in tissue loss by chance. The various treatments are arranged in the order of their effectiveness in preventing gangrene. The probability values indicate that significant degrees of benefit were achieved by the use of non-distensible dressings and by pressure dressings, but favorable results were even more frequently encountered when these dressings were combined with other treatments, especially immediate rapid warming.

TABLE V

Statistical summary of results[4]

Treatment	Number of animals	P
Rapid warming and plastic cast	6	0.000020
Rapid warming and pressure dressing	5	0.000038
Plaster cast	4	0.000170
Pressure dressing	7	0.003300
Plastic cast and cooling	6	0.011000
Plastic cast	9	0.032000
Rapid warming, plastic cast, and cooling	5	0.034000
Multiple incision and pressure dressing	7	0.076000*
Pulsating pressure	13	0.433300**

* Difference from controls of doubtful statistical significance.
** Difference from controls not statistically significant.

DISCUSSION

The methods of treatment of cold injury described in this report have in common the attempt to control fluid loss from the blood stream in the region injured by cold. As measures of prevention, control has been effected through the application of non-distensible dressings before swelling occurred; as aids to the removal of edema fluid, elastic pressure dressings, the incision of swollen tissues, and the application of external pulsating pressure have been employed. The results show that prevention of swelling or the reduction of it by means of elastic pressure dressings is capable of altering the course of changes in tissues severely injured by cold. In contrast to the complete loss from gangrene of the part subjected to injury when no treatment is used, there is a striking reduction in the extent of gangrene following the application of a non-distensible dressing before swelling has occurred or the use of an elastic pressure dressing after swelling is maximal. In general, the amount of tissue saved by the use of measures designed to control swelling are somewhat smaller than the proportion saved by immediate, rapid warming (12). However, the best results obtained with pressure dressing or with casts are equal to those following rapid warming in terms of amount of tissue saved and much superior to those obtained by rapid warming in terms of functional recovery. Cold-injured tissues which escape gangrene and survive following treatment by immediate, rapid warming are thickened by massive induration in the early healing period and later by dense accumulations of collagenous scar tissue. If the injuries are treated by casts or pressure dressings, alone or in addition to rapid warming, induration and accumulations of scar tissue are insignificant.

The success or failure of treatment of cold injury by the application of casts or pressure dressings depended to an important degree upon the manner of application of the dressing and also upon the nature of the material used for padding. Unequal distribution of pressure, especially over bony prominences, contributed greatly to the development of gangrene. The irregular contours of the rabbits' feet, after removal of the hair by clipping, proved to be extremely difficult to pad evenly. Of the various materials tried as padding (paper wadding, absorbent cotton, gauze, and lamb's wool), the wool was the most satisfactory in both casts and pressure dressings. Both paper and cotton tended to become matted and stiff with absorbed exudate, while the lamb's wool without losing resilience permitted the continued drainage of exudate. The almost invariable loss of the toes following the severest injury (exposure of 3 *minutes* at − 55° C.) and the partial loss of

[4] See text for basis of comparison and method of computing values for P.

toes following the less severe degrees of injury may be attributed in part to unsatisfactory application and maintenance of pressure in these parts of the feet. The relationship between the mass and the surface area of the toes tended to facilitate their reaching a lower temperature during exposure, and the larger number of arteriovenous anastomoses contributed to early stasis by diverting blood flow away from the true capillaries (2). The above factors and undoubtedly others, as yet undefined, combine to determine the greater susceptibility of the toes to cold injury.

The results of treatment of cold injury by early mechanical control of the edema, by immediate rapid warming (12), and by the use of heparin as described by Lange and Boyd (14) all confirm the opinion of Bigelow (15) that stasis is not necessarily an irreversible process. The interruption of the transition from temporary arrest of blood flow by stasis to permanent arrest by thrombosis may be accomplished by a variety of means. In spite of the apparently diverse mechanisms of action of these methods of treatment, they have in common the essential feature that all of them must be applied early and continuously over an appreciable time period in order to be effective.

It should be pointed out that the "reversal of stasis," in the literal sense of restoration of blood flow through the identical capillaries once occluded by packed red blood cells, is not a necessary condition determining the survival of tissues severely injured by cold. However it may be accomplished, the necessary condition is the supply of oxygen and nutrients and the removal of metabolites. Resting tissues are maintained under normal conditions with blood flowing through only a very few of the total number of capillaries available, the flux of tissue fluid being adequate for the supply of cells remote from open capillaries (16). If such a flow of fluid can be maintained for a sufficient time in tissues severely injured by cold, new capillary channels may grow to replace those obliterated, initially by stasis and later by thrombosis.

In untreated experimental frostbite, the development of massive edema is accompanied by rising interstitial fluid pressure (17). When the edema reaches its maximum (about 2 hours after the severest forms of injury described in this report) the interstitial fluid pressure is 25 cm. of water. Not only is the rate of filtration sharply limited by the high counterpressure, but many of the minute vessels become closed, both by the rise of pressure surrounding the vessel above that within the lumen and by kinking as the tissues are distorted by edema. An additional harmful consequence of edema is the increased distance over which diffusion exchanges must be accomplished between remaining capillaries and surviving cells.

It is probably safe to assume that the fluid dynamics are essentially the same inside the non-distensible dressings used for the treatment of frostbite as those described by Glenn, Gilbert, and Drinker (5) when such dressings were used for the treatment of experimental burns. Even though a high rate of fluid loss from capillaries may persist, the rigid dressing enforces a uniform rise of pressure in all parts of the foot enclosed within the cast; spatial distortion is prevented and rapid removal of fluid is effected via the lymphatics as well as by seepage through the interstitial compartment. The mechanism of action of elastic pressure dressings is conceived to be fundamentally similar with the exception that such dressings are applied after swelling and hence have, in the early phases, a dynamic rather than a passive role in removal of fluid.

In untreated experimental frostbite, the skin temperature of injured feet of rabbits declined gradually over a period of about 48 hours until the temperature was approximately that of the environment (1). When skin temperature measurements were made on casted feet by means of thermocouples on the skin and enclosed in the cast, it was found that those parts which survived the injury remained warm while those destined to become gangrenous in spite of the treatment suffered the usual fall in temperature. It therefore seems evident that arrest of the usual process of progressive vascular occlusion is in some way brought about by the cast or pressure dressing. Removal of dressings as early as the third or fourth day after injury resulted in gangrene and loss of the entire injured region. Thus, the interruption of the injury process does not become stabilized until the dressings have been left in place for 5 to 7 days. While the exact nature of the change is not known, the time relations are at least consistent with the following hypothetical course of events: (a) primary stasis of true capillaries following the

initial injury, (*b*) persistence of filtration from arteriolar-venular capillaries (16) in amounts sufficient to maintain cells which survive the original injury, (*c*) the growth of new capillaries in sufficient numbers to provide for fluid removal and maintenance of cells by the time the dressings are removed.

SUMMARY

Prevention of gangrene following experimental frostbite in the hind feet of rabbits was attempted by mechanical control of edema with casts and pressure dressings. Combinations of rapid warming and subsequent cooling with casts and pressure dressings were also studied.

The injuries were of sufficient severity (immersion in liquid for 3 minutes at − 55° C.) to produce loss of virtually all of the exposed part of the foot in control animals. In similarly injured animals, treated by the above methods, marked improvement was noted. Gangrene was restricted to the toes or parts of the toes in a highly significant number of cases.

The most favorable results were obtained by the use of rapid warming followed either by casts applied before swelling occurred or by pressure dressings applied after maximum swelling. Casts or pressure dressings alone produced significantly favorable results. The maintenance of low skin temperatures (5° to 10° C.) in casted frostbitten feet produced better results than did casts alone, but the difference was slight. Multiple incisions through the skin of the injured regions, followed by the application of pressure dressings, led to survival of more tissue in the frostbitten feet than was observed in the controls; but the low statistical significance of the difference suggests that the procedure is of doubtful value. External application of pulsating pressure was completely ineffective in preventing gangrene.

Various factors influencing the successful use of the treatments have been discussed and a possible mechanism by which control of edema may prevent gangrene was suggested.

The authors extend thanks to Professor F. W. Weymouth for his advice in the preparation of this manuscript and for the statistical treatment of data.

STUDIES OF THERMAL INJURY. VI.[1] HYPERPOTASSEMIA CAUSED BY CUTANEOUS EXPOSURE TO EXCESSIVE HEAT

By R. McLEAN, A. R. MORITZ, and A. ROOS

(*From the Department of Legal Medicine, Harvard Medical School, Boston, Massachusetts*)

(Received for publication December 18, 1946)

INTRODUCTION

That the rapid release of potassium from erythrocytes during an episode of generalized cutaneous hyperthermia may cause an increase in plasma potassium sufficient to contribute to the occurrence of circulatory failure and death was suggested by Schjerning in 1884 (1). The suggestion was based in part on the fact that postmortem examination of extensively burned persons often disclosed evidence of severe intravascular hemolysis and in part on the fact that a sufficient amount of potassium may be released from erythrocytes *in vitro* to raise the plasma concentration of that element to a level incompatible with continued cardiac function.

In a foregoing study (2) in this series, it was observed that generalized cutaneous exposure to excessive heat may lead to rapidly fatal circulatory failure. In several pigs that died in this manner and whose deaths were preceded by electrocardiographic evidence of severe disturbances in cardiac function, the plasma potassium was found to be increased to levels ordinarily considered incompatible with life. The implication of this observation was such as to warrant further study of the effects of hyperthermia on the potassium concentration of the plasma.

EXPERIMENTAL PROCEDURE

Samples of blood for chemical analysis were obtained from the heart by means of an inlying jugular cannula. Potassium determinations were carried out on the trichloroacetic acid filtrate of plasma and lysed blood according to the method of Lowry and Hastings (3) as modified by Cohn and Tibbetts. Hematocrit was determined in Wintrobe tubes after centrifuging for 30 minutes at 2,500 r.p.m. The method of Bing, *et al* (4), as modified by Ham (5) was used for determining plasma hemoglobin. Whole blood hemoglobin was determined on 0.1 ml. of 1/5 dilution of blood in 5 ml. dilute ammonia by the Klett-Summerson colorimeter.

Before undertaking further investigation of the relationship of hyperthermia to the development of hyperpotassemia, an experiment was undertaken to determine the effect of systemic anoxia on the potassium concentration of the plasma independently of hyperthermia.

A control sample of blood was taken from an 8.2 kgm. pig. The trachea was then exposed and clamped and 4 and 8 minutes later, additional samples of blood were obtained. The animal died at the end of 8 minutes and was allowed to remain on the operating table at room temperature for an hour thereafter, at which time, the fourth and last sample of blood was withdrawn. The analytical results are shown in Table I.

TABLE I

Changes in the blood of a pig during and after death by strangulation

8 min.	48	34	0	130	9.3
8 min.	Animal died				
68 min.	?	?	0	?	16.8

It may be seen that the plasma potassium level was almost doubled during the 8 minutes that elapsed between the onset of asphyxia and death. Most of the increase occurred during the first 4 minutes of this period. There are two obvious sources from which the increment may have been derived, one being the erythrocytes and the other the extravascular tissue. A comparison of hematocrit and hemoglobin content of cells at the end of the 4-minute period indicates that swelling of erythrocytes had occurred. The hematocrit rose from 45 to 49, whereas the hemoglobin dropped from 33 to 31 grams per 100 ml. of cells. It appears that the observed decrease in the con-

[1] This work has been done under Contract NDCrc-169 between the President and Fellows of Harvard College and the Office of Scientific Research and Development who assume no responsibility for the accuracy of the statements contained herein.

centration of intracellular potassium from 132 to 128 meq. per L. was probably due to this swelling of red cells rather than to loss by leakage. Since the actual potassium content of the erythrocytes did not appear to have dropped and since there was no hemolysis, it was inferred that the potassium in the plasma had been increased by diffusion from extravascular sources.

The need for taking blood promptly after death, if reliance is to be placed on analytical results, is illustrated by the rise in plasma potassium that occurred during the first hour postmortem. At death, the plasma concentration of potassium was 9.3 meq. per L., whereas 1 hour later it was 16.8. Although there is no evidence in the data presented in Table I as to the source of the postmortem increment in plasma potassium, unpublished studies indicate that both leakage from red blood cells and diffusion from extravascular tissues may cause a postmortem rise in plasma potassium. So far as the significance of this experiment in providing control data is concerned, it is apparent that a two-fold rise in plasma potassium may occur as a result of severe systemic anoxia independently of hyperthermia.

In order to correlate chemical data with known degrees of cutaneous hyperthermia, it was decided to sub-

* Right heart temperature.

merge animals in hot water rather than expose them to hot air. By the former method, the temperature of the surface of the skin could be controlled with greater precision than was possible by the latter.

The experimental procedure that was followed in submerging animals in hot water is described in detail in Study VII of this series (6). The animals were anesthetized with pentobarbital sodium and between 60 and 75 per cent of the total body surface was immersed in hot water. The effects on the blood of exposing 4 pigs in this manner at 47° C. and 8 pigs at 75° C. are shown in Table II.

RESULTS

Exposure at 47° C.: Although all of the [illegible] animals developed an acute and rapidly fatal systemic hyperthermia, none showed a rise in plasma potassium significantly greater than that which may result from anoxia independently of hyperthermia

In none of these was the magnitude of the increase comparable to that which was observed in some of the hot air exposures reported in Study IV of this series (2).

In the first two animals, it appeared that the potassium increase in the plasma was derived from extravascular sources. In one sample from the third animal the increase could have been due to leakage from red blood cells. In the fourth animal it could have been due in part to leakage from intact erythrocytes, and in part to diffusion from extravascular tissue. Cutaneous hyperthermia of the kind produced in these animals did not result in a significant amount of intravascular hemolysis.

Exposure at 75° C.: The chemical changes in this group were of a different order of magnitude than those observed in animals exposed at 47° C. All animals exposed for more than 3 minutes at 75° C. developed plasma potassium levels in excess of 16 meq. per L. In most instances, such levels were reached during the first few minutes of exposure and were either maintained or increased as the period of exposure was prolonged. If the pig survived for more than a few minutes after the termination of the exposure, there was a slow decline in plasma potassium concentration. Thus, in animal No. 919 the plasma potassium rose from 4.2 to 25.5 meq. during the first 4 minutes of exposure, and during the next 4 minutes declined to 17.4.

The rapidity with which an excessively high plasma potassium level may fall is indicated by the discrepancies that were observed between estimated increments by hemolysis and total amounts actually present in the plasma. Thus, it may be seen in the case of pig No. 913 that with an increment of 7 meq. per L. between the 2- and 6-minute samples by hemolysis, the actual plasma level rose by only 3.5 meq. Similarly, in pig No. 912 the increment by hemolysis between the 1- and 5-minute samples was 14.9 meq. per L. whereas the total plasma potassium actually changed from 16.7 to 16.4 during this period.

In most of the animals exposed at 75° C., there was some increase in the volume of packed cells. The comparison of cell volume and hemoglobin content indicated that most, if not all, of the early increase in cell volume was due to swelling of erythrocytes rather than to loss of plasma or mobilization of cells from storage depots.

It is of interest to note that plasma hemoglobin values as high as 24 per cent hemolysis were observed as early as 5 minutes after the onset of cutaneous hyperthermia. It was estimated that during this period the temperature in the vicinity of the most superficial blood vessels probably rose to approximately 70° C.

Chemical changes in the blood of dogs caused by cutaneous hyperthermia: It was inferred from the foregoing experiments on pigs that most of the potassium responsible for these potentially fatal plasma levels either leaked out of intact red blood cells or escaped from hemolyzed cells. If this inference is correct, fatal hyperpotassemia due to cutaneous hyperthermia would occur only in animals having a high concentration of potassium in the erythrocytes such as man or pig. Its occurrence could not be expected in an animal having a low cellular concentration of potassium as is the case in dog's blood.

To test this assumption, samples of blood were taken from each of 5 dogs before and during immersion in hot water. The results of these experiments are shown in Table III.

The animals were exposed at temperatures ranging between 55° and 75° C. until death occurred. The highest potassium concentration observed in the erythrocytes in control samples of blood from these animals was 9.4 meq. per L., in contrast to the pig whose erythrocyte concentrations ranged between 106 and 145 meq. per L. The greatest potassium increase that occurred in the plasma of the dogs that died as a result of cutaneous exposure to heat was from 3.9 to 8.2 meq. per L.

The increments to the plasma potassium that were observed in these animals could not be accounted for by loss of potassium from the erythrocytes. The potassium content of the red blood cells of the dogs characteristically rose during exposure in contrast to the loss of potassium that occurred from the erythrocytes of the pig. As in the case of the pig, there was severe intravascular hemolysis in animals exposed at 75° C. until death occurred.

It can be inferred, therefore, that the development of a potentially fatal level of hyperpotassemia following cutaneous exposure to heat results from the rapid release of potassium from thermally in-

* Right heart temperature.

jured red blood cells and that a high erythrocyte content of potassium is essential to its occurrence.

In vitro *effects of heat on pigs' blood:* It was thought that more precise information regarding the reciprocal relationships of temperature, time and the release of potassium from erythrocytes could be obtained by heating samples of pigs' blood *in vitro.*

Heart's blood was collected from normal pigs by cardiac puncture in a heparinized syringe where it was mixed and then discharged into heparinized glass stoppered vials. One vial was kept at room temperature as a control; the others were strapped to a mechanical mixer and immersed in a constant temperature bath. Exposure temperatures ranged between 44° and 63° C. during which time the blood was mechanically decanted from one end of the vial to the other at a rate of 6 times per minute. It required approximately 2 minutes for the temperature of the blood to reach that of the water bath. As soon as a sample was removed from the water bath, it was immediately cooled in ice water and analyzed.

It is apparent that there was a progressive increase in the rate at which potassium passed out of the erythrocytes and into the plasma of the blood as its temperature was raised (Table IV). The amount of the plasma increment at the end of 1 hour's exposure at 40°, 44°, 48°, 51°, 52° and 55° C. were respectively 0.6, 1.6, 6.4, 6.4, 6.7 and 14.3 meq. per L. At the lower temperatures (51° C. and under), the increments were due almost entirely to leakage from intact cells. At the end of 30 minutes exposure at 52° and 55° C., the proportion of the plasma increment contributed by hemolysis was 24 and 38 per cent respectively.

Unequivocal evidence of swelling of erythrocytes was first observed at 55° C. although there

* These values must be due to analytical errors.

may have been some swelling in all specimens exposed for more than 30 minutes at 48° and higher.

The rate of change in the blood was much more rapid during exposures at 60° C. and higher. In these experiments the blood remained in the bath for only 5 minutes and the actual time during which it was at the temperature of the water was approximately 3 minutes. The rises in plasma potassium after such brief periods at 60°, 61°, 62° and 63° were respectively 9.0, 16.7, 26.9 and 36.1 meq. per L. The blood was totally hemolyzed at 65° C.

Not until blood was heated at 60° C. or higher in a test tube were the observed increases in plasma potassium comparable to those that occurred in living pigs after cutaneous exposures at 75° C. This is not to imply that the effects of hyperthermia on blood in a test tube are necessarily similar to those effects in a living animal. Attention has already been called to the fact that asphyxia without rise in temperature may cause hyperpotassemia in a living animal. Although the mean temperature of the blood of a living pig is never raised to 60° C., most or all of its blood

may in the course of its circulation through the over-heated dermis be brought to a much higher temperature than would be recorded by a rectal thermometer or intracardiac thermocouple. It will be recalled from the calculations made in Study I (7) of this series that the superficial portion of the dermis of a living pig reaches a temperature of 60° C. within a second after the surface of the skin has been brought to 75° C. It would appear quite possible then that the temperature of a considerable portion of the blood of an animal that had received an extensive cutaneous exposure to water at 75° C. for as long as 5 minutes would have been raised briefly to the neighborhood of 60° C. during its passage through the superficial subcutaneous tissue.

Not until the temperature of the bath was raised to 62° C. did a 5-minute exposure of blood in a test tube result in hemolysis comparable to that observed in living pigs exposed to 75° C.

Attention has already been directed to the fact that unequivocal swelling of erythrocytes was first observed in a test tube after a 15-minute exposure at 55° C. So far as could be judged by the hemoglobin-hematocrit ratios, swelling of erythrocytes continued through 61° C., beyond which it was not observed.

SUMMARY

These experiments have established that severe and extensive cutaneous burning may result in a rapid rise in plasma potassium to levels ordinarily considered incompatible with life. Such levels are attained when a large proportion of the body surface of an animal whose erythrocytes normally have a high potassium content is maintained at temperatures as high as 75° C. for more than a few minutes. That lower surface temperatures may also be responsible for fatal hyperpotassemia is suggested by the fact that potassium may be released rapidly from blood cells *in vitro* at temperatures of 60° C. Because of the slowness with which potassium is released at lower temperatures and the rapidity with which excess potassium leaves the blood stream, it is not likely that thermal exposures of insufficient intensity to cause severe cutaneous burning could cause sufficient damage to the erythrocytes to produce dangerously high plasma levels.

In vitro experiments on pigs' blood indicate that there is rapid leakage of potassium from intact erythrocytes when the temperature is raised over 60° C. and that rapid hemolysis occurs when the temperature is raised above 62° C. Leakage is accompanied by swelling at temperatures ranging between 55° and 61° C. So far as could be judged by the hemoglobin content of the cells, rapid release of potassium occurs without cell swelling at temperatures above 61° C.

It was demonstrated that leakage from and lysis of red blood cells are the principal sources of the hyperthermic potassium increments of plasma. At the lower temperatures (47° C. *in vivo* and 48° C. *in vitro*) hemolysis is negligible. The increase in plasma potassium *in vivo* at these temperatures is due either to diffusion from extravascular sources or to leakage from erythrocytes. It was obvious that in the *in vitro* exposures at relatively low temperatures leakage from erythrocytes was the only source of the plasma increment. Although theoretically enough potassium could be released by leakage alone to account for potentially fatal plasma levels (in excess of 16 meq. per L.) no such increases were observed without accompanying hemolysis. When blood was heated *in vitro* leakage contributed more than hemolysis to the attainment of such levels. In thermal exposures *in vivo* of sufficient duration and intensity to produce such high levels, hemolysis was the more important causal factor.

STUDIES OF THERMAL INJURY. VII.[1] PHYSIOLOGICAL MECHANISMS RESPONSIBLE FOR DEATH DURING CUTANEOUS EXPOSURE TO EXCESSIVE HEAT

By A. ROOS, J. R. WEISIGER, and A. R. MORITZ

(From the Department of Legal Medicine, Harvard Medical School, Boston Massachusetts)

(Received for publication December 18, 1946)

INTRODUCTION

In a previous study in this series (1), attention was called to the fact that acute hyperthermic circulatory failure in some animals was accompanied by, and probably contributed to, by large increases in the potassium concentration of the plasma. An investigation of the circumstances in and the sources from which thermally induced rises in plasma potassium occur has been reported (2).

Although it appears that acute potassium poisoning is probably one, it is obvious that it is not the only mechanism by which cutaneous exposure to heat may cause rapidly fatal circulatory failure. The following experiments were undertaken to investigate more fully the physiological mechanisms by which cutaneous hyperthermia may result in acute circulatory failure and death.

The acute physiological disturbances caused by systemic hyperthermia have attracted the attention of a number of investigators. Heymans (3) injected methylene blue into dogs anesthetized with chloralose. This produced a gradually mounting rectal temperature which reached the lethal level of 43.7° C. to 44.8° C. in 1 to 1½ hours. The heart rate rose gradually from 90 to 120 to 300 to 330 per minute. At first, the respirations were deep and rapid (less than 200 per minute); after the temperature had risen to 41.5° to 43.5° C. they became very shallow and even more rapid (over 300 per minute). Systolic pressure rose and diastolic pressure fell. Respiration almost always failed first, and artificial respiration enabled the heart to continue for a longer time. Reflexes persisted up to the time of respiratory standstill. Uyeno (4) produced hyperthermia in cats, anesthetized with urethane, by exposing them to water of 41° to 42° C. or to a high environmental air temperature. During the 30 minutes of exposure the rectal temperature rose from 35° to 39° C. There was little increase in heart rate, but a pronounced rise in minute-volume output. Shortly after exposure the respiratory rate increased to an average of 200 per minute. This breathing was very shallow (tidal air 2 to 3 ml. per minute) and sometimes resulted in a 29 per cent drop in arterial oxygen saturation. Cheer (5) placed dogs anesthetized with morphine and barbital in a cabinet heated by electric light bulbs. In 2 to 3 hours a lethal (rectal?) temperature of 43° to 45° C. was reached. The heart rate increased progressively until a temperature of 42° to 44° C. was reached, when the heart slowed rather suddenly. Before this stage, electrocardiographic abnormalities were limited to slight abbreviation of the PR interval, slight changes in the QRS complex, and inversion of the T wave. The terminal bradycardia was due to the development of nodal rhythm or of various other types of ventricular rhythm. Systolic and diastolic pressures remained fairly constant up to 41° C., then both dropped, the former more than the latter. The respiratory rate also increased. Respiratory standstill usually occurred before cardiac arrest, vagotomy delaying respiratory failure. A progressive decrease of the blood carbon dioxide was found associated with slight alkalosis and rise of oxygen content which were ascribed to the increased pulmonary ventilation. From the same laboratory, Wiggers and Orias (6) reported observations on the effects of short radio waves on dogs. The cardiac acceleration, increase in rate and depth of the respiration, and primary failure of the respiration were identical with the findings of Cheer (5). However, instead of a decrease in blood pressure, a rise of systolic and diastolic pressure was observed which progressed until death.

Clinical observations on the effect of hyper-

[1] This work has been done under Contract NDCrc-169 between the President and Fellows of Harvard College and the Office of Scientific Research and Development who assume no responsibility for the accuracy of the statements contained herein.

thermia were made by Ferris (7) *et al.* Patients with heat stroke whose rectal temperatures varied from 39.9° to 44.0° C. exhibited a hot dry skin, a normal or elevated systolic pressure, which dropped to low levels only in the terminal stage, and venous pressures of from 2 to 12 cm. of saline. Their respiratory rate was 28 to 50 per minute. Of 29 patients (all comatose) whose temperatures exceeded 41.5° C., 17 died; all others recovered.

Attempts to analyze the disturbances observed in the intact organism by elevating the temperature in one organ have been made since 1872. Fick (8) heated the blood as it passed through the carotid arteries of the dog and noticed marked hyperpnea without change in heart rate or blood pressure. Cyon (9) isolated the circulation of a dog's head. Perfusion of the head with heated blood produced bradycardia and a drop in blood pressure. Kahn (10) warmed the carotid arteries of unanesthetized dogs without producing a rise in rectal temperature. He observed the development of tachycardia and a moderate rise in blood pressure. Moorhouse (11) heated the carotids and simultaneously cooled the jugular veins in dogs. This resulted in tachycardia, rarely preceded by bradycardia, ascribed respectively to increased sympathetic and vagal activity. Coincidentally, tachypnea and peripheral vasodilatation were observed. Heymans and Ladon (12) severed all connections except the vagal nerves between head and trunk of dogs anesthetized with chloralose. Artificial respiration was applied and the circulation in the head maintained by connecting it to a donor dog. The sublingual temperature of the preparation rose to 45° C. in 1½ hours. There was no change in the heart rate which had risen to 160 after severance of the cervical cord. The head exhibited a progressive and pronounced increase in respiratory rate which persisted until a sublingual temperature of 45° C. was reached when the rate rapidly decreased and the reflexes of the head, which had been active up to that time, disappeared.

The effect of hyperthermia on the heart was investigated by Knowlton and Starling (13) using the innervated heart-lung preparation, perfused with heated blood. From 26° C. to approximately 45° C. the heart rate was a linear function of the blood temperature, the rate at 45° C. being 180 per minute. Above this temperature marked slowing occurred and the heart soon stopped. Arrhythmias occurred above 40° C.

Summarizing these data, it can be said that in the dog, the highest rectal temperature compatible with life lies between 43° and 45° C., when this temperature is reached in 1 to 3 hours. Respiratory failure often seems to precede circulatory failure. Tachypnea, tachycardia, and peripheral vasodilatation seem to be, in part at least, of cerebral origin.

The physiological changes of rapidly developing hyperthermia leading to death within ½ hour have not been heretofore studied. As high environmental temperatures are needed for such experiments, the results are necessarily complicated by the damaging effect of heat on the skin directly. Moreover, these high temperatures will produce damage to the red blood cells that are circulating in the small vessels of skin and underlying tissues (Shen *et al*, 14).

EXPERIMENTAL PROCEDURE

Young pigs, weighing from 6.4 to 18 kgm., and adult dogs, weighing from 7.4 to 8.5 kgm., were used as experimental animals. They were anesthetized with pentobarbital sodium (32 mgm. per kgm. intraperitoneally), shaved, and tied to a wooden animal board. This was lowered into a galvanized iron tank (92 × 46 × 41 cm.). The head of the board rested on a metal bar in the tank, so that it was slightly higher than the foot. A similar tank, placed on a high table, partly projected over the former. This tank was filled with water steam-heated to the desired temperature. In the bottom of the projecting part was a circular opening, 13 cm. in diameter, that could be closed with a heavy rubber and metal stopper. Removal of this stopper resulted in immersion of more than ½ the body surface of the animal in 8 to 10 seconds. During immersion, the temperature of the water, which was continuously stirred, was kept within narrow limits by intermittent introduction of steam. Drainage of the water and termination of exposure could also be accomplished in 8 to 10 seconds. Temperatures ranging from 44° to 75° C. were used.

Previous to exposure, all animals were heparinized (3 mgm. per kgm. intravenously). Because of spasmodic closure of the glottis on immersion, a tracheal cannula was inserted. The carotid pressure was recorded with a mercury manometer. The right auricular pressure was measured by means of a rubber catheter introduced into the superior vena cava or right auricle by way of the external jugular vein and connected with a water manometer. The level of the right auricle as determined by opening the chest at the end of the experiment was taken as point of reference. In pigs the hydrostatic pressure did not influence the auricular pressure. In dogs immersion resulted

in a considerable rise in recorded auricular pressure, so that only changes occurring during exposure could be compared. Pneumograms were obtained by means of a copper cannula thrust between the ribs into the pleural space and connected by means of a rubber tube to a writing tambour. In other experiments, a tracheal cannula provided with a sealed-in side tube connected to the tambour was used.

Electrocardiograms were taken with an amplifier type of electrocardiograph. It was only possible to take the first standard lead, as the hind legs of the animal were under water. In some experiments, curarized animals were used and artificial respiration was applied throughout the exposure. Intocostrin (Squibb), 1 mgm. per kgm. diluted with saline, was slowly injected intravenously. The side reactions were limited to a short (20 to 30 seconds) period of mild excitation. The drug had no effect on the arterial pressure. A second smaller dose usually had to be given 20 to 40 minutes later. A Palmer respiration pump for small animals which allows the air to escape spontaneously on expiration was used. When venous pressures were recorded the animals were immersed in such a man-

ner that most of the anterior thorax remained above the water level. This was sufficient to abolish artefacts produced by the increased resistance to the inflow of air.

Temperatures were recorded with a thermocouple introduced to a depth of 7 to 9 cm. into the rectum, which had been cleaned by repeated enemas. The anus was closed around the couple. In 3 experiments, heart temperatures were also recorded by means of a thermocouple introduced through the external jugular vein into the right auricle. In some experiments only initial and final rectal and final heart temperatures were measured with a sensitive thermometer. In a considerable number of animals blood was withdrawn from the jugular vein both before and during exposure for the determination of the hematocrit and of hemoglobin and potassium content of red cells and plasma. In most instances, immersion was continued until death. In some experiments exposure was temporarily interrupted, and in a few cases, immersion was terminated at a time when the animal was still living.

In addition to these observations, 3 pigs were infused with an isotonic (1.12 per cent) solution of KCl. Frequent electrocardiograms (lead I or II) were taken. In one of these pigs, the arterial and right auricular pressure and respirations were also recorded. The latter ani-

mal received the solution in the subclavian vein, the other two in the jugular vein. Blood samples for the determination of potassium were taken from the carotid artery.

RESULTS OF EXPERIMENTS

In Table I are shown the results of 12 experiments in which pigs were exposed for varying periods of time at temperatures ranging between 44° and 73° C. Changes in rectal temperature, arterial pressure, and electrocardiogram are indicated.

In Table II are shown the results of 15 experiments in which pigs were exposed at temperatures ranging between 47° and 75° C. The changes that occurred in the potassium concentration of the plasma are indicated in relation to changes in rectal temperature, arterial pressure, and electrocardiogram.

In Table III are shown the results of 5 experiments in which dogs were exposed for varying periods of time at temperatures ranging between 55° and 75° C. The changes that occurred in the potassium concentration of the plasma are indicated in relation to changes in rectal temperature, arterial pressure, and electrocardiogram.

In Table IV are shown the results of 3 experiments in which pigs received intravenous infusions of isotonic potassium chloride. The changes in the potassium concentration of the plasma and the erythrocytes are indicated in relation to changes in hematocrit, arterial pressure, and electrocardiogram.

sometimes amounted to as much as 140 mm. Hg. This rise also occurred in curarized animals or when hot water was splashed on the skin. It was absent at immersion temperatures of 45° to 47° C.

At temperatures of 44° to 59° C. the blood pressure was maintained at or above pre-immersion level for 16 to 26 minutes. It began to fall at variable times during exposure and reached half of the original value in 17.5 to 41 minutes. The rectal temperature at this time had risen from 34.3° to 40.1° C. to 42° to 44° C. These animals

died after 25.5 to 50 minutes with rectal temperatures of 43.9° to 45.8° C., the heavier pigs surviving somewhat longer than the lighter ones. Heart temperatures were within a few tenths of a degree of these values (Figure 1).

In pigs exposed to water of 60° to 75° C., the arterial pressure was maintained for 1 to 6 minutes, and reached half of its original value in 5.5 to 11 minutes. The animals died after 8 to 15 minutes with rectal temperatures varying from 39.4° to 46.0° C. However, the discrepancy between heart and rectal temperature often was considerable (Figure 1).

The possible reversibility of the fall in arterial pressure was investigated. Immersion of a pig at 47° C. for 33 minutes produced a fall in blood pressure from 104 to 40 mm. Hg (Figure 2). Exposure to cool water brought the pressure back to its original level and lowered the rectal temperature from 43.3° to 42.0° C. Re-exposure to 47° C. again resulted in a fall in blood pressure, and death occurred at a rectal temperature of 44.5° C. In another instance exposure to water of 75° C. for 1 minute reduced the pressure from 140 to 20 mm. Hg in 5 minutes. During subsequent exposure to room air the pressure recovered, and reached 130 mm. Hg after 73 minutes. The animal was still alive after more than 2 hours. Exposure of one animal to water of 75° C. for 5 minutes resulted in a fall in blood pressure from 138 to 75 immediately after immersion. The pressure continued to fall, and the animal died after 18 minutes.

The arterial pressure in dogs behaved in a way comparable to that in pigs at the same temperature. Animals immersed at 60° to 75° C. survived for 13.5 to 25 minutes (Table III).

Right auricular pressure: Intra-auricular pressures of pigs before immersion varied from 32 to − 66 mm. H_2O (average − 23 mm. H_2O). In only 3 out of 15 animals was the pressure in the right auricle higher than atmospheric (+ 13, 20, and 32 mm. H_2O). In most instances, a slight rise occurred following immersion, the control level

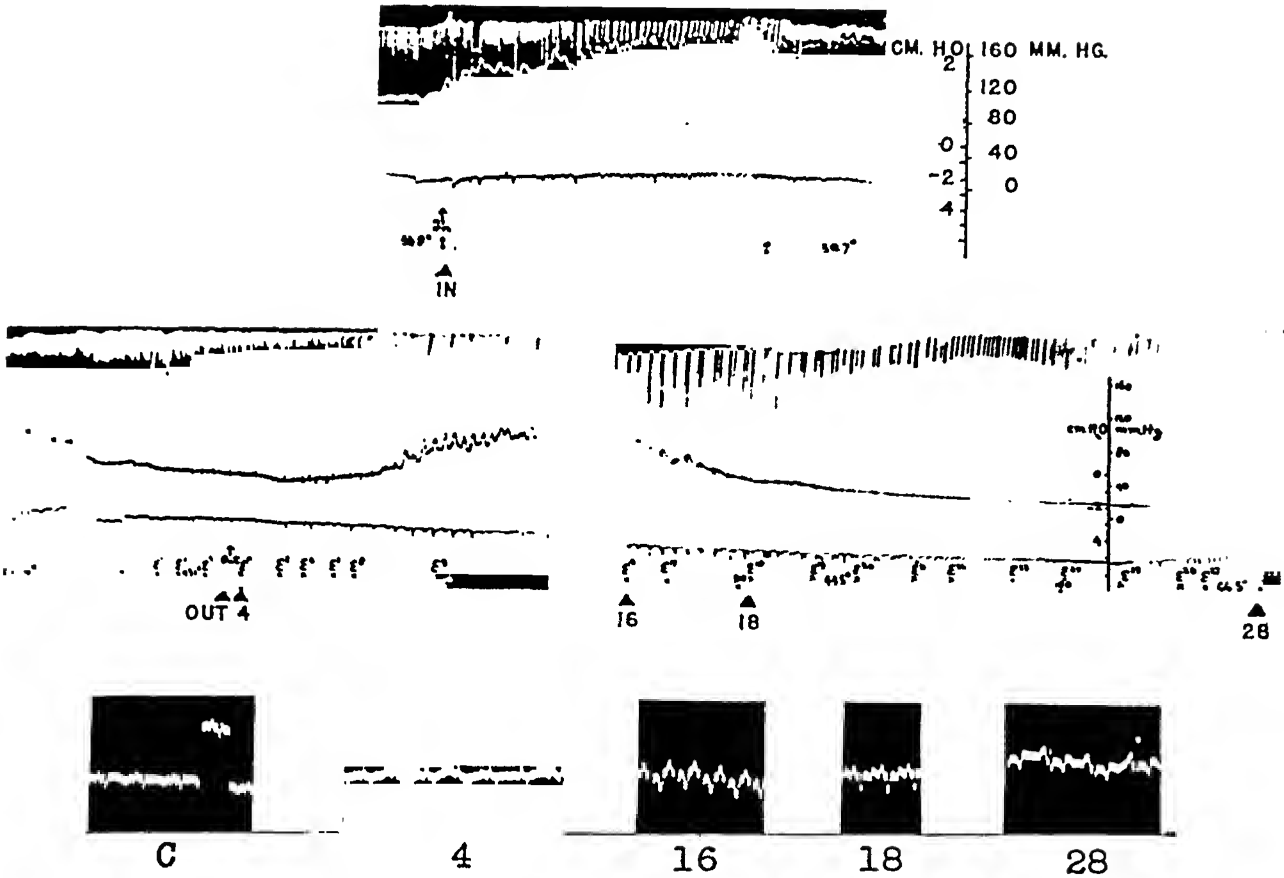

FIG. 2. EFFECT OF 2 EPISODES OF CUTANEOUS HYPERTHERMIA ON PIG NO. 879 (11.8 KGM.) CAUSED BY IMMERSION IN WATER AT 47° C.

The first period of immersion lasted for 33.5 minutes and is indicated by the words "in" and "out" on the first and second segments of the kymograph record. Fifteen minutes after the end of the first period of hot water immersion and between the second and third segments of the record the animal was immersed again at 47° C. and allowed to remain in the bath until dead (56.5 minutes). Between the 2 episodes of hot water immersion the skin temperature was lowered by exposure to cool water. Total duration of experiment was 105 minutes. The upper, middle and lower tracings on the kymograph record represent respectively the pneumogram, the carotid pressure, and the right auricular pressure. The times at which the electrocardiograms were taken are indicated in minutes.

being regained in 0.5 to 3 minutes. In 5 of the 6 animals immersed at 44° to 49° C., this was followed by a gradual drop of 4 to 20 mm. H_2O. There was no rise in venous pressure until 1 or 2 minutes before death. In the sixth pig, immersion did not influence the auricular pressure (Figure 2).

In 7 of the 9 pigs exposed to water of 60° to 75° C., a gradual rise of the right auricular pressure was observed, beginning in the middle of, or even early in exposure, and continuing until death. This rise amounted to 15 to 45 mm. H_2O and occurred at a time when both arterial pressure and respiration were still adequate (Figure 3). In some instances, it was preceded by a fall of 20 to 30 mm. H_2O which rapidly developed 1 to 3 minutes after the exposure had started. In 2 animals, this fall was the only change in auricular pressure that was observed until 1 minute before death when it rapidly rose.

One pig, exposed for only 1 minute to water of 75° C., showed an abrupt fall of 40 mm. H_2O. During the following 70 minutes the auricular pressure gradually returned to the pre-immersion level, coincidentally with recovery of the arterial pressure.

The auricular pressure of 4 dogs was lower than that of the pigs. It ranged from − 77 to − 108 mm. H_2O. Because of hydrostatic effects the auricular pressures before and during immersion could not be compared. However, neither in the 2 dogs exposed to 75° C. nor in those exposed to

55° and 60° C. was there observed any change in the recorded auricular pressure during the period of immersion.

Because of the possible contributions of the type or rate of breathing to the observed pressure changes, some experiments were performed on curarized pigs. Artificial respiration was supplied throughout the experiments. The course of the auricular pressure was found to be identical with that of the spontaneously breathing animals. At 47° to 49° C. a slow and moderate fall was observed; exposure at 75° C. resulted in a rise, beginning early during exposure.

Respiration: In agreement with earlier investigators, it was found that a rise in body temperature was associated with a pronounced increase in respiratory rate. In the pig, the immediate effect of immersion was usually a short period of very deep and fairly rapid respirations, followed by a variable episode of only moderately increased breathing (rate 20 to 40). In the animals exposed to the lower temperature range the onset of respiratory rates of 170 to 200 was often sudden, and occurred in the first 10 minutes of exposure, at rectal temperatures of 39° to 41° C. Deep gasps interrupted this shallow tachypnea. The arterial blood maintained its bright red color. The tachypnea gradually increased, and rates of 300 were not infrequently reached. When the rectal temperature had mounted to 43° to 44° C., breathing abruptly slowed to 10 to 40 per minute and became much deeper. Additional slowing usually continued until death. In the dog, immersion was immediately followed by a tachypnea of 100 to 150 per minute, which gradually increased. Rates over 200 were not encountered.

It is difficult to estimate whether the respiratory or the circulatory system failed first in these animals. If bradypnea is considered as the first manifestation of failing respiration it might be said that the cardiovascular system survived somewhat longer, as judged by the presence of an appreciable arterial blood pressure. However, at least in the beginning of bradypnea, the pulmonary ventilation certainly was as adequate as during the control period. If the onset of prolonged apnea is considered as the end point of adequate respiratory function, both systems failed simultaneously. In 3

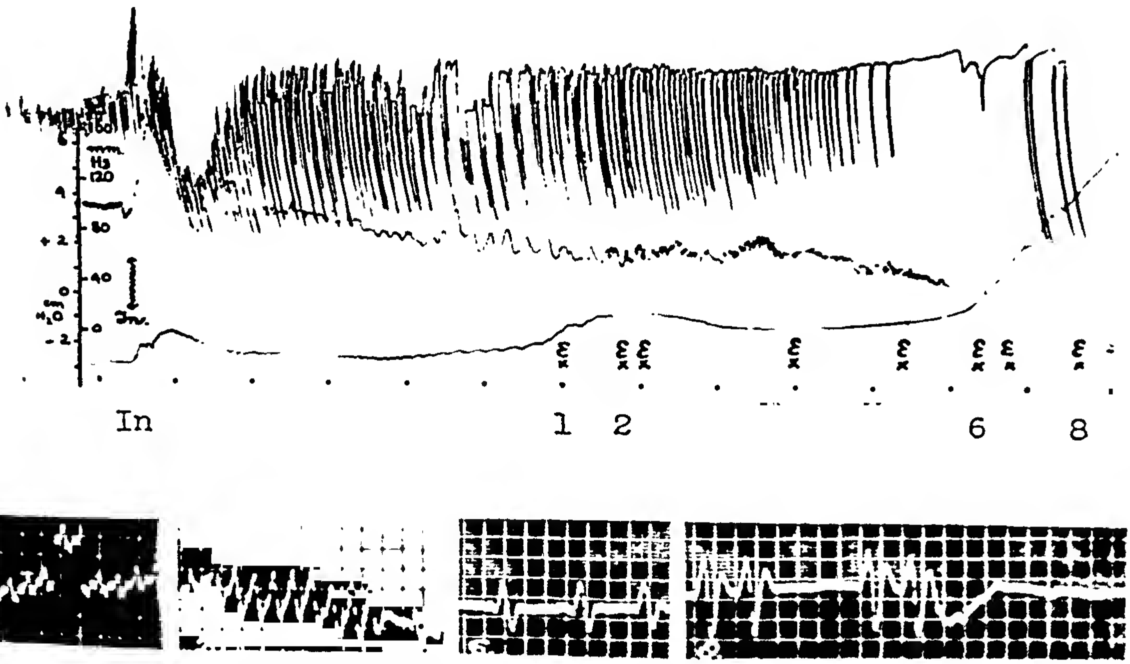

FIG. 3. EFFECT ON PIG NO. 871 (9 [illegible] KGM.) OF IMMERSION IN WATER BATH AT 70° TO 73° C. [illegible] 12 [illegible]

The upper, middle and lower tracings on the kymograph record represent respectively the [illegible] pressure and the right auricular pressure. The sequence in which the electrocardiograms were taken [illegible]

animals, artificial respiration was applied at a time when the arterial pressure was still appreciable (80–90 mm. Hg), without having the slightest effect upon its downward course. Moreover, the final rectal and heart temperatures of the curarized pigs fell well within the range of those of spontaneously breathing animals.

Exposure of pigs to 60° to 75° C. produced an increase in respiratory rate which did not exceed 80 to 90 per minute. The breathing remained deep until the terminal episode of bradypnea, ending in occasional deep gasps. In dogs the respiratory changes were essentially the same as those encountered at the lower temperatures.

Electrocardiographic changes: In both pigs and dogs, the first change, beginning immediately after immersion, consisted of a progressive increase in heart rate to levels of 300 to 350 per minute. Associated with this increase, changes occurred in the QRS complex, consisting of decrease in amplitude of the R wave and deepening of the S wave, or vice versa, with maintenance of the normal QRS interval and inversion of the T wave. The changes in the initial ventricular deflection might, in part at least, be due to variations in type of breathing with resulting changes in the position of the heart (Harris (15)). They occurred only to a minor degree in curarized animals.

In the pig, the abnormalities following this sinus tachycardia varied markedly with the temperature of exposure. Of all animals exposed to water at 44° to 50° C. (Tables I and II) only one showed appreciable widening of the QRS complex and loss of P wave. This occurred 1 minute before death. Another animal showed disappearance of the P waves. The changes in the remaining pigs were limited to sinus bradycardia and sinus arrhythmia that became most pronounced 2 or 3 minutes before death (Figure 2). Occasionally, auriculoventricular block of varying degree was seen during this period.

In contrast, 11 pigs continuously exposed to temperatures of 64° to 75° C. (Tables I and II) all showed the gradual development of exceedingly wide ventricular complexes with very large T waves, and the gradual disappearance of the P wave.[2] The general shape of these complexes resembled that of the original supraventricular ones. Their development was usually associated with definite slowing, although the heart rate remained regular. In some cases, the transitional phase consisted of salvos of fairly rapid and wide ventricular complexes, which interrupted a still-existent sinus bradycardia. In the terminal stage, the initial ventricular deflection could not be separated from the final one. The electrocardiogram consisted either of very slow, extremely wide ventricular waves, separated from each other by isoelectric intervals of 0.2 to 1.0 second, or of more rapid variations at 160 to 240 per minute, in which one wave merged with the next. The latter state might be called ventricular fibrillation (Figures 3 and 4).

In 9 of the 11 pigs, these changes made their first appearance early during immersion, at rectal temperatures of 37.0° to 41.6° C., and at a time when the arterial pressure and respiration were still adequate. In four of these, the blood pressure at the time of onset of the wide complexes was actually equal to, or higher than, that before immersion. In only 2 animals were the abnormalities first noticed when the pressure had fallen to low levels, and it is possible that they would have been demonstrated earlier if more electrocardiograms had been taken. Exposure for 6.5 and 5 minutes similarly resulted in marked widening of the QRS complex, whereas exposure for 3 and 1 minutes did not produce deviations other than those at lower temperatures.

In the dog, the electrocardiographic changes at high temperatures were in no way different from those encountered at 44° to 50° C. (Table III). They were limited to an increase in rate and to minor changes in the ventricular complex. No widening occurred and the auricular manifestations remained present until the end.

Chemical changes: A complete discussion of the effect of temperature on the potassium concentration of the plasma has been reported (2). The potassium concentration of the plasma of 15 pigs in which physiological studies were made is shown in Table II. The initial plasma levels ranged be-

[2] During tachycardia, actual observation of this disappearance was impossible because of overlapping of P and preceding T waves. In these instances, it was assumed that the same changes had taken place as in the instances where the P wave could be followed through a stage of decreasing amplitude to disappearance, as subsequent slowing of the beat similarly revealed the absence of auricular complexes.

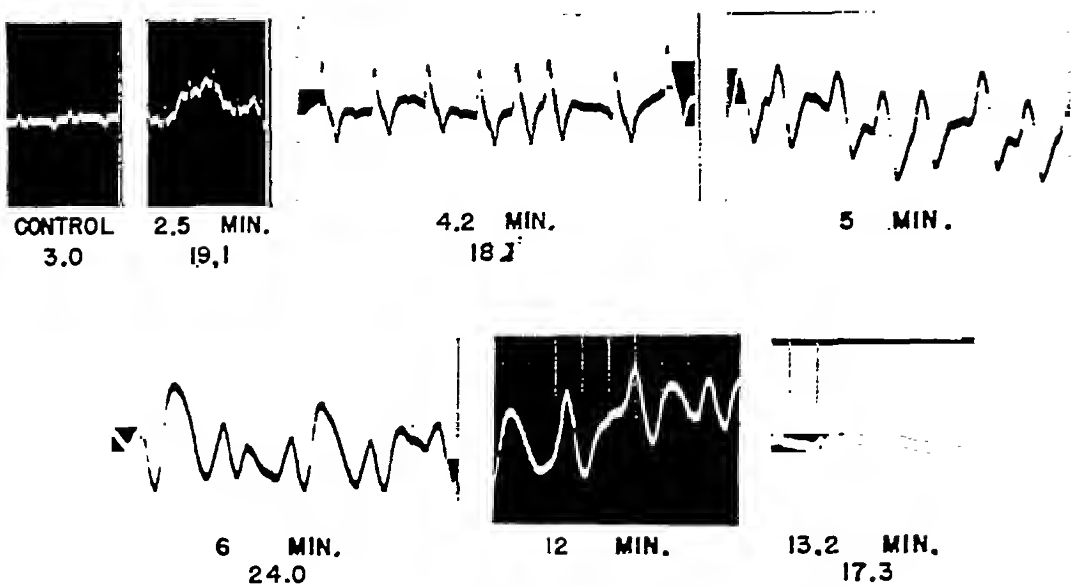

FIG. 4. RELATIONSHIP BETWEEN PLASMA POTASSIUM LEVEL AND CHANGES IN ELECTROCARDIOGRAM (LEAD 1) DURING IMMERSION OF PIG NO. 910 (9.5 KGM.) IN WATER BATH AT 72° TO 75° C.

The plasma potassium values are given in meq. per L. Death occurred 12.5 minutes after beginning of experiment.

tween 3.0 and 4.8 meq. per L. The potassium concentration of the red blood cells ranged from 113 to 145 meq. per L. The course of these concentrations during immersion varied markedly with the temperature.

Immersion of 4 pigs at 47° C. produced a gradual and sustained rise in plasma potassium. Ten minutes exposure resulted in levels of about 6.0 meq. per L. During the rest of the exposure, the level increased by an additional 1 to 4 meq. The highest level was 10.2 meq. per L. obtained 30 seconds before death.

On the other hand, continuous exposure at 70° to 75° C. characteristically resulted in an enormous rise in the plasma potassium level. This increase was found to take place with surprising rapidity. In 5 pigs, the plasma after 1 to 4 minutes of exposure, contained 14.2 to 25.5 meq. per L. of potassium. A sample drawn in this period from one curarized pig was still essentially normal and the peak observed in this animal was only 11.9 meq. Peaks from 16.7 to 25.5 meq. were observed in 6 pigs during exposure. Curare did not prevent rises in this range in 2 pigs; however, no early observations were made on these animals. In some instances, the potassium level fell towards the end. However, it remained markedly elevated.

In some experiments the exposure was terminated before the animal had expired. Immersion for 6.5 and 5 minutes similarly resulted in a tremendous rise of plasma potassium. At the time of death, the level was still very high. Immersion for 3 and 1 minutes produced a less pronounced increase; at the time of death, the level was only 2 to 2.5 times the normal one.

DISCUSSION

These observations show that the physiological disturbances leading to death in pigs exposed to water at 46° to 50° C. are of a different nature from those encountered in animals exposed to temperatures of 60° to 75° C.

In pigs immersed at the lower temperatures, the occurrence of a gradual fall in right auricular pressure followed by a fall in mean arterial pressure, indicates a progressive decrease in venous return to the heart. That this decrease, at least during a major part of the exposure, was due to an increase in capacity of the peripheral vascular bed, rather than to loss of intravascular fluid, is evident from the fact that the changes in circulatory dynamics were found to be reversible to a considerable degree. As the exposure continued the detrimental effects of the heated blood [illegible]

the heart muscle were added to the peripheral effects, and both factors undoubtedly contributed to the lethal ending. That relatively small increases in plasma potassium may predispose to vagal heart failure without causing the characteristic electrocardiographic disturbances of potassium poisoning is suggested by a recent report by Hoff, Humm, and Winkler (16).

It is difficult to say whether cardiovascular failure or respiratory insufficiency was the immediate cause of death. Profound arterial hypotension and pronounced bradypnea were usually encountered at the same time. It can be said, however, that the mean arterial pressure fell considerably before any impairment in respiratory function was evident. Artificial respiration applied at a time when the arterial pressure was still appreciable had no effect upon its downward course. Moreover, curarized pigs did not survive longer than spontaneously breathing animals; all but one animal died after 25 to 51 minutes of continuous immersion. The plasma potassium level increased by 66 to 250 per cent; the highest level found was 10.2 meq. per L. No profound changes in cardiac function, as judged by the electrocardiogram, occurred. As will be shown, plasma potassium levels up to 10 meq. per L. do not produce significant changes in intraventricular conduction.

At immersion temperatures of 60° to 75° C., the pigs survived for only 8 to 15 minutes. In the middle, or even earlier during exposure, at a time when the respiration was still adequate and the mean arterial pressure was still considerable, pronounced changes in cardiovascular function made their appearance. They consisted of a rise in right auricular pressure, and electrocardiographic changes in the form of disappearance of the P wave and progressive widening of the QRS complex, often terminating in ventricular fibrillation. At the same time, the potassium concentration of the plasma reached values of 16 to 19 meq. per L. This was associated with a striking destruction of red blood cells.

These observations strongly suggest that the hyperpotassemia was responsible for the disturbances in cardiac mechanism and for the subsequent myocardial failure, evidenced by the rise in auricular pressure. That the damaging effects of a rising plasma potassium level first of all manifest themselves in the heart is well known. In rabbits and dogs, the infusion of a solution of a potassium salt produces a sequence of electrocardiographic changes similar to those observed in pigs during exposure to high temperatures [Winkler, Hoff and Smith (17), and Nahum and Hoff (18)]. It was found that an identical sequence of changes takes place in infused pigs (Table IV). In 2 animals, infusion rates were maintained that were likely to produce death in approximately the same time as in the burned pigs. It is evident that potassium levels of less than 10 meq. per L. failed to produce either changes in the P wave or widening of the QRS complex, just as was the case in burned pigs. Higher levels resulted in a succession of changes which were similar in all respects to those observed at high temperatures (Table II). In the one animal (Figure 5) in which arterial and right auricular pressure and respirations were recorded, the auricular pressure began to rise 19 minutes (s) after the infusion had started. The potassium level was 12.7 meq. per L.; the P waves had begun to flatten 3 minutes before and had disappeared. Three minutes later widening of the QRS complex began. The arterial pressure and respiration remained normal for another 10 minutes.[3]

That the cardiac changes due to the potassium ion are reversible to a remarkable degree is clear from experiment 901 (Table IV). The usual succession of electrocardiographic changes was observed until, some seconds after a potassium level of 15.5 meq. per L. had been reached, the string shadow remained resting. The infusion was stopped. No electric or auscultatory evidence of cardiac activity could be demonstrated for the following 10 minutes, although the animal continued to breathe at a very slow rate. Then heart action returned and respiration became more rapid. The electrocardiogram had returned to normal. A plasma sample taken 5 minutes thereafter contained 8.7 meq. per L. of potassium. Infusion was started again, the well-known changes were again observed, and the pig died with a potassium level of 17.7 meq. per L.

The rapidity with which potassium is removed from the plasma makes it imperative that the re-

[3] The rate of infusion was slow enough so that the rise in venous pressure could not be ascribed to the administration of the isotonic salt solution *per se* [Altschule and Gilligan (19)].

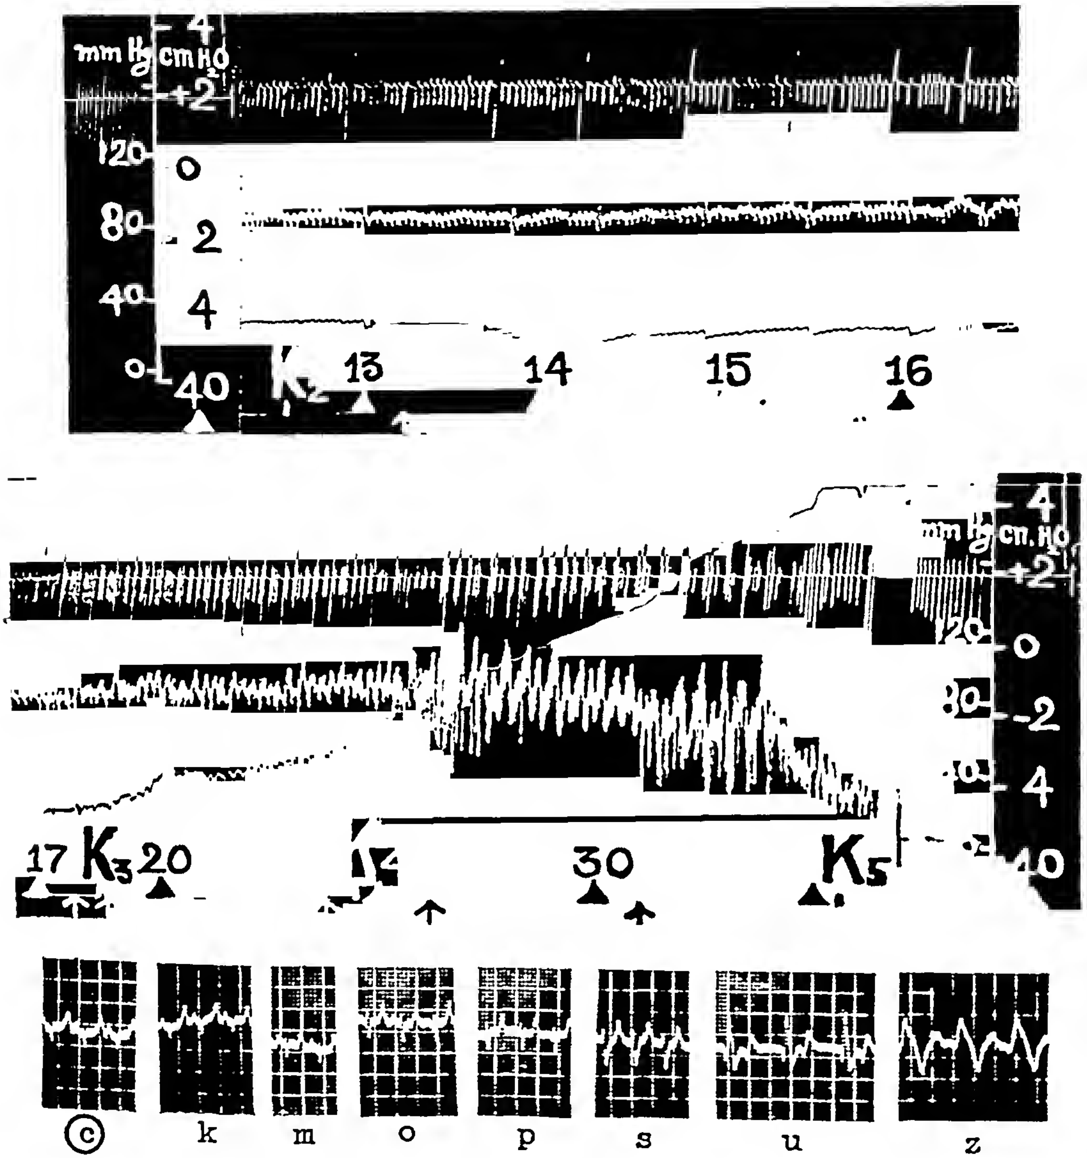

FIG. 5. EFFECT OF CONTINUOUS INTRAVENOUS INFUSION OF 1.12 PER CENT KCl AT THE RATE OF 0.6 ML. PER KGM. PER MIN.

The upper, middle, and lower tracings on the kymograph record represent respectively the pneumogram, the carotid pressure, and the right auricular pressure. The time in minutes is shown at the base of the record. The time at which blood samples were taken is indicated by the symbols K_2, K_3, K_4, and K_5. The times at which the depicted electrocardiograms were taken are indicated by letters from k to z.

lease of the ion into the circulation be intensive enough and be continued for a sufficiently long time to lead to death. This actually occurs in the burned pigs. The liberation of potassium often occurred at so rapid a rate that there was a lag between the rise in potassium and the electric changes. Thus, in pig 910, a level of 10.0 meq. per L. was reached in 2 minutes, whereas more than 4 minutes were required to produce the typical widening. Animals exposed to high temperatures for only 1 or 3 minutes did not release sufficient potassium to produce a characteristic effect on the heart; whereas exposure for 6.5 minutes was adequate in this respect. Exposure to 75° C. for 5 minutes resulted in a tremendous rise in potassium and in electrocardiographic changes, for

even here both manifestations diminished in intensity during the following 14 minutes.

Although it is clear that in pigs exposed to high (60° to 75° C.) temperatures the most striking physiological disturbances are those which result from the release of excessive amounts of potassium, continued exposure results in a progressive and generalized rise in body temperature which undoubtedly causes disturbances other than those due to hyperpotassemia. Thus, the peripheral and central factors that were the cause of death at lower temperatures also come into play at these high temperatures.

In order to evaluate the relative contributions of red blood cells and fixed body cells to the increase in plasma, potassium experiments were performed on dogs (Table III). Whereas the potassium concentration of their fixed cells is similar to that of the pig, their red cells contain only small amounts. Immersion at 75° C. resulted in an intense hemolysis, but the potassium level did not rise above that encountered in pigs at 47° C., and electrocardiographic changes characteristic of hyperpotassemia were not seen.

The distribution of the potassium in human blood is similar to that in pig's blood, the potassium concentration of the red cells being approximately 110 meq. per L., that of the plasma approximately 4 to 5 meq. per L. [Kramer (20), Scudder (21), and others]. High plasma potassium levels should therefore be expected in humans in whom a major part of the body surface has been exposed to high environmental temperatures. Several minutes of exposure would probably be required to result in the very high levels encountered in these experiments. It is also probable that, if the immediate effects of the exposure were survived, a markedly elevated plasma potassium, occurring immediately following the injury, would fall within the next hour. It should be remembered, of course, that a rise in plasma potassium is a normal postmortem phenomenon.

SUMMARY

There are 2 principal mechanisms by which exposure of the surface of the body to excessive heat may cause rapid circulatory failure and death.

In one, the systemic hyperthermia caused by conduction of heat to the interior of the body by way of the blood stream leads to a rapid and progressive decline in blood pressure and failure of circulation due principally to peripheral vascular collapse.

In the other, the circulatory failure is principally central and is due to the effect on the heart of an excessively high concentration of potassium in the plasma. Central circulatory failure is likely to occur when the overheating of the skin and subcutaneous tissue is so intense, prolonged, and generalized that potassium is released from the erythrocytes so rapidly and in such large amounts as to result in maintained plasma levels in excess of 11 meq. per L.

In the case of thermal exposures of low intensity, peripheral circulatory failure may occur without sufficient rise in tissue (and blood) temperature to cause a dangerous rise in plasma potassium. When a thermal exposure has been of sufficient severity to cause fatal hyperpotassemia, the central circulatory effects are likely to be complicated by peripheral vascular collapse.

It is essential to the development of hyperthermic potassium poisoning that the erythrocytes have a high original concentration of this element. Thus, fatal hyperpotassemia, due to hyperthermia, may occur in the pig but not in the dog. Since man and pig have similar potassium concentrations in their erythrocytes, it is inferred that they are probably similarly susceptible to the development of fatal hyperpotassemia following cutaneous exposures to excessive heat.

Although thermally induced disturbances of the respiratory centers may contribute to either type of hyperthermal circulatory failure, maintenance of pulmonary ventilation by artificial respiration does not prevent death or cause significant prolongation of the survival period.

STUDIES OF BREATHING, PULMONARY VENTILATION AND SUBJECTIVE AWARENESS OF SHORTNESS OF BREATH (DYSPNEA) IN NEUROCIRCULATORY ASTHENIA, EFFORT SYNDROME, ANXIETY NEUROSIS[1]

By MANDEL E. COHEN and PAUL D. WHITE

(From the Medical and Psychiatric Clinics and the Cardiac Research Laboratory of the Massachusetts General Hospital, Departments of Medicine and Diseases of the Nervous System, Harvard Medical School)

(Received for publication December 23, 1946)

Patients with neurocirculatory asthenia (N.C.A.), anxiety neurosis, or effort syndrome commonly complain of shortness of breath, inability to draw a satisfactory breath, and incapacity for work caused by breathlessness. Such symptoms have been noted in the classic works on this subject by DaCosta (1) and Sir Thomas Lewis (2) among others.

The present report deals with studies carried out to investigate in a quantitative way characteristics of breathing in N.C.A. These studies included investigations of (*1*) patients' symptoms as compared with those of control subjects; (*2*) study of characteristics of breathing at rest, including respiratory rate, minute respiratory volume, tidal air, oxygen consumption, incidence of sighs, variation in respiratory rate and in respiratory depth; (*3*) studies of breathing during exercise, of ventilation index, and of the relation of ventilation index to awareness of shortness of breath, *i.e.*, dyspnea; (*4*) studies of ventilation and ventilatory efficiency while walking and running on a treadmill. Details of technique will be described in each section.

In general, studies were done on 74 patients with chronic N.C.A. and on 27 patients with acute N.C.A. These two groups of patients were differentiated on grounds of history alone (3). Those who had a lifelong course and could never do hard work or athletics were designated as chronic N.C.A. Those who gave convincing evidence of good health, ability to do muscular work or athletics, and emotional stability previous to the development of illness were designated as acute N.C.A. In addition to studies related to breathing the patients were subjected to a wide variety of other tests which are reported elsewhere (3).

For control subjects we used 129 healthy subjects, of whom 117 were soldiers, and 25 soldiers who were convalescing from infected war wounds.

Incidence of symptoms

Method. A series of questions was administered to 74 patients with chronic N.C.A., 25 patients with acute N.C.A., 25 convalescent controls, and 55 healthy control subjects. The presence of the symptom was noted on a printed check list by plus, the absence by zero.

In addition, during the 20-inch step test (4, 5), patients and control subjects were asked to perform for 5 minutes at the pace of 30 trips per minute for a maximum of 5 minutes. The subjects were asked what stopped them when they did not go on for the full 5 minutes. The incidence of breathlessness among other symptoms was tabulated for control subjects and patients.

Results. The incidence in N.C.A. of symptoms involving breathing is presented in Table I, which shows that there is a high incidence of symptoms related to breathing in N.C.A. It is of further note that there is consistently, for each symptom, a higher incidence in the chronic N.C.A. group than in the acute; there is a slightly greater incidence of such symptoms as breathlessness and inability to get a satisfactory breath in convalescent subjects as compared to healthy controls.

The feeling of breathlessness may be present at any time in the patients. In addition, patients commonly have the feeling that they do not breathe in a satisfactory manner, that they do not get in enough air while breathing, or that their breathing does them no good.

Difficulties in breathing are quite marked when the patients attempt to wear a gas mask or while they are attempting to swim.

[1] This work was done under contract recommended by the Committee of Medical Research of the Office of Scientific Research and Development and the Massachusetts General Hospital.

With the technical assistance of Mary P. Lennon, Audrey Y. Dennison, and Jane R. Brown.

TABLE I

Incidence in neurocirculatory asthenia of symptoms involving breathing *

Group studied	Patients with N.C.A.		Controls	
	Chronic	Acute	Conv.	Healthy
Number of subjects	74	25	25	55
From present illness				
1. Breathlessness	99	79	24	13
2. Inability to get a satisfactory breath	74	41	16	2
3. Panting	62	52	4	5
4. Sighing	61	39	12	9
5. Gas mask trouble	55	17	12	15
6. Smothering	50	28	8	5
From past history				
7. Trouble breathing in water (while swimming)	75	22	12	10
8. Always short of breath	41	0	8	7
During hard work test				
9. Breathlessness severe enough to cause patients to stop	62		18	

* Significance of differences in incidence of symptoms: Chronic N.C.A. vs. healthy controls—all differences significant; chronic N.C.A. vs. acute N.C.A.—all differences significant except for 3, 4 and 6; chronic N.C.A. vs. convalescent controls—all differences significant; acute N.C.A. vs. convalescent control subjects—all differences significant except 2, 5, 6 and 7; acute N.C.A. vs. healthy control subjects—all differences significant except for 5 and 7; convalescent control subjects vs. healthy control subjects—only 2 show significant difference.

When patients and subjects were questioned as to what stopped them in the 20-inch step test, 60 per cent of the patients reported that they were winded or that their wind gave out, in contrast to 18 per cent of the healthy controls. This was true even though the healthy controls lasted much longer in the performance of the test.

Summary. N.C.A. patients have many complaints referable to breathing; symptoms are of higher incidence in chronic N.C.A. When questioned at the end of hard exercise, many N.C.A. patients state that shortness of breath causes them to stop before the test is finished.

Studies of characteristics of breathing at rest

Method. Respiratory measurements were made after 30 minutes rest, in a fasting condition and while breathing oxygen, in 50 men with N.C.A. and in 34 healthy men. The usual procedure for doing a basal metabolic rate test was employed (6) using a 12-minute record. The measurements were as follows: (*1*) Minute respiratory volume in liters of oxygen breathed per minute—this was obtained by measuring each inspirational length in a minute, multiplying the sum by the appropriate calibration factor. (*2*) Minute respiratory volume was adjusted for body surface by dividing by surface area obtained from height and weight tables (7). (*3*) Respiratory rate was counted in breaths per minute. (*4*) Tidal air was calculated for each minute by dividing ventilation per minute by respiratory rate per minute. The mean tidal air for the record was obtained from averaging the tidal air for each minute. (*5*) Tidal air was also adjusted for body surface by dividing the mean tidal air for each patient by his surface area. (*6*) A sigh was defined for purposes of this study as an inspiration which was at least 2½ times the depth of the previous inspiration if it was representative; if not, the first such breath in that minute was used as a basis of comparison. (*7*) Basal metabolic rate was calculated in the usual manner (6). (*8*) Coefficient of variation was calculated for rate in each patient by dividing the standard deviation of respiratory rate by the mean respiratory rate. Table II presents the mean of the coefficient of variation for respiratory rate. (*9*) Coefficient of variation for depth of inspiration was obtained by dividing standard deviation of the depths of inspiration for 6 minutes by the mean inspiratory depth (tidal air). The latter two measurements were made to discover whether the breathing of patients with N.C.A. was more irregular in rate and in inspiratory depth than was true of healthy control subjects.

Results. Table II shows that minute respiratory volume and oxygen consumption are the same for the two groups. However, respiratory rate is definitely more rapid in patients, and the breathing in patients is more shallow. This is true even after adjusting for differences in body size. Sighing is more frequent in patients than in control subjects, but not significantly so in this series.

Summary. N.C.A. patients resting, fasting, and breathing oxygen as compared with healthy control subjects show: (*1*) a higher respiratory rate, (*2*) shallow breathing, (*3*) a greater coefficient of variation in depth of inspiration.

TABLE II
Breathing measurements

	Units	Healthy controls	N.C.A. patients	Signif. ratio
Number of subjects		34	50

Mean of depth of respiration		20.25	25.12	1.71

the feeling of shortness of breath correlate with measurable changes in ventilation or vital capacity, the usual correlates of dyspnea (8, 9)? (*2*) Do patients with N.C.A. show differences in minute respiratory volume during and after comparable amounts of varying degrees of exercise as compared with healthy control subjects? (*3*) Is ventilation index, an objective measure proposed by Harrison and associates (10) as a quantitative objective correlate of dyspnea, abnormal in N.C.A.? (*4*) Do N.C.A. patients develop dyspnea at an abnormal level of ventilation index?

Method. Ventilation index studies described by Harrison and associates (10) were done in 58 patients with N.C.A. and in 55 healthy soldiers. Formula for ventilation index is:

$$\text{Ventilation index} = \frac{\text{ventilation}}{\text{vital capacity}} \times \frac{1 + \dfrac{\text{ideal weight}}{\text{actual weight}}}{2}.$$

All control subjects were healthy American soldiers. The N.C.A. patients consisted of 33 soldiers, 16 sailors, 2 marines, and 7 civilians. There were 41 cases of chronic N.C.A. and 17 of acute N.C.A.

The test was carried out by having the subject walk over a set of steps with measurements of ventilation before, during, and after the exercise. The steps used have been described by Harrison and have the following measurements: low step 17 cm., high step 32 cm., length of platform 64 cm.

The patient was given a demonstration of the 4 paces of the test. He practiced a few steps at each pace in order to familiarize himself with the steps. He then sat in an Adirondack reclining chair for 30 minutes. At the end of this period the patient was connected to the Tissot spirometer. The resting ventilation for 3 minutes was measured along with pulse rate and respiratory rate. The exercise then proceeded for 2 minutes and the patient then rested for a 5-minute recovery period, the ventilation being measured continuously during this 7-minute period (comprising 2 minutes exercise and 5 minutes recovery period). The pace of the step test was regulated by a metronome. The first exercise consisted of 6 trips, the second of 12 trips, the third of 16 trips, and the fourth of 24 trips in 2 minutes. One observer, using a stopwatch, counted off the pace for the patient, slowed him down or speeded him up if he lost the pace, held the tubing connecting him to the Tissot to avoid his being entangled in it, and for certainty checked the number of trips with a Veeder counter. Second observer read and recorded the Tissot units and also counted respiratory rate during the test.

Pulse recovery rate was determined also by the first observer. The pulse was counted after the patient sat down from 1 to 1½ minutes, 2 to 2½ minutes, and 4 to 4½ minutes. At the end of each 5-minute recovery period the patient was confronted with a printed card with the questions: Were you short of breath? Not at all? A little? Moderately? Severely? Were you very uncomfortable or did you feel distress? Yes or No. The patient was asked to point out the answer to each question which described best his subjective feelings during the test. In addition to this, one of the observers tried to estimate whether the patient seemed to be in respiratory distress—slightly, moderately, severely, or not at all. During the 1 minute between tests when the patient reported his subjective feelings by pointing to the question card, the Tissot level was readjusted, if necessary; the metronome was set to the next speed; and the patient was asked to stand about 15 seconds before the beginning of the next test. Then the next exercise began.

Vital capacity was determined on the patient in a sitting position. This was carried out by the method previously described (11), the highest of 3 determinations checking within 50 ml. being accepted. Age, height, and weight of the patient were determined and surface area was taken from standard Benedict-Roth tables (7). Room temperature, Tissot temperature, and barometric pressure were recorded.

Results. *Ventilation index:* Figure 1 shows that for each exercise the mean Ventilation Index is higher in the N.C.A. patients than it is in the healthy control subjects. The differences between

VENTILATION INDEX

	NORMAL 54	PATIENT 56
I SLOW	15.4	18.7
II MILD	18.3	23.2
III BRISK	20.7	26.2
IV FAST	28.6	36.9

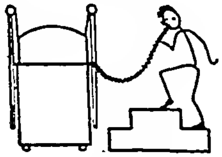

Fig. 1

The means of ventilation index for 56 N.C.A. patients as compared with 54 control subjects are compared above, for the 4 paces of exercise. The ventilation index is significantly higher in N.C.A. for each exercise. The differences were progressively greater as the speed of exercise increased. The figure illustrates schematically the patient during exercise breathing to the Tissot spirometer.

the controls and the patients are statistically significant (see Tables III and IV).

It is of further interest that patients with chronic N.C.A. show higher ventilation indices than do patients with acute N.C.A., this difference being consistent for all 4 exercises.

TABLE III

Ventilation index—means and statistics in neurocirculatory asthenia and healthy controls

Exercise	No	Controls V.I.	Controls 6	S.E.	No.	N.C.A. V.I.	N.C.A. 6	S.E.	S.E.diff.	Signif. ratio	Odds
I	53	15.4	2.39	.328	56	18.7	6.67	.892	.950	3.53	2,200–1
II	54	18.3	2.39	.325	56	23.2	9.09	1.216	1.257	3.86	8,000–1
III	54	20.7	2.81	.353	56	26.2	10.35	1.383	1.435	3.85	8,000–1
IV	54	28.6	4.11	.559	56	36.9	13.15	1.758	1.849	4.50	20,000–1

No. = number of subjects exercised; V.I. = Ventilation Index; 6 = Standard deviation of the observations in the sample; S.E. = the standard error of the mean; $S.E._{diff.}$ = standard error of the difference between the two means; Significance ratio = $S.E._{diff.}$ ÷ difference between means; Odds = the probability of the difference arising once in this number of times by chance.

TABLE IV

Ventilation index

Acute N.C.A. (17 cases) compared with chronic N.C.A. (39 cases)

	Acute N.C.A.	Chronic N.C.A.
Exercise I	16.9	19.6
Exercise II	21.4	24.0
Exercise III	23.9	27.3
Exercise IV	34.7	37.9

Vital capacity: The high ventilation index in N.C.A. is not due to abnormal vital capacity, as vital capacity in N.C.A. does not differ from vital capacity of healthy control subjects of similar size; Table V shows that the vital capacity in ml. and per square meter of body surface is 2,419 for healthy control subjects, 2,426 for N.C.A. patients.

TABLE V

Vital capacity

(Neurocirculatory asthenia vs. healthy controls)

	Number	V.C.	V.C.
		ml.	*ml. M²*
Controls	54	4,443.3	2,419.4
N.C.A.	54	4,395.1	2,425.5

Vital Capacity—Standard Error of Difference between means = .92; significance ratio = .52. Vital Capacity per meter squared of body surface—Standard Error of Difference between means = 50.9; significance ratio = .12. Thus, neither the slight differences in vital capacity nor those in vital capacity per M² between N.C.A. and controls are statistically significant.

The slight differences in vital capacity between N.C.A. and healthy controls are obviously not significant. The significance ratio of the differences for vital capacity is .52, for vital capacity per square meter is .12.

Although vital capacities were the same in value in the two groups, it was of interest that more trials were required to obtain 3 checking values in N.C.A. A mean of 3.3 extra trials was required to check the controls, as against 5.44 extra trials for patients. This difference was significant, significance ratio being 2.36. Two controls and 12 patients never checked within 50 ml.; in those we used the highest value for calculation purposes.

Total ventilation during and after exercise: The total of ventilation (2 minutes during and 5 minutes of recovery after exercise) is shown in Table V to be higher for each exercise, in N.C.A. than in healthy control subjects. The mean ventilations in liters for 7 minutes are: *Exercise I*—Controls 72.3, N.C.A. 85.2; *Exercise II*—Controls 86.0, N.C.A. 105.8; *Exercise III*—Controls 97.2, N.C.A. 119.8; *Exercise IV*—Controls 13[illegible].2, N.C.A. 169.8. The differences between N.C.A. cases and controls become greater as the exercise pace increases.

The difference in ventilation index between N.C.A. and control subjects is thus due to the ventilation factor, not to the vital capacity factor.

Minute respiratory volume during and after exercise: Figure 2 shows that for each minute during and after exercise the mean minute respiratory volume is higher in N.C.A. than in healthy controls. The differences become greater as the pace of exercise becomes more rapid. Figures 2 and 3 further illustrate that the differences are more marked after exercise than during exercise. The percentage difference between the mean ventilation in N.C.A. and in healthy control subjects, using the mean ventilation of the healthy subjects for that minute as a baseline, reaches its peak during the second recovery minute, as shown in Figure 4.

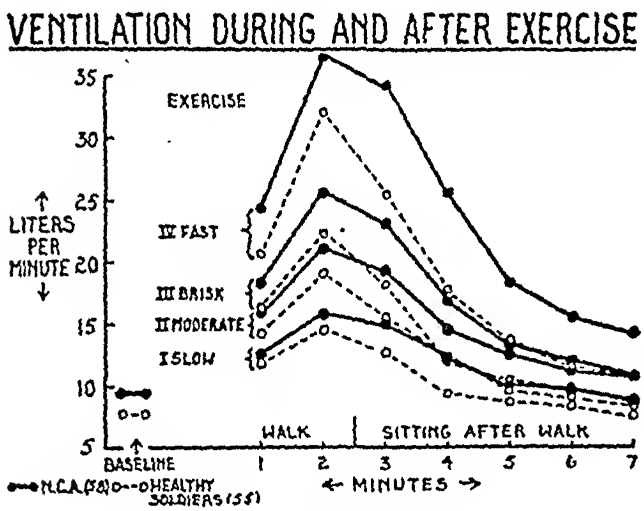

FIG. 2

The ordinate shows liters per minute of pulmonary ventilation; on the abscissa are marked off the time intervals during 2 minutes of exercise and 5 minutes of recovery. For all minutes and all exercises the patients show higher minute respiratory volume than do the controls.

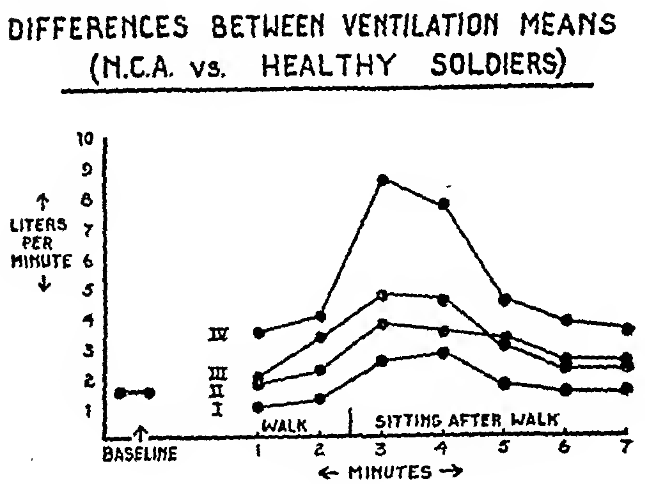

FIG. 3

The ordinate shows the excess between minute respiratory volume for each minute and each exercise in N.C.A. The abscissa marks off the difference at rest (baseline), and the time intervals during 2 minutes of exercise and 5 minutes of recovery. Roman numerals indicate progressively increasing speeds of exercise. The differences are more marked in the early recovery period.

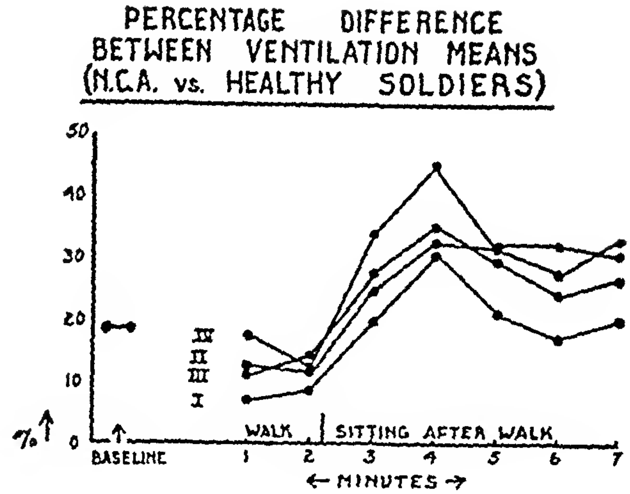

FIG. 4

The ordinate shows the percentage difference between ventilation means of N.C.A. and controls, using the controls as a basis of comparison, for each minute and each exercise. The abscissa marks off the time intervals, baseline indicating the initial resting value, and the time intervals during 2 minutes of exercise and 5 minutes of recovery. Roman numerals indicate progressively increasing speeds of exercise. The percentage differences are more marked in the early recovery period.

Respiratory rate and tidal air: The respiratory rate was greater in N.C.A. than in controls. Table VI shows that this is true during the preliminary baseline observations and for each exercise, the data for the fourth minute (*i.e.*, second recovery

TABLE VI

Respiratory rate and tidal air

Exercise II	31	91	3.9	14	61	5.2
Exercise III	46	92	3.8	14	67	6.0
Exercise IV	74	96	4.5	25	73	5.1

minute) being presented. Table VI also shows that the tidal air, adjusted for body size, is greater in N.C.A. during the recovery period after each exercise.

Calculation reveals that the maximum percentage rise in respiratory rate is 33 per cent in N.C.A. as compared with 15 per cent in controls; the maximum rise in tidal air is 100 per cent in N.C.A. as compared with 99 per cent in controls. This shows that the differences in minute respiratory volume between N.C.A. and controls are largely due to the disproportionate rise in respiratory rate in N.C.A. The maximum difference in tidal air during this time interval between N.C.A. and controls is 10 per cent, in respiratory rate 32 per cent.

Subjects' awareness of dyspnea and distress as related to level of ventilation index (see Table VII): Table VIII shows that for the same range

TABLE VIII

Percentage incidence of "dyspnea" and "distress" at ventilation indices 15 through 25

	Shortness of breath				Distress
	None	Slight	Moderate	Severe	
Controls	63	28	8	1	15
N.C.A.	13	49	32	68	51

of ventilation index a higher incidence of patients reports shortness of breath and distress or discomfort as compared with controls. Not only do more patients feel shortness of breath but they also report feeling a greater degree of shortness of breath. For example, at this level of ventilation index 68 per cent of N.C.A. patients felt severe shortness of breath in contrast to only 1 per cent of healthy controls.

This demonstrates that at the same level of ventilation index, the "objective correlate of dyspnea," more patients feel distress and shortness of breath, and to a greater degree, than do control subjects. This shows that the incidence and degree of dyspnea in N.C.A. is not only out of proportion to the amount of exercise, but also is out of proportion to the amount of ventilation and ventilation index.

Appearance of objective respiratory distress: Table IX shows that by our impressionistic method of estimating the presence and degree of objective respiratory distress N.C.A. patients showed a higher incidence of objective respiratory distress than controls for the same amount of exercise. At the same amount of ventilation index, the patients exhibited a higher incidence of appearance of objective respiratory distress with a greater degree of it.

TABLE IX

Appearance of respiratory objective distress in 54 N.C.A. patients and 54 healthy controls

Percentage incidence of appearance of objective distress during each exercise

Exercise	Controls	N.C.A.
I	11	58
II	33	91
III	50	96
IV	89	100

Percentage incidence of appearance of objective distress and its severity for ventilation indices 15 through 25

	Percentage incidence of appearance of objective respiratory distress			
	None	Slight	Moderate	Severe
Controls	60	29	11	0
N.C.A.	19	58	21	9

When we compared our estimates of the 3 degrees of severity of objective breathlessness with the 3 degrees of the patients' subjective reports, there was noted a tendency for the patients to report feeling more than we estimated, for the controls to report less. This comparison is obviously impressionistic, and this must be taken into consideration when evaluating this type of data.

SUMMARY. 1. Ventilation index is higher in patients for each exercise than in controls, the difference becoming greater as the rate and amount of exercise increase.

2. Vital capacity does not differ from that of controls.

3. Total pulmonary ventilation is higher, during and after exercise, the difference being greater as the rate and amount of exercise increase.

4. The high ventilation index in N.C.A. is due to the high ventilation, therefore, and not to the vital capacity factor.

5. The resting minute respiratory volume, with persons seated and breathing air, is slightly but significantly higher in patients.

6. Minute respiratory volume is higher in N.C.A. for each minute and for each exercise. The greatest minute respiratory volumes are noted at the beginning of the recovery periods, not during the exercise.

7. Both respiratory rate and tidal air are higher in N.C.A. than in controls, as judged from the second recovery minute.

8. The differences in minute respiratory volume between N.C.A. and controls are largely due to the disproportionate rise in respiratory rate in N.C.A.

9. For the same amount and rate of exercise patients complain in higher incidence and of a greater degree of shortness of breath than do controls.

10. For the same amount and rate of exercise patients complain in higher incidence of distress and discomfort.

11. For the same amount and rate of exercise more patients exhibited objective respiratory distress than did controls.

12. For the same level of ventilation index more patients exhibited objective respiratory distress than did controls.

13. In comparing our estimates of patients' objective respiratory distress with patients' subjective reports, there was noted a tendency for the patients to report more than we estimated, for the controls to report less.

14. Both the awareness of and outward appearance of shortness of breath are related in N.C.A. to some factor or factors other than amount of pulmonary ventilation.

Breathing while walking and running on a treadmill

METHOD. Ventilation and ventilatory efficiency were studied in N.C.A. patients while running at 7.0 miles per hour and while walking at 3.5 miles per hour on a treadmill, Grade 8.9 per cent [2] by methods described by Robinson (12). Other aspects of this study have been reported elsewhere (3, 13).

RESULTS. Table X shows that during running ventilation starts higher but ends lower; as the run progresses ventilatory efficiency is lower at all intervals of run for N.C.A. Data from a group of younger men (14) are included for comparison and the N.C.A. patients differ even more from them.

During the walk there is a higher pulmonary ventilation and a lower ventilatory efficiency in N.C.A.

SUMMARY. Ventilation is higher in N.C.A. for moderate work than in controls, is higher in N.C.A. as hard work begins but becomes lower as hard work progresses. Ventilatory efficiency is

[2] Referred to in previous Harvard Fatigue Laboratory publications as 8.6 per cent.

TABLE X

Pulmonary ventilation and ventilatory efficiency N.C.A. vs. controls

While running on a treadmill—7.0 miles per hour at 8.9 per cent grade, pulmonary ventilation in ml. per kilo and min.

	Age	No.	½–1 min.	1–2 min.	2–3 min.
Healthy men	20	46	730	1,027	1,231
Healthy men	29	20	645	977	1,216
N.C.A.	28	20	829	1,037	1,108

Ventilatory efficiency $\left(\frac{O_2 \text{ consumed}}{\text{Ventilation}}\right)$

	Age	No.	½–1 min.	1–2 min.	2–3 min.
Healthy men	20	46	5.34	4.90	4.23
Healthy men	29	20	5.29	4.59	3.92
N.C.A.	27	18	5.29	3.68	3.46

While walking on a treadmill, 3.5 miles per hour, 8.9 per cent grade

	No.	Ventilation	Ventilatory efficiency
		ml. per kilo and min.	
Healthy men	20	574	5.1
N.C.A.	20	657	4.5

lower in N.C.A. than in healthy controls for moderate and hard muscular work.

DISCUSSION AND SPECULATION

In neurocirculatory asthenia, anxiety neurosis, or effort syndrome many respiratory symptoms occur in high incidence. They constitute a characteristic and therefore diagnostic feature of the disorder; the absence of such symptoms makes the diagnosis of N.C.A. improbable. The complete mechanism of these symptoms is unknown. It is of interest that when respiration is investigated objective abnormalities are found, just as when other symptoms of N.C.A. are investigated with objective methods (3), which demonstrates that the abnormalities are not all in the subjective sphere.

The abnormalities at rest and breathing oxygen are few; while breathing air at rest M.R.V. was higher; during exercise the abnormalities become more pronounced, the deviations from the normal becoming greater as rate and amount of excercise increase. This is of interest particularly since the patients' disability involves especially hard work.

Ventilation index was higher in N.C.A. than in controls. This was true, but to a lesser degree, in cases of "cardiac neurosis" described by Harrison (15) who felt that the differences were not noteworthy. The differences between N.C.A. and controls are more marked in this study, probably due to the fact, as suggested to us by Harrison (16), that his healthy controls were less fit than ours and our N.C.A. patients were sicker clinically than those he studied. In fact, this corresponds with a general scheme in which the most fit and youngest subjects show lowest values, the healthy men in the late twenties are next, N.C.A. higher, the most severe being highest (Table XI).[10, 15, 17] Patients with heart disease, of course, are highest (10).

TABLE XI

Levels in ventilation index in various groups of healthy men and in N.C.A. patients

Subjects	No.	Exercise	
		II	IV
Athletes (Harrison, 17)	13	16.4	23.7
Medical students (Harrison, 17)	41	17.3	28.6
Healthy soldiers	54	18.4	29.0
Under 30 years of age (Harrison, 10)	10	20.8	34.8
Cardiac neurosis (Harrison, 15)	16	22.2	
Neurocirculatory asthenia	55	23.2	36.9

The ventilation factor accounts for the high ventilation index. The ventilation is highest after exercise, disproportionately so in N.C.A. as compared with controls. This may be related to other evidence of increased oxygen debt in N.C.A. and high blood lactate after exercise (3, 5, 13). It is possible that the higher blood lactate concentration during and after exercise in N.C.A. may participate as a stimulus to augmented ventilation. No crucial data are at hand that bear on these points. It is not known to what extent factors of physical training and patients' attitudes affect these results.

It is of further interest that the greater the stress or stimulus the greater and the more frequent the respiratory abnormality in N.C.A. This corresponds with patients' clinical history, with observations such as earlier ones made by one of us (White, 18) that running while wearing a gas mask was especially difficult and extremely abnormal in patients with effort syndrome and neurosis. The general rule that the greater the stimulus the more obvious the abnormality in N.C.A. is true of phenomena other than respiratory ones, for example, response to pain (3).

There has been a certain amount of discussion as to the proper definition of dyspnea. Means (19) defines it as a "symptom that arises whenever in carrying on the respiratory function difficulty is encountered." He points out that "when, however, the respiratory organs do meet with embarrassment in the performance of their task, then not only do their movements enter the field of consciousness, but they enter it unpleasantly and produce discomfort, that is to say dyspnea." Meakins (20) states "dyspnea is the consciousness of the necessity for increased respiratory effort." Harrison (10) regards dyspnea as a subjective phenomenon purely. Wright (21) states that "when the breathing enters consciousness unpleasantly and produces discomfort it is called dyspnoea." Christie (22) takes exception to this point of view, feeling that dyspnea should describe "difficult, painful, bad, or disordered breathing. The word can therefore be used objectively as well as subjectively and the more elastic definition of dyspnea as breathing associated with effort is fully justified." He points out that if one adopts too rigidly the definition of dyspnea as a subjective complaint "the absurdity is admitted that the hysterical patient who shows no evidence of increased ventilation or respiratory embarrassment but complains of inability to get enough air into the lungs is truly dyspneic; while the patient with pneumonia who, though distressed, refuses to admit a feeling of breathlessness is not dyspneic."

It is not clear to us what the proper usage of the word dyspnea should be. If the word is used at all, however, it should be used uniformly to mean the same thing by all observers. It is clear from this study that the subjective feeling of shortness of breath and distress is not based entirely on the amount of ventilation, since N.C.A. patients feel more shortness of breath and distress for the same amount of ventilation than do controls. This is true in addition to the fact that for the same amount of work N.C.A. shows higher ventilation and ventilation index.

It is important, therefore, that the subjective complaints of shortness of breath, distress, and discomfort be considered as not identical with the phenomenon of increased respiratory volume. There is, it might be added, no definite evidence as yet as to what area or areas of the brain are associated with the localization of the subjective feelings of dyspnea.

The tendency of N.C.A. patients to react more to uncomfortable stimuli is present in other spheres of discomfort, such as thermal pain and uncomfortable hand gripping (3, 5), and is also evidenced in other functions such as pulse rate (3). These facts do not explain the phenomenon but make it important to realize that it is not an isolated one, since N.C.A. patients react more than do controls to other types of stimulus and with other systems.

We were not able to confirm the finding of low vital capacity in effort syndrome patients in whom similar studies of respiration were made (23). These observers reported vital capacity mean of 2,840 ml. in patients and 4,172 ml. in controls. It is possible that difficulty in checking vital capacity results in N.C.A. may account for this difference. We found that patients and controls had identical vital capacity values as determined by our strict technique, but patients took more trials for a check. Whether this was due to poor motivation, poor voluntary control of respiratory movements, different type or stage of illness studied, or to other factors is unknown.

The evidence of poor ventilatory efficiency corresponds interestingly, although it may not explain, another symptom which patients have which is that they "can't get in enough air" or that "air doesn't seem to do as much good as it should."

CONCLUSIONS

1. In neurocirculatory asthenia, effort syndrome, or anxiety neurosis there are many symptoms referable to respiration.

2. At rest, while breathing oxygen, patients show rapid respiratory rate and abnormally shallow breathing.

3. While breathing air, minute respiratory volume is significantly higher in N.C.A. at rest and during moderate exercise than in controls, becoming lower as hard exercise progresses.

4. The greatest disproportion in pulmonary ventilation between patients and controls occurs in the early minutes of the recovery period after exercise, suggesting a relation to the high blood lactate and oxygen debt mechanism.

5. Vital capacity is normal in neurocirculatory asthenia.

6. Ventilation index, an objective correlate of dyspnea, is high in neurocirculatory asthenia.

7. The incidence and degree of dyspnea are out of proportion to the severity of exercise, the pulmonary ventilation, or the ventilation index in N.C.A.

8. Ventilatory efficiency is low in neurocirculatory asthenia both in moderate and in severe muscular exercise.

TRAUMATIC SHOCK. XIV. THE SUCCESSFUL TREATMENT OF HEMORRHAGIC SHOCK BY VIVI-PERFUSION OF THE LIVER IN DOGS IRREVERSIBLE TO TRANSFUSION [1]

By ARNOLD M. SELIGMAN, HOWARD A. FRANK AND JACOB FINE

(From the Surgical Research Department, Beth Israel Hospital, Boston, and the Department of Surgery, Harvard Medical School, Boston)

(Received for publication January 1, 1947)

The development of irreversibility to transfusion in the dog in hemorrhagic shock can be prevented by vivi-perfusion of the liver with arterial blood from a donor animal (1). The peculiar relationship of the liver to hemorrhagic shock is emphasized by the fact that vivi-perfusion via other channels does not prevent the development of irreversibility to transfusion. If the loss of integrity of the liver parenchyma is the key to the problem of peripheral circulatory collapse in shock, it becomes important to determine to what extent the damage to liver cells, if allowed to occur, may be corrected by restoring normal oxygen and volume flow requirements to the damaged liver cells. This problem was attacked by allowing the dog to develop irreversibility to transfusion and then perfusing the liver by cross-circulation with a donor dog. Repair of liver cell injury should then be reflected in a reversal of the rapidly progressive deterioration of the peripheral circulation characteristic of advanced shock. This communication will present data showing that hemorrhagic shock which has not responded to transfusion can be successfully treated by cross-circulation of the liver via the splenic vein with a healthy donor dog and that cross-circulation via a systemic vein is not effective.

METHOD

Hemorrhagic shock was induced in non-anesthetized dogs who had been given a single intramuscular injection of morphine (2 mgm. per kgm.). Incisions were made under local anesthesia. Those dogs which were to be perfused via the splenic vein were prepared 1 to 3 weeks in advance by splenectomy and subcutaneous implantation of a large splenic vein. In a few instances this vein was found to be occluded. Such dogs together with other normal dogs were used for perfusion via a systemic vein. Shock was induced by bleeding from a femoral artery attached to an elevated reservoir so that the blood pressure was maintained at 30 mm. Hg until "irreversibility" was considered to have developed in accordance with standards previously described (1). All shed blood was then rapidly infused via a femoral vein and the post-transfusion course was observed until it was clear that the animal had again relapsed into shock. At this time cross-circulation with a normal donor dog of about the same size was started (Figure 1). Blood from the donor dog's femoral artery, which was connected by means of clean (alkali-treated), but not sterile, rubber and glass tubing to the splenic or femoral vein of the dog in shock, was returned to the donor's femoral vein from the femoral artery of the dog in shock. Flowmeters were interposed in the delivery and return circuits. These were constructed as previously described (1) except that the dimensions of the return flowmeter were altered to accommodate the flow from the recipient at a higher pressure than obtained in the previous series (1). Continuing failure of the shocked dog's circulation was manifest by progressive decline in the recipient's blood pressure and evidence of exsanguination of the donor into the recipient. Both animals were maintained above shock levels of blood pressure by adding heparinized blood taken from other normal dogs. Cross-circulation was continued until the recipient dog was obviously terminal or had recovered sufficiently to maintain a normal blood pressure without added blood. Cross-circulation was then terminated. All vessels were ligated, sulfanilamide powder was placed in the wounds, and the incisions were closed.

Lactic acid, glucose, amino acid nitrogen, and non-protein nitrogen were measured in specimens of arterial blood by the methods previously used (1). Blood urea nitrogen was determined by the method of Karr (2).

RESULTS

Data on 9 liver-perfused and 9 control dogs are given in Tables I and II. No evidence of a toxic substance passing from the dog in irreversible shock to the donor was noted. Drops in donor blood pressure were considered as evidence of "taking-up" [2] by the recipient dog. When the vol-

---

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

[2] If the dog in hemorrhagic shock bleeds into an elevated reservoir, connected to a large artery, until the falling

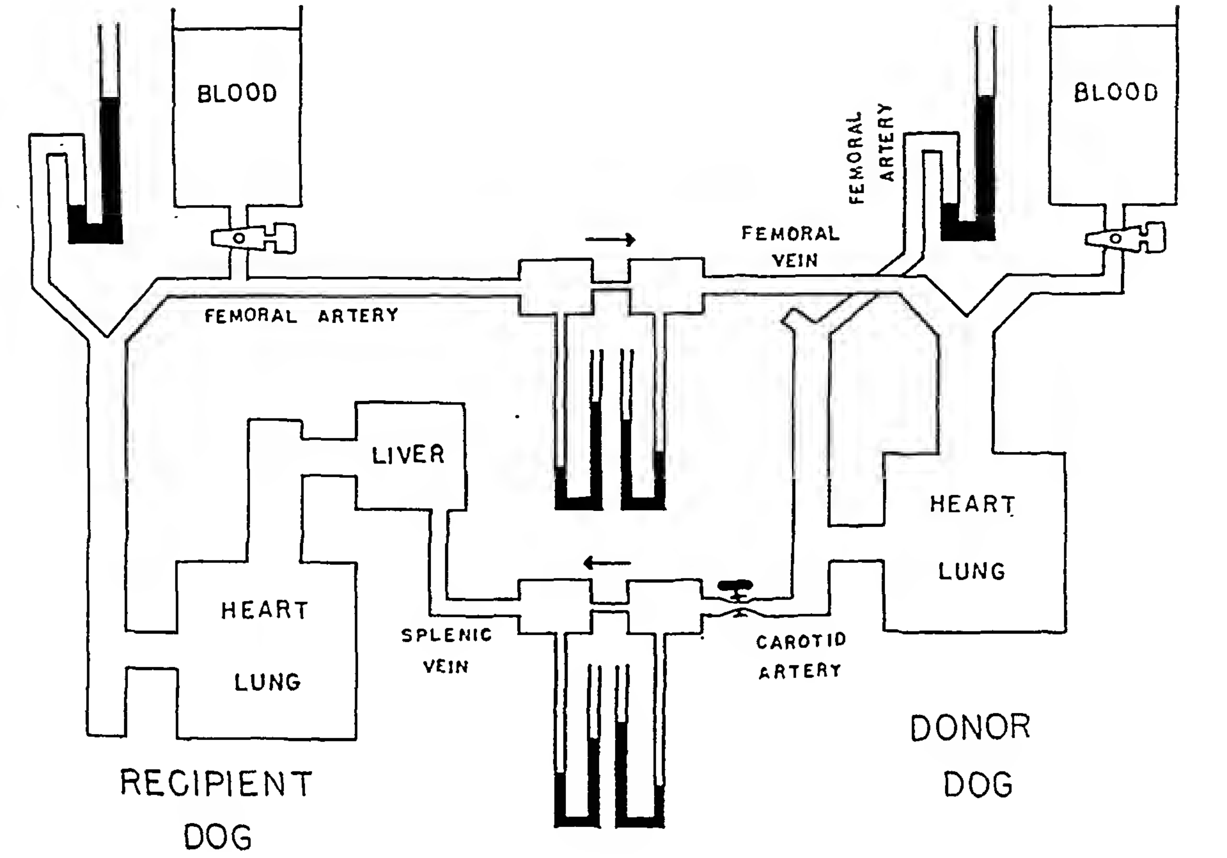

FIG. 1. DIAGRAMMATIC REPRESENTATION OF THE VASCULAR CIRCUIT IN LIVER PERFUSION

ume of blood lost to the recipient during the "taking-up" period was replaced and the donor's blood pressure returned to normal, the donor remained in good condition for the rest of the experiment. Several experiments in which technical accidents resulted in death of the donor dog were discarded.

blood pressure equals the hydrostatic pressure (30 mgm. Hg) in the reservoir, the dog remains stabilized at this pressure until after some time, varying from 1½ to 3 hours, when blood begins to return from the reservoir to the artery. The sustaining effect of this additional blood on the blood pressure is slight and short-lived and the "*taking-up*" of blood by the dog from the reservoir proceeds continuously or intermittently but with increasing speed until death. If one substitutes for the reservoir a donor dog in circuit with the dog in shock before the "taking-up" process begins or while it is in progress, the donor dog will serve as a reservoir and his blood pressure will fall as he exsanguinates himself into the recipient. The added blood pools in the recipient's peripheral vascular bed, which, having lost tone, dilates passively to receive the blood. This "taking-up" phenomenon, previously described in Paper XIII of the series (1), is an objective method of visualizing the progressive collapse of the peripheral circulation in the dog in shock.

The control dogs (Table I) showed little or no benefit from the cross-circulation. "Taking-up," which is an objective demonstration of paralysis of peripheral vascular tone and trapping of blood (3), not only continued after cross-circulation was started but often increased in the next hour or two so that it became difficult to sustain the blood pressure of the recipient (Table III). The blood pressure continued to fall in spite of the infusion of 1 to 2 or 3 times the estimated total blood volume in addition to the original transfusion. Cross-circulation was discontinued when the blood pressure declined to 30 mm. Hg and the dog was virtually in terminal shock. The period of cross-circulation was shorter in the control series than in the liver-perfused group because of the rapid decline and early death. Seven of the 9 dogs died within 12 hours after starting cross-circulation. Some of these dogs had severe bloody diarrhea. One dog died in 18 hours and one dog (LT 26) survived 1 day. The latter dog might have lived this long without cross-circulation, because the [illegible]

fusion period of decline in blood pressure to the level selected for beginning cross-circulation was exceptionally long (3¾ hours).

The liver-perfused dogs (Table II) exhibited several interesting phenomena. "Taking-up," which was as active as in the controls for the first hour or two of cross-circulation, gradually slowed up or disappeared (Table III), an index, we believe, of the recovery of tone in the peripheral vascular system. The blood pressure, which at first was difficult to maintain above 70 to 80 mm. Hg, climbed steadily and eventually stabilized at or above 100 mm. Hg. After some 5 hours of cross-circulation, marked clinical improvement was evident from the return of alertness, restlessness, quick response to environmental stimuli, and the excretion of urine. At this stage cross-circulation was discontinued. After the wounds were

repaired, the dogs were removed from the operation table, appeared strong, walked, and drank water.

Of 9 dogs, 8 survived 1 or more days, which is considered survival from the point of view of the shock state. Dog 7, which died 1 hour after beginning cross-circulation, showed such rapid and unabated "taking-up" as to indicate the onset of terminal shock before liver repair could be achieved. No precautions against infection were observed during the experiments and no after-care was provided for the surviving animals. Bloody diarrhea was observed in 3 dogs. The blood NPN level was normal several days after the experiment in the 2 dogs in which this determination was made. One dog, which died after 48 hours, showed bilateral pneumonia. Three were sacrificed after 7 days. Another, which developed a temporary severe hypotension when the splenic pedicle was tied upon discontinuing the perfusion, became decorticate and, though not in shock, died some 28 hours later. In unanesthetized dogs, gross evidence of brain damage does not appear during the interval of these experiments at blood pressure levels of 30 mm. Hg or higher. But even momentary drops below this pressure result in respiratory failure and signs of decortication. Such drops occasionally occurred in these experiments. Their immediate correction restored normal respiration, but if signs of decortication persisted, the survival period after recovery from shock did not last more than 1 to 2 days.

Data are given in Table IV showing the effects of cross-circulation on the blood concentration values of 4 metabolites. It will be observed that the blood lactic acid, which has already been reduced by the original transfusion (4), is still further reduced by cross-circulation. But since the magnitude of the reduction is equally great in both series, it may be concluded that the lactic acid level bears no relation to the outcome of the shock state. A similar conclusion was reached from other data (4). The fall in blood glucose that occurs after the original transfusion is not alleviated by cross-circulation. The sustained glucose level of the donor in the liver-perfused series indicates that the demand on the donor animal for glucose from the liver-perfused recipient is not so great as from the control recipient. The amino acid level in the liver-perfused series is somewhat reduced [illegible]

TABLE IV

Analyses of blood from the shocked dog before and during vivi-perfusion, in liver-perfused dogs and in controls

Each figure is an average of all experiments. The number of determinations represented in the average is given in the right upper corner of each box. The figure in parenthesis is the average value for the analyses of samples of the donors' blood, taken at the same time as the recipients'.

circulation, but is uninfluenced in the control series. Urea synthesis proceeds during the shock state and the donor is unable to reduce the blood-urea level. The shifts in the levels of these metabolites affect donor and recipient about equally, with the exception of glucose in the liver-perfused series. There is no evidence from these data that alterations in the blood levels of these metabolites bear any relation to survival or death of the dog in hemorrhagic shock.

DISCUSSION

These experiments demonstrate that vivi-perfusion of the liver for 5 to 9 hours with arterial blood from a donor animal is an effective therapeutic agent for the treatment of hemorrhagic shock which fails to respond to restoration of normal blood volume and to other agents (5). The contribution of the donor animal consists at least in furnishing a sufficient volume flow of arterial blood to the liver. Does the donor animal contribute something more, such as supplies of glucose and other metabolites, electrolytes, enzymes, and detoxifying or equilibrating processes not available to the dog in shock, *e.g.* renal function? Since such additional benefits are also available to the control dog, the specific and crucial service furnished by the donor must be related to what is supplied directly to the recipient's liver. It is the response of the recipient's liver to this service which results after several hours of cross-circulation in the slowing up and disappearance of the "taking-up" phenomenon and the concurrent recovery of peripheral vascular tone, which is evident from the progressive improvement in the hemodynamics and the disappearance of the shock state.

Our data in a previous publication do not contradict or support the inference that a toxic factor, such as the vaso-depressor material of Shorr *et al* (6), can be implicated as the chief factor in the collapse of the peripheral vascular mechanism. The data herewith presented likewise do not allow of such an inference. It should be added, however, that, if such an inference is not permissible, it is equally invalid on the same evidence to conclude that a protective factor, such as a normally secreted humoral product of hepatic origin, may be invoked to account for the stability or recovery of the peripheral circulation—else why should the donor with a healthy liver fail to support the failing circulation of the control animal?

Whether those functions provided by the donor, which are also available to the control recipient, are or are not indispensable accessories to those supplied by liver perfusion remains to be determined.

What is quite clear from the data at hand is that "irreversibility" in hemorrhagic shock under the experimental conditions described is a result of hepatic injury and that the solution of the problem must be directed toward prevention or correction of hepatic injury.[3]

"The interesting facts stand out that a trifling injury (to the liver) due to phosphorus or chloroform can

[3] The relationship between hepatic injury and shock was observed by Whipple and his coworkers (7) who wrote the following:

be tolerated by a dog with no clinical reaction. But if at this time . . . we perform a plasmapharesis of small volume which was previously tolerated by the same dog with little to no intoxication, we immediately precipitate severe or fatal shock. . . . The chloroform or phosphorus causes an injury to many liver cells and these cells are more susceptible to other injurious agents than are normal liver cells. A sudden change in the protein content of the blood which bathes these injured cells will react more unfavorably upon them than upon the healthy and more resistant normal liver cells. These damaged (phosphorus) and then shocked (plasmapharesis) liver cells form substances which are taken up by the blood and carried to all living cells of the body. If these poisonous substances are sufficient in amount, we observe the development of lethal shock. . . .

"We observe in other experiments that cell injury of other organs (kidney, pancreas, and intestine) does not modify the familiar reaction following a moderate exchange. The control and poisoning experiments give similar reactions. This indicates a peculiar relation of the liver cells to the shock reaction associated with plasma depletion."

SUMMARY AND CONCLUSIONS

Eight of the 9 dogs in hemorrhagic shock irreversible to transfusion recovered after perfusion of the liver by cross-circulation via the splenic vein with a healthy donor dog. Seven of 9 dogs similarly treated, except that the donor's blood entered the femoral instead of the splenic vein, did not survive.

These observations demonstrate (*1*) that liver damage is intimately related to the collapse of the peripheral vascular mechanism in advanced hemorrhagic shock, (*2*) that restoration of the integrity of the liver is necessary for recovery of function of the peripheral vascular system in advanced hemorrhagic shock, and (*3*) that restoration of this aspect of liver function can be accomplished by providing adequate blood flow from a donor dog to the liver, even after "irreversibility" to transfusion has been demonstrated.

TRAUMATIC SHOCK. XV. CARBOHYDRATE METABOLISM IN HEMORRHAGIC SHOCK IN THE DOG[1]

By ARNOLD M. SELIGMAN, HOWARD A. FRANK, BENJAMIN ALEXANDER AND JACOB FINE

(From the Surgical and Medical Research Departments, Beth Israel Hospital, Boston, and the Departments of Surgery and Medicine, Harvard Medical School, Boston)

(Received for publication January 1, 1947)

Traumatic shock may be regarded as a process of rapid biologic disintegration resulting from progressive tissue anoxia consequent to peripheral circulatory failure. This concept explains the recent growth of interest in the intermediary metabolic derangements in shock, which have been found to be severe, involving many enzyme systems concerned with protein and carbohydrate metabolism. Since the liver is a master organ in this respect, it deserves close scrutiny. That this organ should suffer at least as severely as any organ in shock is suggested by the sharp reduction in volume and velocity of flow through the portal system (1, 2) and by the observed reduction of liver excretory functions early in shock (3). Moreover, the recent demonstration that cross-circulation of the dog in hemorrhagic shock from a donor dog via the liver is capable of preventing the onset of irreversibility to transfusion (4) and of curing such irreversibility when established (5) indicates that liver damage plays a primary role in the shock phenomenon. It is, therefore, natural that a relationship should be sought between metabolic derangements in large part normally under liver control and the progressive deterioration characteristic of the late stages of the shock syndrome when therapy is no longer effective.

The metabolism of pyruvic and lactic acids and glucose shows abnormalities in shock (6, 7). In shock the rise in blood pyruvic acid and the simultaneous and usually disproportionately greater rise in lactic acid, producing an increase in the lactic to pyruvic acid ratio, are due to anoxia. Even though changes in blood concentration of these metabolites are not specific manifestations of traumatic shock, since they occur also in fever, following vigorous exercise, epinephrin injection, and in other conditions, a change in the L/P ratio is considered evidence of an abnormal carbohydrate metabolism as, for example, in thiamine deficiency (8). It was considered necessary to explore the possible relationship between spontaneous and induced shifts in the blood concentration of these substances and the progressive deterioration in hemorrhagic shock leading to the development of irreversibility to transfusion.

This communication reports the results obtained from a study of tolerance curves of glucose, lactic and pyruvic acids administered intravenously in various stages of hemorrhagic shock, both before and after transfusion.

METHOD

Irreversible hemorrhagic shock was produced in morphinized dogs by a technic described elsewhere (4). The injection of compounds was followed by arterial blood sampling every 15 minutes for 1 hour thereafter. Tolerance curves were obtained before hemorrhage, during hemorrhagic shock at a constant blood pressure of 30 mm. Hg, and after transfusion of all shed blood. Pyruvic acid[2] (Merck) was given as the sodium salt (neutralized to phenolphthalein) in doses of 0.5 to 1 gram for each tolerance test. Lactic acid (Merck, 85 per cent pure) was given as the sodium salt (neutralized to phenolphthalein) in 1-gram doses.

Blood pyruvic acid was determined by the method of Bueding and Wortis (9), blood lactic acid by the method of Barker and Summerson (10), total amino acid nitrogen by the colorimetric method of Frame, Russell, and Wilhelmi (11). Blood glucose was determined by the method of Folin (12).

RESULTS

1. *Blood levels of lactic, pyruvic, and total amino acids in hemorrhagic shock*

A. In 4 dogs (M–22, 23, 27, 28) there was a progressive rise in blood concentration of all 3 acids before therapeutic transfusion. The rise in lactic acid was steeper than that in pyruvic acid

[1] The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

[2] The pyruvic acid was distilled within 1 week prior to the time of injection.

with a resulting 2- to 4-fold elevation of the lactic/pyruvic acid ratio. Figures 1 and 2 give the data for dogs M–23 and M–27, which are typical.

B. In the same 4 dogs after therapeutic transfusion, which was ineffective for survival, the lactic acid level fell proportionately more than the pyruvic acid level, with a return of the L/P ratio to near normal. The amino acid level did not change. In dog M–27, observed for 5 hours after transfusion, a secondary rise in lactic and amino acid occurred after the blood pressure had again fallen below 60 mm. Hg.

2. *Lactic and pyruvic acid blood levels following epinephrin injection in normal dogs*

A continuous intravenous injection of epinephrin hydrochloride (3 mgm. per kgm. per min.) in a volume of 2 to 4 ml. of 0.85 per cent sodium chloride solution was performed in 3 normal dogs (M–15, 38, 39). The lactic and pyruvic acid levels rose promptly in all 3 dogs and the L/P ratio rose in 2 dogs. The lactic acid concentration leveled off after one hour in 2 dogs, but continued to rise in the third dog (M–38), which went into shock during the injection (2 hours) and died 15 minutes after discontinuance of the intravenous drip. In 2 of 3 dogs, elevation of the blood glucose level was followed by a fall to below the initial concentration during the second and third hours. The third dog (M–15) maintained an elevated blood glucose level throughout the experiment which lasted 3 hours. All dogs showed systolic blood pressure levels of about 200 mm. Hg during the epinephrin drip. Dog M–15 survived; dog M–39 (Figure 3), whose systolic blood pressure was 100 mm. Hg after discontinuance of the injection, died 12 hours later.

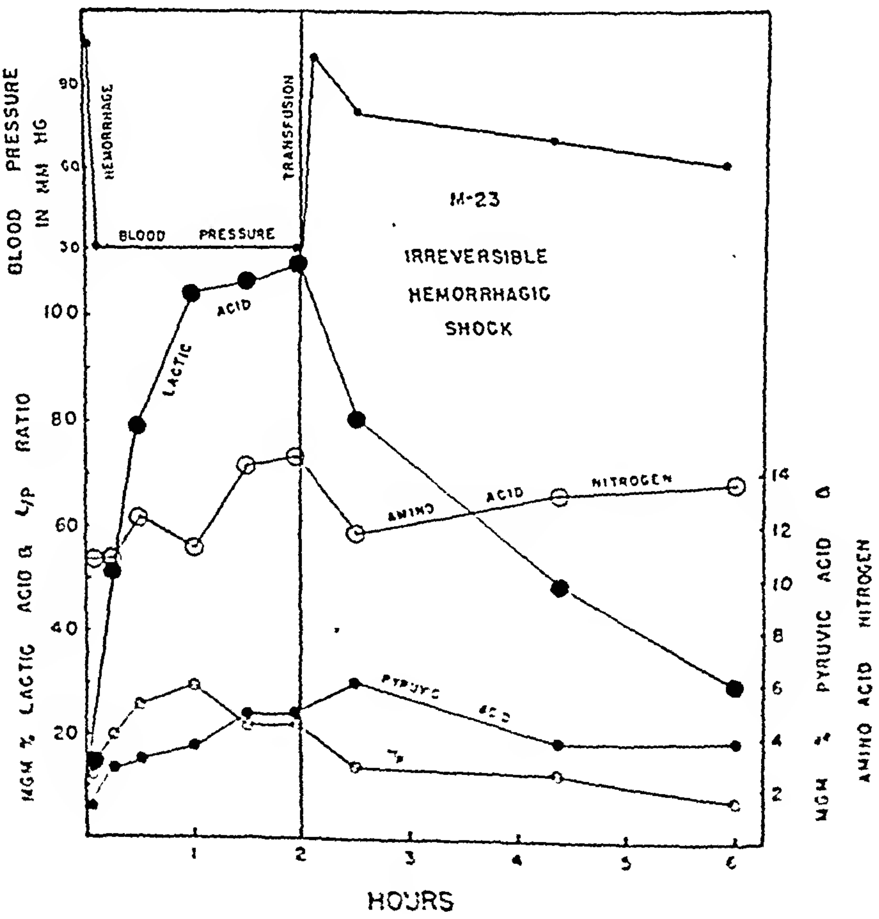

FIG. 1.

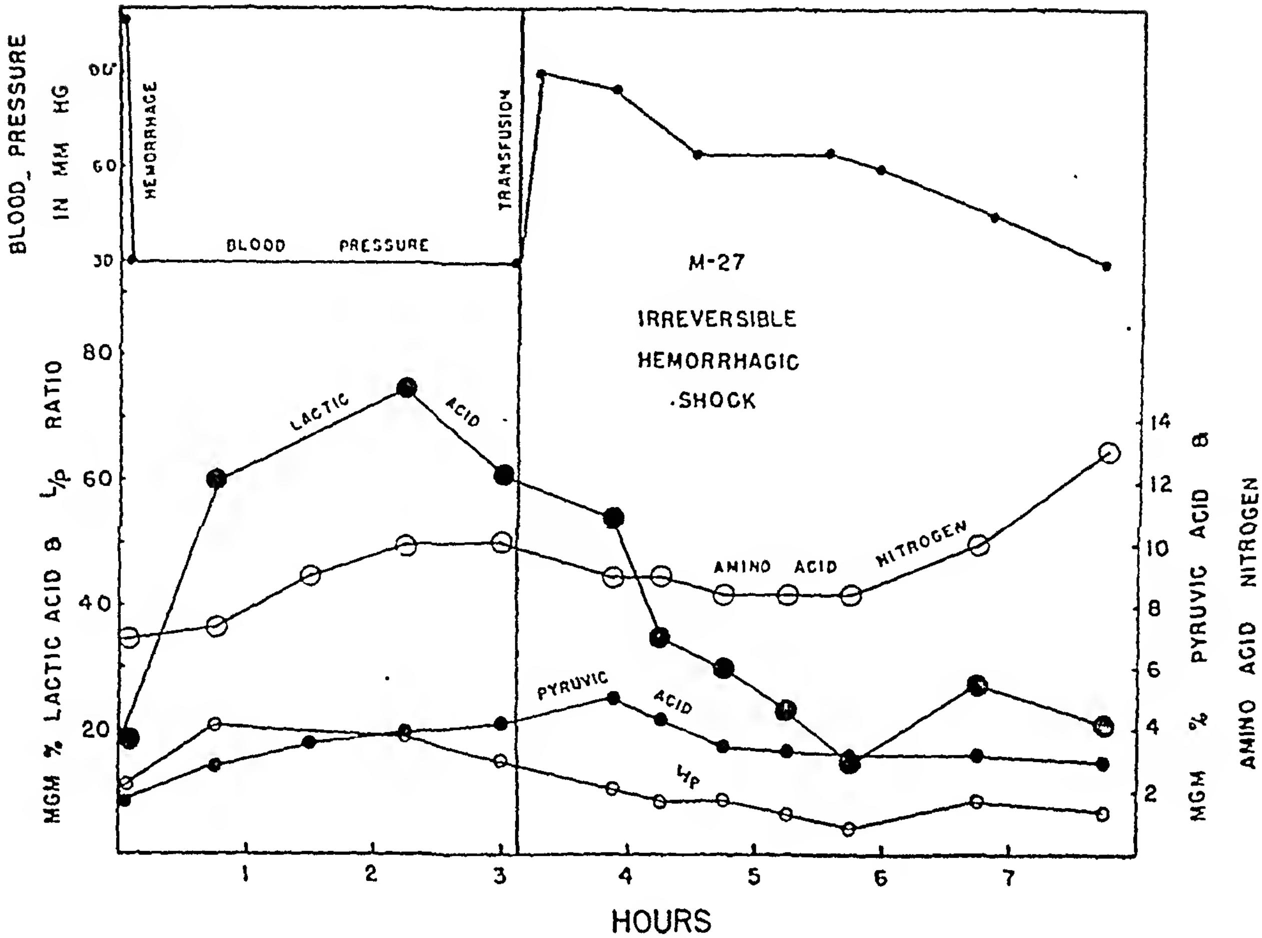

Fig. 2.

The changes in blood lactic and pyruvic acids in these experiments were not unlike those observed during vigorous exercise (8), but of a lower order of magnitude than was observed in hemorrhagic shock.

Comment: The changes in blood lactic and pyruvic acids in shock, therefore, are not referable entirely to epinephrin secretion or to the blood pressure level.

3. *Blood levels of lactic and pyruvic acids in hemorrhagic shock in adrenalectomized dogs*

To determine the relationship of the blood levels of these acids in shock to total adrenal secretion, unilateral adrenalectomy was followed in 2 weeks by removal (under local anesthesia) of the second adrenal. Immediately thereafter hemorrhagic shock was induced. Poor tolerance to hemorrhage and poor response to transfusion were observed. In 5 dogs (M–36, 37, 40, 41, 42) so studied (Figure 4, M–36) though the blood glucose fell, prompt rises in lactic and pyruvic acid and in the L/P ratio similar to those noted above (Section 1) were observed. The lactic and pyruvic acid levels remained elevated after transfusion.

Comment: These changes in shock, therefore, cannot be attributed to epinephrin or cortical hormone secretion. It also appears that they bear no relationship to the level of blood glucose.

4. In vitro *experiments*

To determine to what extent the observed shifts in lactic and pyruvic acids may reflect intravascular changes apart from those due to the activity of tissues other than blood, *in vitro* experiments were made as follows: 650 mgm. of glucose were added to 260 ml. of sterile arterial heparinized blood drawn under oil, with a resulting rise in glucose concentration from 70 mgm. per cent to 330 mgm. per cent. The blood was kept at 37.5° C. under oil for 2 hours and sampled at 20-minute intervals. It took on the color of venous blood during the period of observation. The glucose concentration remained unchanged but the L/P

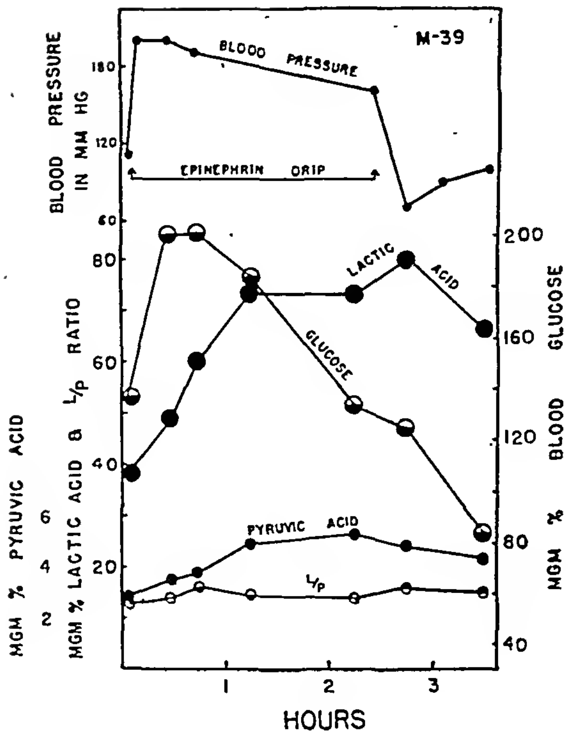

FIG. 3.

ratio rose slightly, though significantly, in 2 hours, in part at least because of a fall in the pyruvic acid, a phenomenon not observed in shock. The

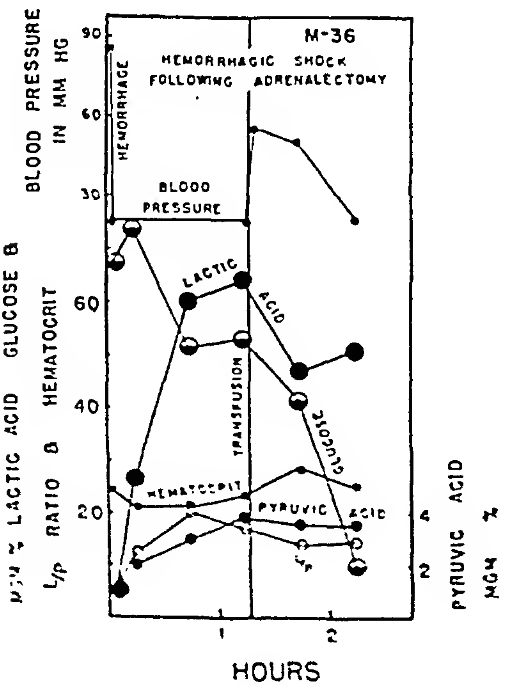

FIG. 4.

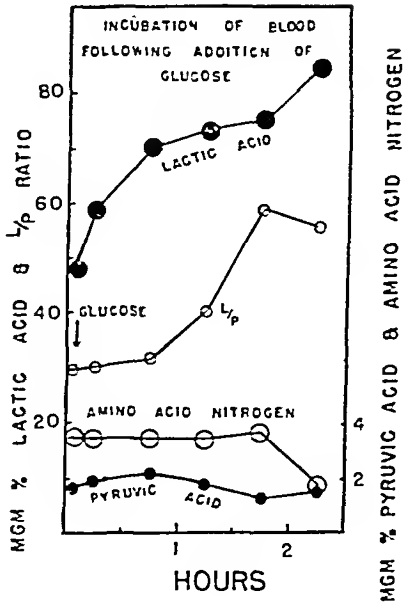

FIG. 5.

changes in lactic acid, pyruvic acid, and amino acid concentration are shown in Figure 5.

One hundred fifteen mgm. pyruvic acid neutralized with NaOH was added to 300 ml. arterial heparinized blood drawn under oil and kept at 37.5° C. The pyruvic acid concentration rose from 4.8 mgm. to 32 mgm. per cent immediately following the addition of pyruvic acid and dropped to 30 mgm. per cent in 1.5 hours. There was a concomitant rise in lactic acid, presumably derived

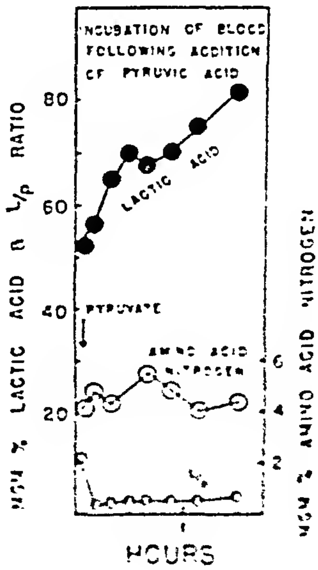

FIG. 6.

from the added pyruvate through the action of the red cells, Figure 6.

Comment: These observations indicate that a decline in blood oxygen content *per se* does not account for any substantial fraction of the rise in the blood lactic acid in shock.

5. *Glucose tolerance curves in hemorrhagic shock*

Seven dogs (M–16, 29, 30, 33, 34, 47, 48), in which irreversible hemorrhagic shock was produced, were given 1 gram per kgm. of glucose intravenously before hemorrhage, again during shock, and again following transfusion. Glucose, lactic and pyruvic acid levels in arterial blood were determined at 15-minute intervals after each injection.

The disappearance of injected glucose from the blood in 4 normal dogs required more than 1 hour. The disappearance rate during hemorrhagic shock was prolonged, but following transfusion it was near normal, whether the subsequent decline in blood pressure was precipitous or gradual.

Comment: The lactic and pyruvic acid levels characteristic of shock appeared not to be influenced by the injection of glucose (Figure 7).

6. *Lactic acid tolerance curves in hemorrhagic shock*

Sodium lactate, injected into normal dogs, increased the blood lactic acid concentration from 10 to 30 mgm. per cent at the peak of the rise. The lactate was usually, but not always, completely cleared. In one experiment the arterial blood pH was lowered from 7.4 to 7.2 (glass electrode). No significant alteration in blood pyruvic acid occurred.

Following the injection of lactate in hemorrhagic shock (Figure 8, M–19), the resulting superimposed rise in the blood lactic acid level was no greater than that following the injection of lactate in the normal dog. The shocked animal was able to clear the blood of injected lactate about as well as the normal dog.

Following transfusion, injected lactate was cleared from the blood at a normal or greater than

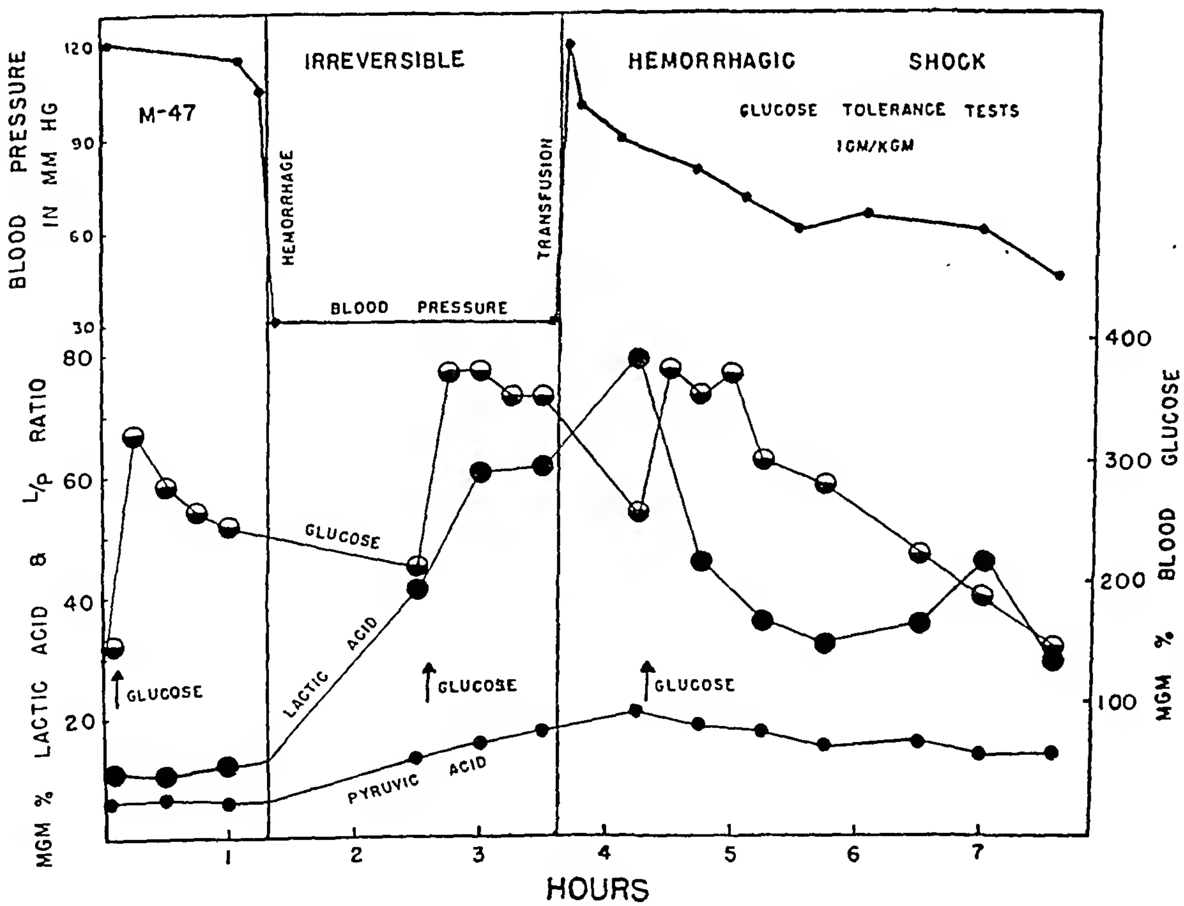

Fig. 7.

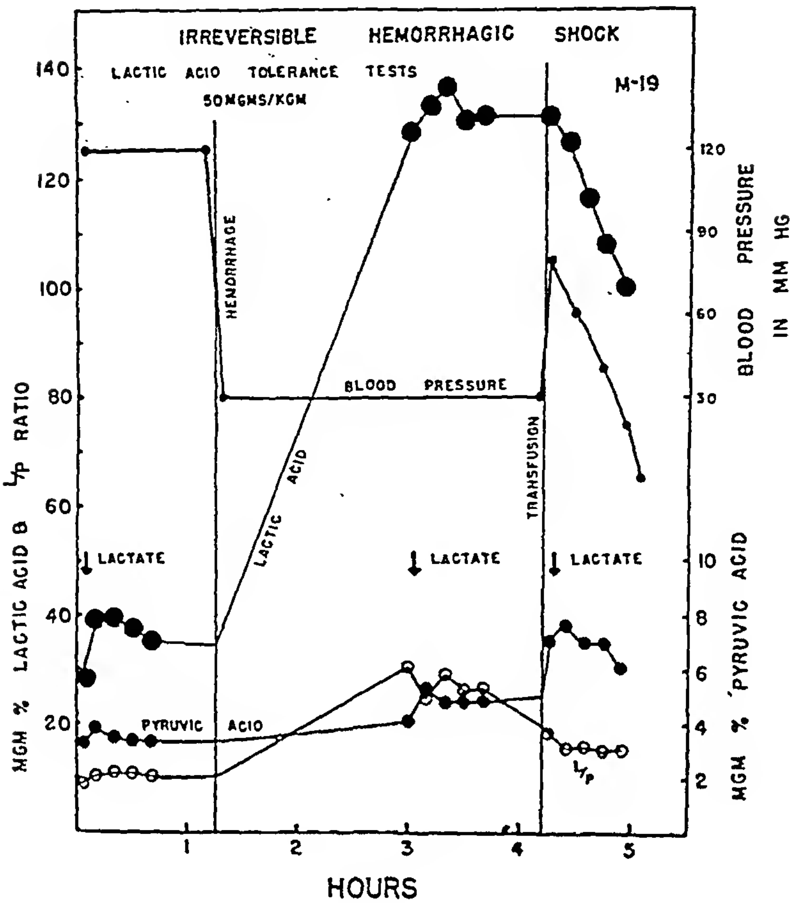

Fig. 8.

normal rate. In one experiment (Figure 8, M–19) the expected fall in blood lactic acid level was so rapid as to mask completely the increase due to injected lactate, even though a transfusion was ineffective and was followed by a rapid decline in blood pressure.

Comment: Since injected lactate is cleared from the blood in hemorrhagic shock at a normal rate even when the animal is dying after an ineffective transfusion, the deterioration of the organism in shock cannot be accounted for by the failure of enzyme systems to catabolize this carbohydrate intermediate. The foregoing data also suggest that an increase in the rate of lactic acid production is not the sole determinant of the level achieved. An alteration in the equilibrium between lactate and pyruvate or other carbohydrate intermediates may exist and be due in part to impairment of volume and velocity of blood flow rather than to damage to enzyme systems.

7. Lactic acid tolerance in acidosis

To learn whether the concentrations of lactic and pyruvic acids are determined by acidosis prevailing in shock, 1-gram doses of neutralized lactic acid were injected intravenously into normal dogs before and after the production of acidosis by intravenous hydrochloric acid. In one dog (M–53, Figure 9) the lactic acid tolerance curve following the injection of 1 gram of lactate was the same before and 10 minutes after the injection of 25 ml. of a 10 per cent solution of hydrochloric acid.

In another dog (M–52), 1 gram of lactate raised the arterial pH from 7.4 to 7.6. In the course of 30 minutes, 250 ml. of 0.1 N HCl were then injected. During the injection the blood pressure dropped to 70 mm. Hg, then to 30 mm. Hg and the arterial blood pH dropped to 7.2, but the blood lactic acid rose only 10 mgm. per cent. Death occurred a few minutes later. In this experiment

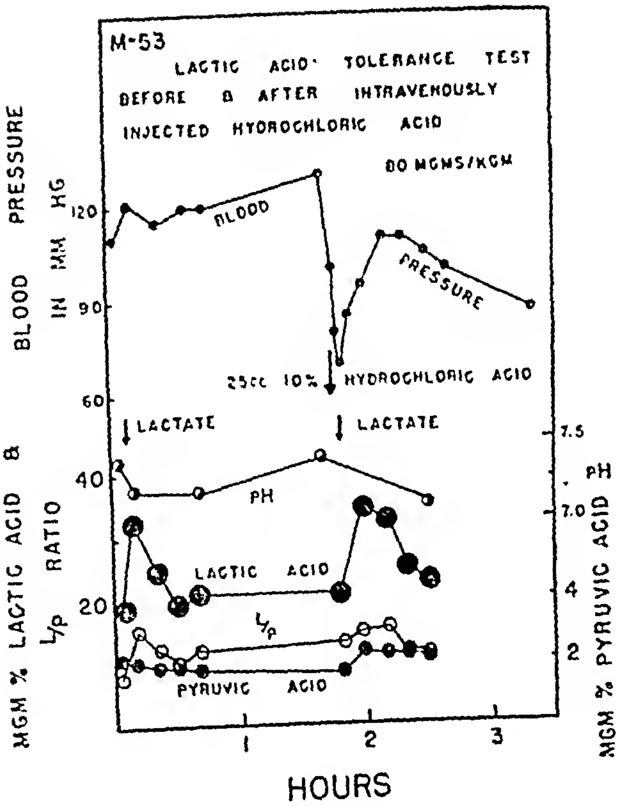

FIG. 9.

8. *Pyruvic acid tolerance in normal dogs*

Following the injection of pyruvic acid (0.05 to 0.1 gram per kgm. dog) neutralized to phenolphthalein, the return to the basal value occurred within 45 minutes in 13 of 17 normal dogs. The original level was not reached in this time in 4 dogs. The increase following the injection of pyruvate varied from 0 to 1.0 mgm. per cent. Concomitant lactic acid determinations showed very slight rises or no effect, but drops in lactic acid of 5 to 10 mgm. per cent below the starting level were noted in nearly each case at the end of 45 minutes (Figure 11). In 6 of 9 dogs the amino acid nitrogen was also depressed 2 or more mgm. per cent 45 minutes after the injection of pyruvic acid in 6 of 9 dogs.

9. *Pyruvic acid tolerance in hemorrhagic shock cured by transfusion*

In 4 of 7 dogs cured of hemorrhagic shock by transfusion, the pyruvic acid tolerance curves were the same before and after transfusion as in the nor-

acidosis more severe in degree than occurs in hemorrhagic shock did not produce so great an elevation of the blood lactic acid level as is found in shock.

In a third dog (M–51, Figure 10) repeated injections of 1 N hydrochloric acid caused a steady fall in the CO_2 combining power of the blood and in arterial blood pH. At the same time there was a steady rise in blood lactic acid, while pyruvic acid changed very little. Though the L/P ratio rose, it remained within normal limits. During this time the injection of 0.5 gram of lactate produced a normal tolerance curve (superimposed on the steadily rising blood lactic acid level) similar to that observed in hemorrhagic shock (Figure 8). The dog developed circulatory collapse and died when acidosis became severe.

Comment: It appears that the dog in acidosis metabolizes lactic acid as well as the normal or shocked animal. The rise in the blood levels of pyruvate and lactate (see Figures 9 and 10), following the production of a severe grade of acidosis, is not of the magnitude observed in hemorrhagic shock. The changes in these acids seen in hemorrhagic shock are not determined by the concurrent acidosis.

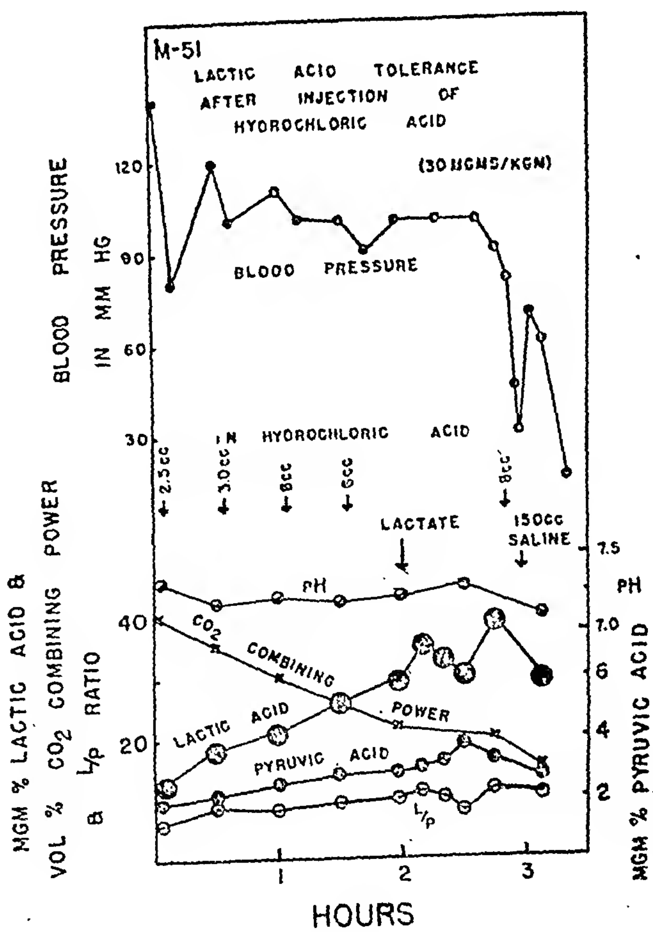

FIG. 10.

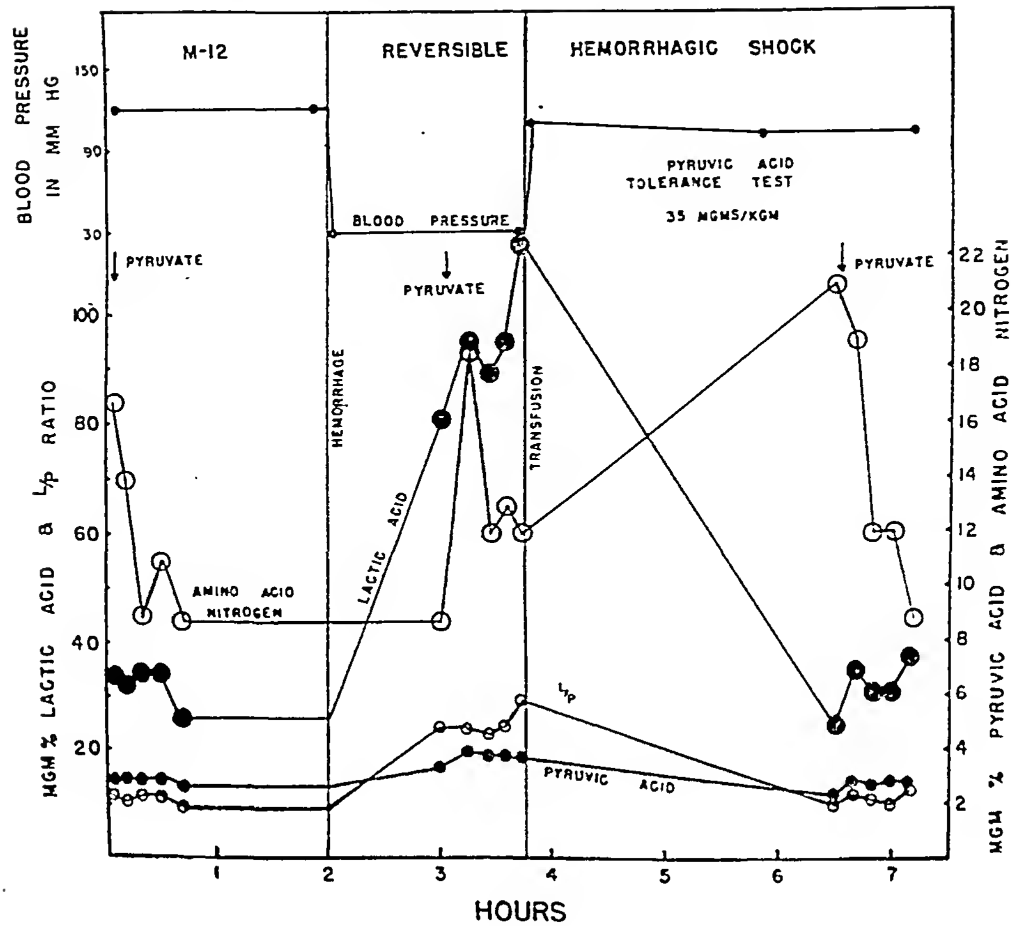

FIG. 11.

mal or preshock stage, although the preinjection levels of bloods pyruvate were higher during the shock state than before shock was instituted. In the remaining 3 dogs the last point of the tolerance curves during shock before and after transfusion were slightly higher than the preinjection level (Figure 11). The maximum rise in pyruvic acid during shock was in some instances slightly higher than in the normal. In some experiments evidence of lactic acid production from injected pyruvate during shock was suggested by the rapid rises in lactic acid levels immediately after the injection of pyruvate. Subsequent depressions in amino acid levels were observed. The usual rise in the L/P ratio during shock and its return toward normal following transfusion was in no way altered by pyruvate injections.

Comment: Elevation of the pyruvic acid level in shock is not due to inability of the organism to clear the blood of pyruvic acid. The significance of the drop in amino acid nitrogen following pyruvate injection will be discussed in a subsequent publication.

10. *Pyruvic acid tolerance in hemorrhagic shock not remediable by transfusion*

Similar results were obtained in 3 of 9 dogs in hemorrhagic shock which did not respond to transfusion (M–9, Figure 12). In 5 dogs, a somewhat poorer clearance occurred during shock than in the normal or in the post-transfusion stage. One dog (M–21) showed very poor clearance before and after transfusion as compared to the normal. Although this dog received twice the usual dose of pyruvate, 2 others which received the double dose showed only a slightly poorer clearance in the shock stage than in the normal. The injection of pyruvate in the n[illegible] [illegible] in some [illegible] One normal d[illegible]

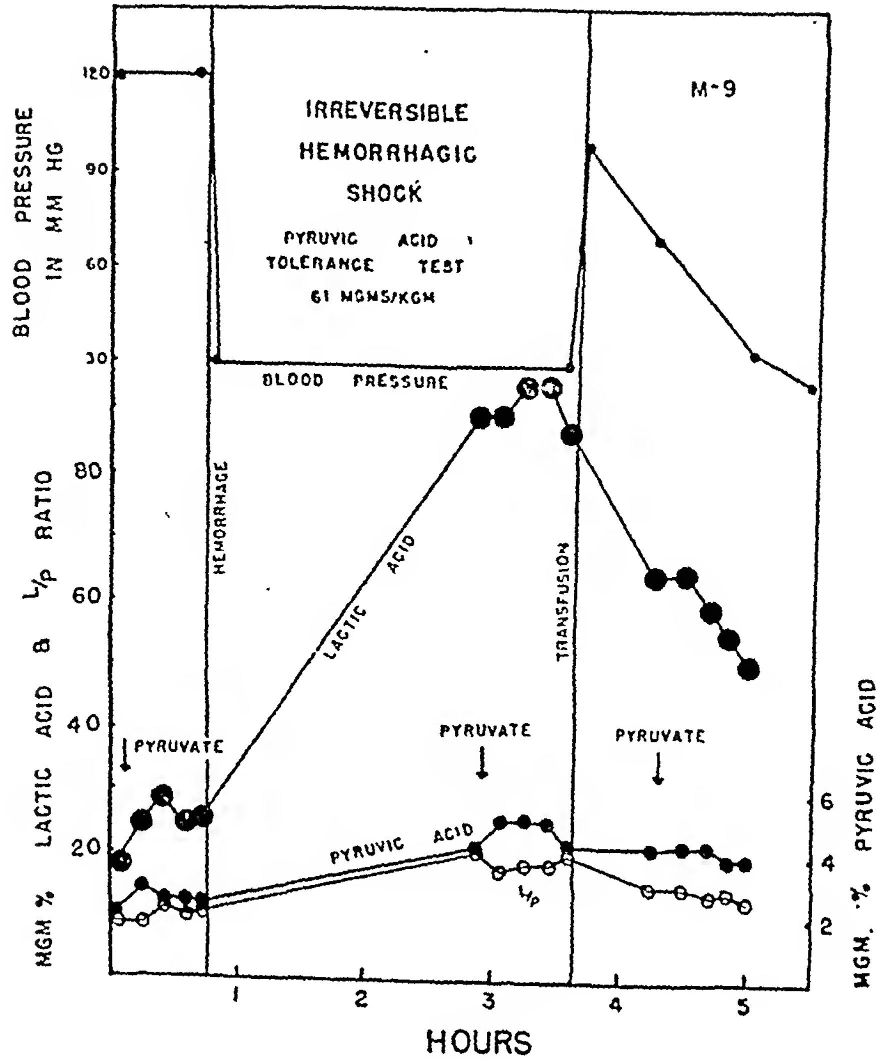

FIG. 12.

into shock for a considerable time following the injection of a double dose. Figure 12 shows that the rise of lactic acid during shock and the fall following transfusion are not altered by the injection of pyruvic acid. Depression of the amino acid level was noted among these dogs as well as in the previous group (*cf.* Figure 11 with Figures 1 and 2).

Comment: It is concluded that non-toxic doses of pyruvate are cleared by the dog in shock somewhat less well than in the normal before transfusion and about as well as normal after transfusion, whether reversible or irreversible to transfusion. These results suggest that the slightly decreased clearance in the pre-transfusion stages is due to decreased blood flow, particularly through the liver, rather than to any specific damage to the enzyme systems involved, for if damage to enzyme systems were responsible for defective clearance, one would not expect so prompt a recovery of clearance function following transfusion, and one would expect a disparity between the results in irreversible and reversible shock.

DISCUSSION

It has been demonstrated in traumatized rats (13) that the accumulation in the blood of lactic acid, inorganic phosphate, and phosphopyruvic acid occurs simultaneously with a progressive exhaustion of energy reservoirs in tissues (14), particularly in liver and brain. A correlation has been said to exist between survival and the magnitude of the original rise in the blood level of these intermediary metabolites as well as in the speed of their return to normal values (13). If the blood concentrations of these metabolites reflect the extent of the biochemical lesion in the tissues, a study of their behavior in response to therapeutic transfusion in hemorrhagic shock in dogs might provide a key to the nature of the irreversible lesion and at the same time demonstrate whether they are essential components of the lethal process or

merely concurrent phenomena of secondary importance.

Russell *et al* (7) concluded that since eviscerated (liverless) rats do not show elevations in the L/P ratio comparable to those in non-eviscerated rats or eviscerated shocked rats, peripheral anoxia rather than liver failure is largely responsible for the increase in the L/P ratio. Dogs in hemorrhagic shock show a progressive increase in lactate and a fall in glucose in the venous as compared to the arterial blood, suggesting an increased conversion of glucose to lactate caused by the anoxia of peripheral vascular failure (15). Our experiments are consistent with these conclusions. They indicate further that the actual level of blood lactate achieved is controlled by a factor other than the mere rate of production of lactic acid.

The rise in the L/P ratio in hemorrhagic shock results from the predominance of anaerobic over aerobic carbohydrate metabolism, especially in muscle (16), in the presence of peripheral circulatory failure. In this situation energy is derived largely from glycolysis, whose end product is lactic acid. This is much less efficient than aerobic oxidation since 8 to 14 times as much substrate is required to yield the same amount of energy (17).

In spite of the rise in lactic and pyruvic acids and the increase in the L/P ratio in shock, additional loads of these acids and of glucose are metabolized almost as well as in the normal state,[8] regardless of the severity of the shock state or the response to transfusion. The return of the L/P ratio to normal following transfusion indicates a return to aerobic metabolism of carbohydrate. Since this is the case whether or not the transfusion is therapeutically effective, it appears that even a temporary improvement of blood flow is capable of restoring the normal rate of carbohydrate breakdown but is not capable of restoring the integrity of the factor responsible for maintenance of normal function of the peripheral vascular system. It follows that the distortion in carbohydrate metabolism, as reflected by the blood changes studied, is probably not a primary factor in peripheral vascular failure. If it were otherwise, death from ordinarily fatal shock would not be prevented by liver perfusion, during which the distortion of carbohydrate metabolism is of the same kind and magnitude as is seen in shocked dogs not perfused or perfused via another route (4). To be sure, our blood analytical data may not disclose persisting metabolic abnormalities in certain vital tissues, whose function, therefore, continues to be adversely affected; for example, the brain stem may suffer from the decrease in oxygen supply (14) in spite of the apparently normal enzymatic behavior suggested by the blood findings. But there is no evidence to indicate that in the circumstances of our experiments any organ apart from the liver is of critical importance with respect to the collapse of the peripheral vascular system in shock, since such organs, including the brain, respond well to transfusion after exposure to a degree of hypotension and hypoxia which the liver cannot tolerate. Since the liver has been shown to be the critical organ with respect to the integrity of the peripheral vascular system in shock, the damage it suffers involves at least another category than that of carbohydrate oxidation.

[8] We do not assume that the disappearance of these metabolites from the blood in shock is necessarily achieved by the mechanism prevailing in the normal state.

SUMMARY

1. Morphinized dogs bled into shock showed rapid elevation of blood lactic acid, pyruvic acid, amino acid nitrogen, and the lactic/pyruvic acid ratio.

2. A rapid return toward normal of blood lactic and pyruvic acids and the lactic/pyruvic acid ratio followed transfusion, whether or not the transfusion was curative.

3. The blood amino acid nitrogen remained elevated following transfusion.

4. A continuous drip of epinephrin produced elevations in blood glucose, but much smaller elevations in blood lactic and pyruvic acids and in the lactic/pyruvic acid ratios than occur in hemorrhagic shock.

5. In adrenalectomized dogs, whose tolerance to hemorrhage was poor, the blood levels of lactic and pyruvic acid and the lactic/pyruvic acid ratio increased even though the blood glucose level fell.

6. Arterial blood under oil kept at body temperature showed a slight increase in lactic acid and the lactic/pyruvic acid ratio.

7. The disappearance of injected glucose from the blood was poor or nil during hemorrhagic shock. Following transfusion (even in irreversible shock) this clearance was normal.

8. The clearance of injected lactate from the blood during shock was normal. The restoration of the elevated lactic acid level to normal by transfusion is such as to mask completely the expected increase in level from injected lactate.

9. Clearance of injected lactate in normal dogs was not altered by acidosis induced by the intravenous administration of mineral acid.

10. In normal dogs the pyruvic acid level in the blood returned to normal within 45 minutes following the injection of pyruvate.

11. The elevated lactic/pyruvic acid ratio in shock was only temporarily altered by injected pyruvate.

12. Dogs in irreversible hemorrhagic shock showed disappearance rates for injected pyruvate similar to the normal in the post-transfusion phase of shock but somewhat poorer in the hypotensive pre-transfusion phase of shock, when doses of pyruvic acid that were not toxic were used (under 0.1 gram per kgm.).

CONCLUSIONS

It is concluded that while hemorrhagic shock may interfere with the functional efficiency of the enzyme systems involved in carbohydrate metabolism, the integrity of the enzyme systems involved in lactic and pyruvic acid metabolism is not seriously damaged, because they show a rapid return to normal function following transfusion. The occasionally lowered tolerance to injected glucose and pyruvic acid noted during the oligemic phase of hemorrhagic shock is due to deficient velocity and volume of blood flow through tissues. The accumulation of these metabolites in the blood results from the combined effects of poor blood flow and an increased rate of production in anoxic tissues.

The development of irreversibility to transfusion in hemorrhagic shock is not due to inability of the liver to metabolize lactic and pyruvic acids. Abnormalities in carbohydrate metabolism, so far as they are reflected in the elevations of lactic and pyruvic acids, are not related to the development of irreversibility to transfusion.

STUDIES OF CONGENITAL HEART DISEASE. I. TECHNIQUE OF VENOUS CATHETERIZATION AS A DIAGNOSTIC PROCEDURE[1]

By L. DEXTER, F. W. HAYNES, C. S. BURWELL, E. C. EPPINGER, R. E. SEIBEL, and J. M. EVANS

(From the Medical Clinic and the Department of Radiology, Peter Bent Brigham Hospital, and the Departments of Medicine and Radiology, Harvard Medical School)

(Received for publication January 5, 1947)

Recent advances in the surgical treatment of congenital disorders of the heart (1 to 4) have increased the importance of accurate diagnosis. Physical and x-ray signs are not easily understood or interpreted, partly because there is relatively little systematic knowledge of the dynamics of the circulation in patients with congenital heart lesions. In the past it has been difficult to acquire such knowledge. Many of the methods of measuring cardiac output are applied with difficulty, if at all, in patients with congenital heart disease, and certain aspects of the pulmonary circulation have heretofore been almost immune from measurement.

The introduction by Forssman (5) of the cardiac catheter and its practical improvement by Cournand and Ranges (6) have offered a new opportunity for the study of congenital heart disease. By these techniques, pressures may be measured in the great veins, the right auricle and ventricle, and the pulmonary artery. Analysis of blood samples obtained from these areas and from a systemic artery permits the calculation of the cardiac output by the Fick principle. This communication describes the methods as they have been applied to patients with congenital cardiac defects. Subsequent papers will describe results obtained in controls and in patients with various congenital cardiac lesions.

METHOD

Patients with congenital heart disease are admitted to the hospital, preferably for a period of 4 days and 3 nights. Record is made of the history, physical examination, red blood cell count, hemoglobin, hematocrit, vital capacity, and usually the circulation time (cyanide or decholin) and venous pressure. X-ray films are taken and fluoroscopic examination of the heart is carried out. The catheterization routine as developed has been designed specifically for the investigation of congenital heart disease in order to assist in the diagnosis and to contribute additional information relative to the disordered circulation in the presence of the congenital abnormality. The following routine of measuring oxygen consumption, carrying out venous catheterization, and obtaining blood by arterial puncture in sequence instead of simultaneously is not the customary procedure for calculating cardiac output, but has been developed because it allows multiple sampling from each chamber. The advantages of multiple sampling will be dealt with in subsequent communications (7, 8).

At 7:30 on the morning of the third hospital day, the basal metabolic rate is measured and the oxygen consumption calculated. Immediately after this procedure the patient is transferred to the fluoroscopy room for venous catheterization. Although the technique of this procedure has been described in detail by Cournand and his associates (9), certain modifications have been introduced to meet specific problems. The patient lies on a radiolucent mat of sponge rubber, 2 inches thick, on the fluoroscopy table. This aids in maintaining comfort and, hence, in avoiding venous spasm. Ten thousand units of penicillin are administered intramuscularly before and again after catheterization even though there seems to be little risk of producing bacterial endocarditis by this procedure. No medication other than penicillin and novocaine without adrenalin is administered. With aseptic precautions, a No. 8-F or No. 9-F radiopaque catheter,[2] 100 cm. long, with the hole at the tip and with the end curved at an angle of about 45°, is used. The technique of right heart catheterization as described by Cournand *et al* (9) has been followed closely. Once the tip has been introduced into the right auricle and the right ventricle, it is directed upward so that it is deflected from the left wall of the right ventricle, through the pulmonary valve, and into the main stem of the pulmonary artery. Since the curve of the tip of the catheter at this point is to the patient's right, it usually passes easily into the right pulmonary artery. To introduce the catheter into the left branch it

[1] This investigation was aided in part by a grant from the John and Mary R. Markle Foundation and from the Proctor Fund of the Harvard Medical School.

[2] This catheter can be obtained from the [illegible] Catheter & Instrument Corp., [illegible] New York. For this procedure a fairly stiff [illegible] to be far less traumatic than a limp [illegible] custom to heat harden the catheter [illegible] by placing it in a [illegible] dry air oven at 120° C.

is withdrawn to the main stem of the pulmonary artery and is rotated in such a fashion as to turn the curved tip to the patient's left. It may then be directed into the left pulmonary artery. This rotation is sometimes difficult to accomplish since the tip of the catheter is at the end of a horseshoe bend.

Samples of blood from pulmonary "capillaries" are obtained by introducing the catheter as far out as possible into a distal ramification of one of the pulmonary arteries (see Figure 1) in such a fashion as to obstruct the vessel. If the catheter is properly placed, fully oxygenated (arterial) blood may be withdrawn through the lumen of the catheter (7, 10).

Blood samples are withdrawn through the catheter under oil as described by Cournand *et al* (9), x-ray films are taken, and pressures with a Hamilton manometer (11) are routinely recorded at each position of the catheter. Blood samples and pressures are obtained first from the pulmonary artery, next from the right ventricle, and finally from the right auricle and superior vena cava. This

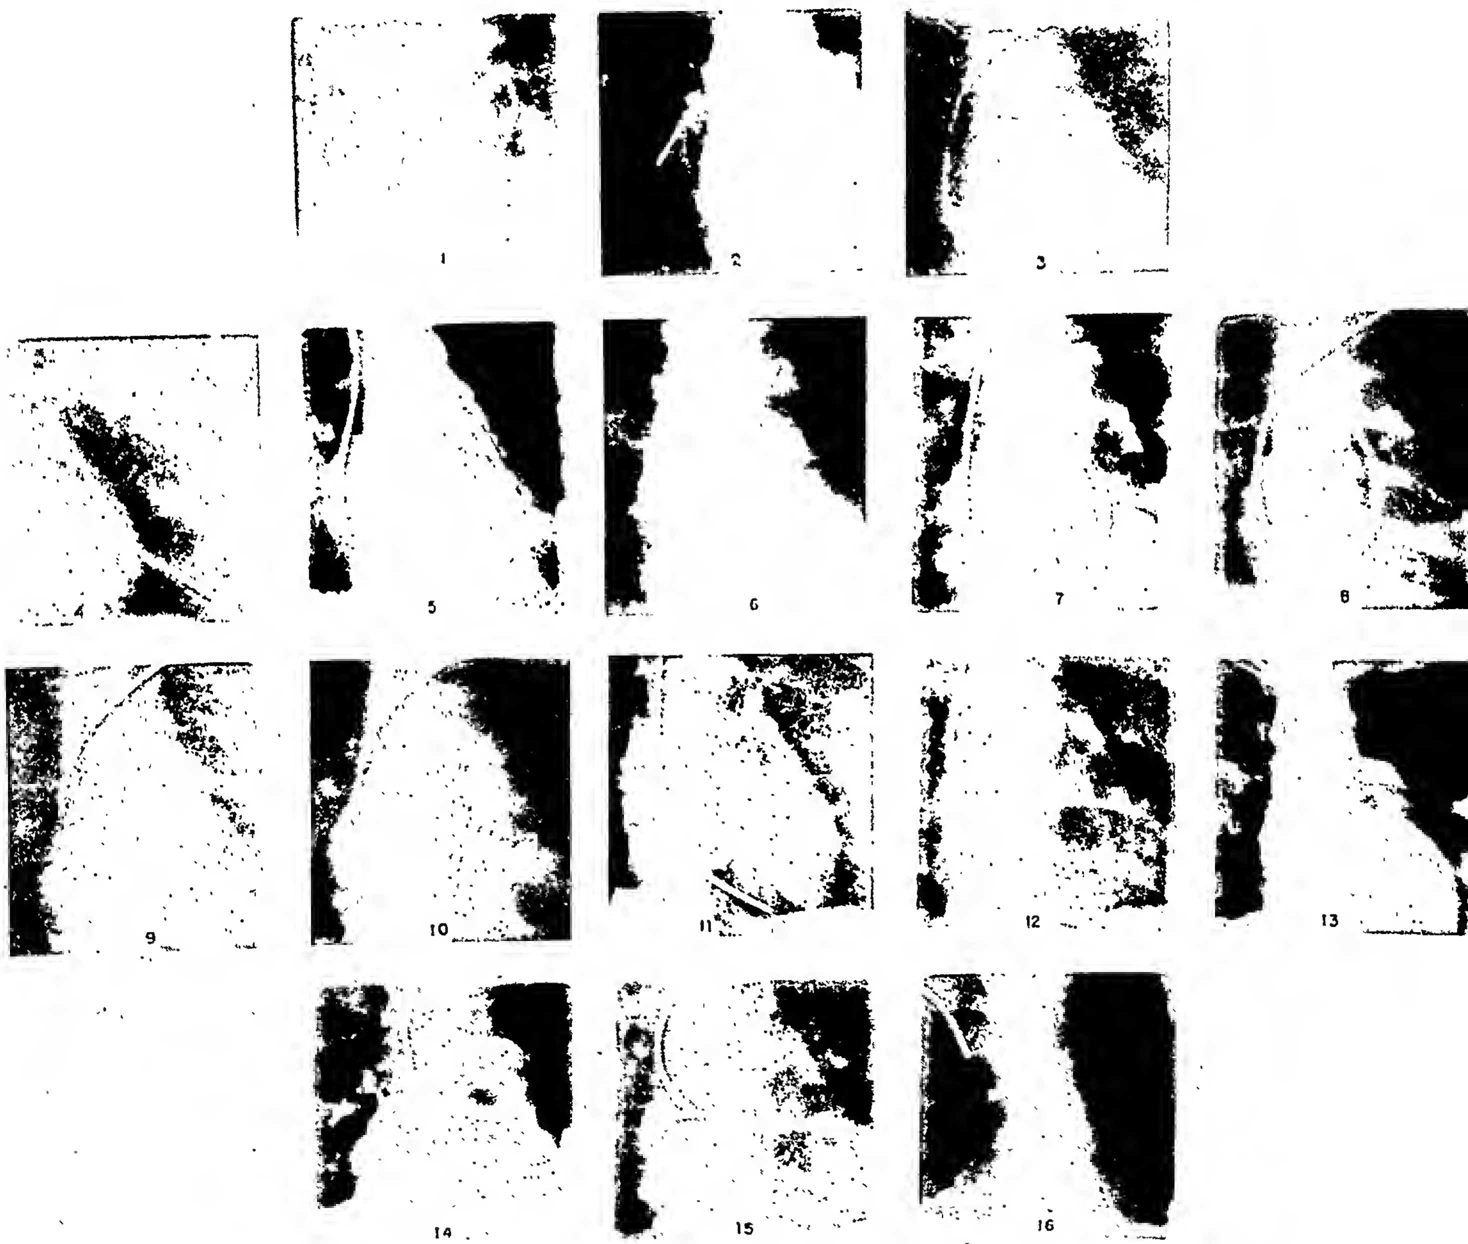

Fig. 1. X-Rays Showing the Catheter in Different Parts of the Heart and Pulmonary Artery

(1) Right and (4) left pulmonary "capillaries"; (2) and (3) right pulmonary artery; (5) and (6) left pulmonary artery; (7) main trunk of pulmonary artery; (8) right ventricle near pulmonary valve; (9) middle of right ventricle; (10) right ventricle near tricuspid valve; (11) lower part of right ventricle; (12) right auricle near tricuspid valve; (13) lower part of right auricle; (14) middle of right auricle; (15) upper part of right auricle; (16) superior vena cava.

order of sampling is followed in order to avoid the dilemma encountered when venous spasm prevents all manipulation of the catheter except its withdrawal. In this way, multiple sampling from each chamber is ensured.

Sites of routine sampling are as follows (see Figure 1):

1. Pulmonary artery.
   a. As far out as possible (for pulmonary "capillary" blood) (7, 10).
   b. Several centimeters beyond bifurcation.
   c. Main stem.
2. Right ventricle.
   a. Near pulmonary valve.
   b. Mid-position.
   c. Near tricuspid valve.
3. Right auricle.
   a. Lower part.
   b. Near tricuspid valve.
   c. Upper part.
4. Superior vena cava.

While it is often not feasible or possible to obtain samples from each of these positions, at least 2 and preferably 3 samples are withdrawn from different parts of each chamber in every case.

Knowledge of the precise location of the tip of the catheter is essential for proper interpretation of data. While an approximation of the location may be made by fluoroscopic observation, it is frequently impossible to ascertain on which side of a valve the catheter tip lies. Under these circumstances, observation of the deflections of the Hamilton manometer before and after the sampling gives precise information regarding the position of the tip of the catheter since the character of the pulse wave and the pressures are quite different in pulmonary artery, right ventricle, and right auricle (7).

Following the advice of Cournand (12), we have not ligated the vein following removal of the catheter. Instead, the skin edges have been approximated with flamed adhesive and a pressure dressing with an elastic bandage has been applied. Usually, little soreness and only local thrombosis of the vein ensue. After 3 days the patient himself may remove the bandage and, in a week, the adhesive strip.

At the conclusion of venous catheterization, a sample of blood is withdrawn under oil from the femoral artery using novocaine as an anesthetic. The oxygen content of each blood sample is determined by the method of Van Slyke and Neill (13). Since at least 10 samples are taken during the procedure, duplicate determinations have been performed only on those samples exhibiting a deviation from neighboring samples.

Clotting of samples is at times troublesome, especially in polycythemic patients. This has been consistently avoidable by injecting about 2 ml. of a 0.05 per cent solution of heparin through the catheter just before sampling.

Oxygen capacity is determined routinely on the arterial and at least one of the venous samples by the method of Van Slyke and Neill (13). Ordinarily the oxygen capacity of different blood samples is essentially the same. The capacity may vary considerably, however, especially in samples of blood with a high hematocrit. Hemoglobin concentrations are, therefore, determined photocolorimetrically on all samples, and those at variance are then corrected by determining the oxygen capacity. Variations in oxygen capacity may thus be detected and the corresponding contents corrected.

DISCUSSION

The procedure described in this report has been formulated with the specific purpose of studying the cardiovascular dynamics in congenital heart disease and of applying the knowledge so obtained to diagnosis.

Calculation of blood flow: The most accurate method at present available for the estimation of cardiac output in man is based on the principle outlined by Fick (14) in 1870. Some of us (15) applied this principle in a group of patients with patent ductus arteriosus in 1941. Since its application in patients with abnormal cardiac communications presents special problems, it seems appropriate to restate the principle and discuss its application in patients with this and other types of congenital heart disease which the catheter method has enabled us to investigate.

Fick (14) derived an equation for the calculation of cardiac output which may be restated as follows:

$$\text{Cardiac output (l. per min.)} = \frac{\text{Oxygen intake (ml. per min.)}}{\text{Arteriovenous oxygen difference (ml. per l.)}}.$$

Similar data derived from determinations of carbon dioxide can be used. Carbon dioxide data have been omitted, however, since the results of these determinations are variable (16). In normal individuals without shunts between cardiac chambers, the calculation is based on the determination of oxygen consumption, oxygen content of arterial blood, and oxygen content of mixed venous blood. The first two determinations are easily obtained. The procurement of well-mixed venous blood is more difficult. In normal individuals, samples from the right auricle and right ventricle may show considerable variation, whereas those taken from the proximal parts of the pulmonary artery show minimal variation and represent acceptable values for mixed venous blood (7).

In patients with congenital heart disease, as will be shown (8), it is frequently impossible to obtain samples of blood that are adequately mixed if these samples are taken near a shunt. Although this detracts from the accuracy of the estimation, nevertheless reasonable approximations of flow through the various chambers may be obtained.

To estimate the blood flow through a shunt, the peripheral blood flow and pulmonary blood flow must be calculated separately. The peripheral blood flow may be calculated in the usual fashion except that the sample of mixed venous blood must be obtained proximal to the shunt. For example, in cases with patent ductus arteriosus, it must be obtained by multiple sampling from the right ventricle; in cases with ventricular septal defect, from the right auricle; and in cases of auricular defect, from the vena cava. Since true mixing becomes progressively poorer in this sequence, errors in the application of the Fick principle of blood flow become greater.

Determination of the pulmonary artery blood flow necessitates measurement of the oxygen content of pulmonary arterial and of pulmonary venous blood. Normally, blood in the main branches of the pulmonary artery is completely mixed. In our limited experience, this is also true in most cases of auricular septal defect. In ventricular septal defect and in patent ductus arteriosus, mixing may be less complete. In these cases, multiple sampling in the pulmonary artery usually yields a representative value from which the calculation of pulmonary blood flow can be made. The oxygen content of pulmonary venous blood is most easily obtained in individuals with a normal circulation and in those with left-to-right shunts by determining the oxygen content of systemic arterial blood since these two are identical. In individuals with right-to-left shunts (cyanotic group), the oxygen content of pulmonary venous blood can be obtained by measuring the oxygen content of pulmonary "capillary" blood (7, 10). Failing this, a value of 95 to 98 per cent saturation must be assumed. This assumption is admittedly open to criticism, especially when pulmonary disease with imperfect oxygen diffusion exists.

The catheter technique does not afford information relative to the collateral circulation between systemic arteries and the pulmonary artery such as sometimes occurs in patients, especially with pulmonary stenosis, if these collateral channels deliver blood to the pulmonary artery beyond the point where catheter samples are obtained. Bing (17) has utilized a combination of the catheter technique and respiratory methods for calculating the magnitude of blood flow through the collateral circulation in these individuals.

The volume of flow through single, one-directional shunts may most easily be estimated by calculating the difference between the pulmonary and peripheral flows. If the shunt is in both directions, as not infrequently occurs, the following formulae,[3] derived by Dr. S. Howard Armstrong, Jr., may be used:

---

[3] Let pulmonary artery inflow = a ml. per min. (Determined by Fick equation from pulmonary artery and left auricle oxygen saturations and oxygen consumption).
Let oxygen saturation vena cava inflow $= b$ per cent.
Let oxygen saturation pulmonary vein outflow $= c$ per cent.
Let oxygen saturation pulmonary artery inflow $= d$ per cent.
Now pulmonary artery inflow has 2 components:
(1) from vena cava, x ml. per min.,
(2) from shunt, left-to-right, y ml. per min.
Therefore

$$x + y = a, \tag{1}$$

$$\frac{bx + cy}{x + y} = d. \tag{2}$$

Solving for y, from (2)

$$(b - d)x + (c - d)y = 0$$

$$x = \frac{(d - c)y}{(b - d)}$$

and from (1)

$$y = \frac{a}{1 + \frac{(d - c)}{(b - d)}} = a\,\frac{(b - d)}{(b - c)} \text{ ml. per min.} \tag{3}$$

Now if this is the amount of pulmonary vein blood shunting from left to right and out the pulmonary artery, the remainder must go out the aorta. The other component of aortic flow will shunt from right to left and have the same saturation as right auricular blood, and must equal in amount the return from the vena cava *less* that which has gone through the pulmonary artery. The total caval return and aortic outflow will be assumed to be equal during measurements. Therefore, for total aortic output, u (in ml. per min.), the 2 components are:
(1) from shunt right to left, v ml. per min.,
(2) from the pulmonary veins,

$$e = a\left(1 - \frac{b - d}{b - c}\right) = a\left(\frac{d - c}{b - c}\right).$$

Therefore, $u = v + e$. (4)
Now let f per cent be the oxygen saturation of the peripheral arterial blood. Then

$$f = \frac{bv + ce}{v + e}. \tag{5}$$

Solving (4) for v,

$$(f - b)v = (c - f)e$$

$$v = \frac{(c - f)}{(f - b)}\,e. \tag{6}$$

Where v = right-to-left shunt (l. per min.), y = left-to-right shunt (l. per min.), a = pulmonary blood flow (l. per min.), b = oxygen content (ml. per l.) of mixed venous blood proximal to the shunt (venae cavae, right auricle, or right ventricle), c = oxygen content (ml. per l.) of pulmonary venous blood, d = oxygen content (ml. per l.) of pulmonary arterial blood, and f = oxygen content (ml. per l.) of systemic arterial blood, then

$$y = a\frac{(b-d)}{(b-c)} \qquad v = a\frac{(c-f)(d-c)}{(f-b)(b-c)}.$$

When 2 shunts in the same direction are present in the same heart (*e.g.*, auricular and ventricular septal defect with left-to-right shunts), calculation of the approximate sum total of the shunts is possible, whereas it is not feasible to attempt much more than a guess at the amount of each shunt due to the impossibility of obtaining mixing between the chambers.

All of these difficulties indicate that the Fick principle, when applied to congenital heart disease, gives an estimation of blood flow which is at best an approximation. It is useful to make the calculation, but the assumptions on which such calculations are based must be clearly borne in mind.

Blood pressures: Mean pressures are easily recorded through the venous catheter by means of a simple saline manometer of the venous pressure type. Considerably more information may be obtained with the optical manometer of Hamilton (11). We have experienced difficulty in obtaining suitable pulse wave tracings from the pulmonary artery and from random positions in the right ventricle. With care, good right ventricular pulse wave tracings can be obtained. Artefacts are often set up, apparently by the motion of the catheter within the heart. The natural frequency of the membrane falls from about 170 vibrations per second when recorded through a needle and lead tubing to about 30 vibrations per second when recorded through the catheter and lead tubing. The systolic and diastolic pressures seem to be accurate in that systolic and diastolic pressures in the right ventricle of dogs have been identical when recorded through the catheter and through a No. 18 needle inserted through the chest wall directly into the right ventricle.

The peak of the pressure curve in both pulmonary artery and right ventricle is taken as the systolic pressure, and the level just before the systolic rise is taken as the diastolic pressure. The right auricular pressure is recorded as mean pressure.

The location of the proper level of zero pressure is still controversial since it is different for right auricle, right ventricle, and pulmonary artery. It likewise varies with systole and diastole. Until a standard reference level has been agreed upon, we have chosen to use the level described by one of us (18), which is 10 cm. anterior to the skin of the back with the subject in the supine position. In addition, the anteroposterior diameter of the chest between the sixth thoracic spine and the sternum at the level of the second rib has been recorded with an obstetrical pelvimeter. The pressures, therefore, may be easily recalculated if it is desired to use other zero points.

It has been customary to obtain pressure tracings in the pulmonary artery, right ventricle, and right auricle. A continuous pressure tracing is usually obtained as the catheter is slowly withdrawn from pulmonary artery to right ventricle and from right ventricle to right auricle. In this way comparable pressures are recorded. If the double-lumen catheter of Cournand, Bloomfield, and Lauson (19) is used, pressures may be obtained from 2 chambers simultaneously.

Complications of venous catheterization: That venous catheterization is a benign procedure even in fairly ill patients has been affirmed repeatedly (20, 21, 22), and our experience confirms this. Two sources of mild discomfort have been observed occasionally during venous catheterization. The first is [illegible]

Thus

$$u = c\left(1 + \frac{(c-f)}{(f-b)}\right) = a\frac{(d-c)(c-b)}{(b-c)(f-b)},$$

an expression completely defined in terms of our original quantities measured.
Simplifying algebraically:

Left-to-right shunt $= a\dfrac{(b-d)}{(b-c)}$.

Note that if $(b-d) = 0$, *i.e.*, mixed venous and pulmonary artery blood have same saturation, this means negligible left-to-right shunt.

Right-to-left shunt $= a\left(\dfrac{c-f}{f-b}\right)\left(\dfrac{d-c}{b-c}\right)$.

Note that if $(c-f) = 0$, *i.e.*, left auricle and artery blood have same saturation, this means negligible right-to-left shunt.

ence has been almost uniformly associated with bodily discomfort but has not derived from apprehension. Every effort is made to prevent discomfort. The site of the incision is injected with novocaine about every 10 minutes, the fluoroscope table is covered with a 2-inch sponge rubber mat, pillows are used judiciously for support of the head and shoulders, and the whole procedure is dispatched as quickly as possible (usually about 45 minutes). When venous spasm occurs, it has rarely been possible to relieve it except by removing the catheter from the vein for several minutes.

Ventricular extrasystoles may at times be a source of discomfort to the patient (9). In 27 of 42 patients, irregularity of the heart was shown to occur during venous catheterization. This was demonstrated by electrocardiogram, by pulse tracing, or by palpation. Only 14 of the 27 patients had symptoms referable to this irregularity, and in only 1 were the symptoms of sufficient severity to interrupt the procedure. Five of 12 patients who had electrocardiograms recorded at frequent intervals developed premature ventricular beats. The ventricular extrasystoles are produced especially when the catheter touches the wall adjacent to the tricuspid valve. They usually disappear when the tip of the catheter is in the ventricle, but at times the irregularity persists, apparently due to movement of the catheter with each heartbeat with consequent stimulation of the region of the tricuspid valve. Two patients developed transient auricular fibrillation which subsided spontaneously in the course of half an hour.

In obtaining pulmonary "capillary" blood, the catheter is introduced into the distal portion of a branch of the pulmonary artery so as to obstruct the vessel. It remains in this position for only a few minutes. In no case has there been any change in pulse and respiratory rates and no patient has had untoward symptoms. In dogs a main lobar branch of the pulmonary artery must be obstructed for approximately 1 hour before x-ray and pathological evidence of congestion or infarction appears (23). The vessels occluded by a No. 9–F catheter are roughly 3 mm. in diameter. Since there is a slow drip of physiological saline through the catheter, it seems doubtful whether infarction would occur for many hours.

Auscultation and phonocardiography have revealed no demonstrable changes in the heart sounds or production of murmurs as the catheter passes through either the tricuspid or pulmonary valve. In one patient with pronounced pulmonary stenosis, a catheter about 3 mm. in diameter was introduced past the valve into the pulmonary artery without symptoms. Following a subsequent operation the patient expired, and at autopsy the pulmonary valve orifice was found to measure only 5 mm. in diameter. Cournand, Bloomfield, and Lauson (19) recorded pressure tracings simultaneously in right auricle and right ventricle and concluded that there was no indication of tricuspid insufficiency as a result of inserting the catheter through the tricuspid valve. It seems doubtful, therefore, that venous catheterization produces a functional stenosis or insufficiency of the tricuspid or pulmonary valve under a rather wide range of pathological conditions.

Pathological examination of the endothelium, valve leaflets, chordae tendinae, and papillary muscles in dogs purposely exposed to traumatic venous catheterization of the right auricle, right ventricle, and pulmonary artery has revealed no recognizable pathological lesions resulting from this procedure (24). No evidence of pulmonary embolism from clot formation around the catheter was observed. Post-mortem examinations have been performed on 10 of our patients on whom venous catheterization had previously been performed. In no case was death directly or indirectly attributable to the procedure. In no instance were there any demonstrable lesions of the veins, heart, pulmonary artery, or lung attributable to the passage of the catheter.

SUMMARY

1. The venous catheter technique of Cournand and Ranges (6) has been applied to the diagnosis and study of the hemodynamics of congenital heart disease.

2. Oxygen consumption is measured, and pressures and blood samples (for the oxygen content) are obtained from various parts of the pulmonary artery, right ventricle, right auricle, and from the vena cava and the femoral artery.

3. Details of the procedure are described, and the Fick principle for the calculation of blood flow in patients with congenital heart disease is discussed.

STUDIES OF CONGENITAL HEART DISEASE. II. THE PRESSURE AND OXYGEN CONTENT OF BLOOD IN THE RIGHT AURICLE, RIGHT VENTRICLE, AND PULMONARY ARTERY IN CONTROL PATIENTS, WITH OBSERVATIONS ON THE OXYGEN SATURATION AND SOURCE OF PULMONARY "CAPILLARY" BLOOD[1]

By L. DEXTER, F. W. HAYNES, C. S. BURWELL, E. C. EPPINGER, R. P. SAGERSON, and J. M. EVANS

(*From the Medical Clinic and the Department of Radiology, Peter Bent Brigham Hospital, and the Departments of Medicine and Radiology, Harvard Medical School*)

(Received for publication January 5, 1947)

The venous catheter of Cournand and Ranges (1) permits the measurement of pressure and oxygen content of blood in the pulmonary artery, right ventricle, and right auricle of patients with congenital heart disease. To interpret the data so obtained, it is necessary to be cognizant of the variations in these measurements that occur in patients without congenital cardiac defects. The present report deals with the findings in a group of control patients.

METHODS AND MATERIAL

The procedures of measuring oxygen consumption, of blood sampling, and of pressure recording in various parts of the right side of the heart have been described in detail in a previous paper (2). The oxygen content of blood was determined by the method of Van Slyke and Neill (3), and pressures were recorded by the optical manometer of Hamilton (4). As noted previously, the zero point for all pressures was taken as 10 cm. anterior to the skin of the back with the patient in the supine position (5). In addition, the anteroposterior diameter of the chest between the sixth thoracic vertebra and the angle of Louis has been recorded for the benefit of those wishing to use another point of reference.

In 13 patients without any evidence of congenital heart disease, the oxygen content of blood and pressures in various parts of the pulmonary artery, right ventricle, and right auricle have been studied (see Table I).

Fifteen patients with a variety of disorders but without clinical or laboratory evidence of auricular septal defect, as noted in Table II, were studied for the purpose of comparing the oxygen content of blood in the right auricle with that in the superior and inferior venae cavae.

In a third group of 16 patients with a variety of abnormalities but without cyanosis (see Table III), the oxygen content of blood obtained from the pulmonary "capillaries" was determined. In addition, 3 patients with right-to-left shunts have been included (see Table IV). Two of these patients had auricular septal defects (confirmed by autopsy in one case), and the third had the tetralogy of Fallot.

By consulting Tables I, II, and III, it will be noted that the majority of patients were not normal. They were chosen on 2 bases: that they had no defect which would interfere with the interpretation of the results and that they did have a number of abnormalities, such as cardiac failure, anemia, and pulmonary disease, which are sometimes associated with congenital heart lesions. It is believed, therefore, that the values obtained in these patients serve as useful controls for the values observed in patients with congenital cardiac defects.

OBSERVATIONS AND INTERPRETATIONS

Pressures: Figure 1 illustrates pressure tracings from the pulmonary artery, right ventricle, and right auricle in a normal individual. Gross differences in the pulse wave forms in the different chambers are apparent.

The recording of pressures in patients with congenital heart disease is of particular value in the detection of pulmonary stenosis (6). The systolic pressures in the pulmonary artery and right ventricle were identical within the limit of respiratory variations in each of the patients in Table I. This is in contrast to the findings in pulmonary stenosis where the pulse pressure in the pulmonary artery tends to be narrow and the systolic pressure in the right ventricle is clearly higher than that in the pulmonary artery (6). It is believed that the systolic and diastolic pressures recorded through the catheter with the Hamilton manometer are accurate (2). The finer structure of the pulse waves, especially in the pulmonary artery, is so subject to artefacts that it has not been used by us for analytical purposes. Nevertheless, differences in the gross configura-

[1] This investigation was aided in part by a grant from the John and Mary Markle Foundation, and from the Proctor Fund of the Harvard Medical School.

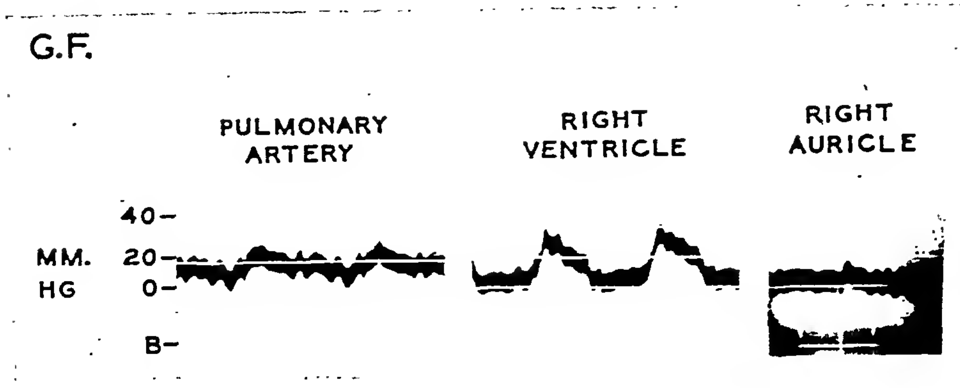

FIG. 1. PRESSURE TRACINGS IN PULMONARY ARTERY, RIGHT VENTRICLE, AND RIGHT AURICLE OF A NORMAL PATIENT

The systolic pressures in the pulmonary artery and right ventricle are almost identical, the differences observed being attributable to respiratory fluctuations. Artefacts in the tracings are probably due to the motion of the catheter within the heart and pulmonary artery.

tion of these waves are of the utmost value in identifying the chamber in which the tip of the catheter is located, especially when it lies close to either the pulmonary or the tricuspid valve. This can easily be accomplished at the time of catheterization by noting the deflection of the light beam as the catheter is withdrawn from one chamber to another.

Variations of oxygen content between different chambers: In congenital heart disease, left-to-right shunts introduce arterial blood into the right auricle, right ventricle, or pulmonary artery, thereby increasing the oxygen content of blood within the chamber. Recognition of a significant increase of oxygen in the blood of a given chamber requires a knowledge of the variations that may occur normally. In our control patients (Tables I and II), the greatest increase in the oxygen content of blood in the right auricle over that present in the superior vena cava was 1.9 volumes per cent (Table II, patient 9). The greatest increase in the oxygen content of blood in the right ventricle over that present in any part of the right auricle was 0.9 volume per cent (Table I, patients 5 and 12). The greatest increase in the oxygen content of blood in the pulmonary artery over that present in any part of the right ventricle was 0.5 volume per cent (Table I, patient 4). These values are at the moment considered as maximal normal variations with the tentative postulation that a wider divergence is indicative of a shunt of arterial blood into the given chamber. With a larger series of control patients, it is possible that variations encountered between the various chambers would be greater.

It is obvious that left-to-right shunts of small size may be easily overlooked unless the operator can place the tip of the catheter in the stream of arterial blood flowing through the abnormal communication rather than in areas where the arterial stream has become mixed with the surrounding venous blood. This requires knowledge of the probable location of such a shunt as regards not only the chamber involved but also the location of the defect within that chamber. Careful evaluation of the patient by other diagnostic methods is, therefore, essential before performing venous catheterization.

Attempts were made to obtain representative samples of blood from the inferior vena cava by withdrawing the catheter from the region of the renal vein to a point a few centimeters below the diaphragmatic shadow and withdrawing blood samples without further manipulation of the catheter. The oxygen content of blood from the inferior vena cava was uniformly higher than the maximal value obtained from the right auricle. This may well have been due to withdrawal of blood coming predominantly from the renal vein which contains a high content of oxygen (7). In view of this uniform finding, we have [illegible] the sampling of blood from the inferior vena cava [illegible] for comparative purposes [illegible] from the superior vena cava.

** (+) denotes a higher value in the right auricle than in the vena cava; (−) denotes a lower value.

Variation of oxygen content within each chamber: The maximal variation of oxygen content of blood samples obtained from different parts of the right auricle was 11.4 volumes per cent (Table II, patient 4), and 5.5 volumes per cent (Table II, patient 5). In each instance, one sample was highly unoxygenated. The maximal variation within the right ventricle was 0.8 volume per cent (Table I, patient 2). Greater variations than these have been observed in the right ventricle of patients not included in Table I. In 2 patients, variations of 4.5 and 8.4 volumes per cent have been recorded, one of the samples in each case being highly unsaturated. The maximal variation between the trunk and one of the main branches of the pulmonary artery was only 0.4 volume per cent (Table I, patient 6) and 0.3 volume per cent (Table I, patient 2).

The accuracy of the direct Fick method for the determination of cardiac output under a given set of conditions depends on the accuracy with which the oxygen consumption and the oxygen content of arterial and mixed venous bloods are determined. This problem has been discussed critically by Cournand (8), who pointed out that whereas the first two factors are determinable with reasonable accuracy, the third (mixed venous blood) may occasionally be difficult to obtain from the right auricle. Holt and Knoefel (9) reported that true mixing did not occur in the right auricle of dogs. In man, however, Cournand and his associates (8, 10, 11) concluded that, if the tip of the catheter is located with care in the right auricle close to the tricuspid valve, mixed venous blood is usually obtainable. They showed, however, that even with the catheter in this position in the right auricle, the samples withdrawn were sometimes poorly mixed, as in our case 13 of Table I and in cases 4 and 5 of Table II. Warren, Stead, and Brannon (12) found a maximum variation of oxygen content in the auricle of 2.3 volumes per cent, and in the ventricle 1.8 volumes per cent. They concluded that neither the auricle nor the ventricle could be considered [illegible]

venous blood in individual cases, although if groups of cases were treated statistically, good mixing could be considered to have taken place.

Our data confirm the findings of Cournand and his associates and of Warren, Stead, and Brannon in indicating that although adequate mixing usually occurs in the right auricle and right ventricle, unreliable values may at times be obtained. The abnormal values are almost uniformly attributable to low oxygen content of one sample, presumably due to the entrance of coronary venous blood with its low oxygen content (13) into the right ventricle by way of Thebesian vessels and into the right auricle by way of the coronary sinus. It is possible that hepatic venous blood which is low in oxygen (14) may be responsible for the low values in some of the samples obtained from the right auricle.

In contrast to the occasional discrepancies in the oxygen content of blood obtained from right auricle and right ventricle, there was remarkable uniformity in the values obtained from the pulmonary artery. The maximal variations observed hardly exceeded the error of the method of determining oxygen content. It is believed, therefore, that true mixing of venous blood occurs uniformly in the pulmonary artery in man, and that the use of the pulmonary artery as a source of mixed venous blood in determining cardiac outputs by the direct Fick principle will overcome one of the major sources of error of this technique.

Pulmonary "capillary" blood: The oxygen content and saturation of blood obtained through the catheter, when it is introduced into a distal branch of the pulmonary artery so as to occlude it, are shown in Table III. It will be observed that in all cases there was close agreement between the oxygen saturation of this blood and that taken from the femoral artery. In no case did the oxygen saturation of blood from the pulmonary "capillaries" exceed that from the femoral artery by more than 2 per cent. Samples taken from other locations in the pulmonary artery uniformly had lower oxygen saturations. This was also true in the 3 patients with patent ductus arteriosus.

The arterial blood withdrawn when the pulmonary artery is obstructed by the catheter might be derived from anastomoses with bronchial arteries or from the pulmonary capillary and venous bed. The existence of bronchial artery anastomoses proximal to the pulmonary capillaries under normal conditions is doubtful (15, 16), although un-

TABLE III

der certain circumstances anastomoses between large bronchial arteries and pulmonary arteries may be striking (17). The finding of a significantly higher oxygen saturation of blood withdrawn from the distal part of the pulmonary artery than in that from the femoral artery in 3 patients with cyanosis from a right-to-left shunt (Table IV) indicates that the blood so obtained does not derive from direct anastomoses with the systemic arterial circulation. It seems justifiable to conclude that it is aspirated mainly from the pulmonary capillary and venous bed. A small pre-capillary source cannot be excluded by these data.

The finding of an oxygen saturation of 95 to 100 per cent in the pulmonary "capillary" blood excludes the existence of pulmonary disease with oxygen diffusion difficulties. The finding of a diminished oxygen saturation, however, does not indicate the presence of pulmonary disease since there may well have been only partial obstruction of the pulmonary arterial branch with some admixture of venous blood from the pulmonary artery. If, in cyanotic patients, values for oxygen saturation in femoral artery and pulmonary "capillaries" are found to be identical and reduced, it is presumptive evidence that the oxygen unsaturation is on the basis of disordered pulmonary function.

Diminution of the oxygen capacity of some of the samples obtained from the pulmonary "capillaries" (see Table II) may well be related to the decreased hematocrit of capillary blood which has been found in samples taken elsewhere in the body (18). Studies of the cause of the variations observed are in progress.

SUMMARY

1. Venous catheterization of the venae cavae, right auricle, right ventricle, and pulmonary artery has been performed in control patients with various diseases but without congenital defects affecting the factors studied.

2. Pressures and multiple samples of blood for oxygen analysis have been obtained from each chamber.

3. The greatest increase in oxygen from the superior vena cava to the right auricle was 1.9 volumes per cent; from the right auricle to the right ventricle, 0.9 volume per cent; and from the right ventricle to the pulmonary artery, 0.5 volume per cent.

4. The systolic pressure in the pulmonary artery was almost identical with that in the right ventricle over a wide range of pressures.

5. Arterial blood may be obtained from the distal branches of the pulmonary artery by obstructing the artery with the catheter and withdrawing blood through the catheter lumen. Evidence is presented indicating that this blood originates in the pulmonary capillary and venous bed rather than in pre-capillary anastomoses with systemic arteries.

6. The oxygen content of bloods obtained from several sites within the right auricle and right ventricle showed at times considerable variation, while those from the pulmonary artery were remarkably uniform. It is concluded that mixed venous blood for the determination of cardiac output may be obtained consistently from the pulmonary artery but not uniformly from the right auricle and right ventricle.

ACKNOWLEDGMENT

The authors wish to express their appreciation to Miss Barbara Jacobs for her technical assistance.

STUDIES OF CONGENITAL HEART DISEASE. III. VENOUS CATHETERIZATION AS A DIAGNOSTIC AID IN PATENT DUCTUS ARTERIOSUS, TETRALOGY OF FALLOT, VENTRICULAR SEPTAL DEFECT, AND AURICULAR SEPTAL DEFECT[1]

By L. DEXTER, F. W. HAYNES, C. S. BURWELL, E. C. EPPINGER, M. C. SOSMAN, and J. M. EVANS

(From the Medical Clinic and the Department of Radiology, Peter Bent Brigham Hospital, and the Departments of Medicine and Radiology, Harvard Medical School)

(Received for publication January 5, 1947)

Previous communications have outlined the technique of cardiac catheterization as applied to the study of congenital heart disease and defined the variations in pressures and oxygen content observed in a group of control patients (1, 2). This paper sets forth the results of study in 6 patients with 4 varieties of congenital heart disease as examples of the type of information which can be acquired by the catheter technique in such patients.

OBSERVATIONS

Patent ductus arteriosus

Patent ductus arteriosus is a persistence after birth of the vascular anastomosis between the pulmonary artery and the aorta. While in the fetus blood flows from the pulmonary artery to the aorta, the flow is from the aorta to the pulmonary artery after birth, as Eppinger, Burwell, and Gross (3) have demonstrated.

Case 1. I. G. was a 26-year-old woman. In early infancy she was found to have a heart murmur. She developed normally but was subject to palpitation, dyspnea, and fatigue on exertion. On physical examination, she was a well-developed woman without cyanosis or clubbing. Arterial blood pressure was 125/65 mm. Hg. The heart was enlarged to the left. There was a machinery murmur in the pulmonic region. The first sound at the apex and the second sound at the pulmonic area were accentuated. The lungs were clear, the liver was not enlarged, and no edema was apparent. X-ray of the heart (Figure 1) showed it to be about 20 per cent enlarged with prominence in the region of the pulmonary artery and with hilar engorgement. An electrocardiogram was normal.

Venous catheterization was performed, and Table I records the pressures and oxygen contents of blood samples obtained from the various points shown in Figure 1. It will be noted that the oxygen content of blood in the pulmonary artery was 2.2 volumes per cent higher than of that from the right ventricle. This is taken as indicating the entrance of arterial blood into the pulmonary artery. Arterial shunts, other than patent ductus arteriosus, are exceedingly rare in this region. The systolic pressures in the pulmonary artery and right ventricle were elevated. The shunt was calculated to be 7.6 l. per min.

A few days later, Dr. Robert E. Gross ligated and divided a patent ductus arteriosus. Two weeks later, venous catheterization was repeated, at which time the patient was weak and moderately anemic (hemoglobin 9.9 grams). Results

TABLE I

I. G. Age 26. Patent ductus arteriosus

Sample	Oxygen content	Pressure
	vol. per cent	*mm. Hg*
Left pulmonary artery (near bifurcation)	15.1	63/35
Right pulmonary artery (near bifurcation)	15.1	
Right ventricle (near pulmonary valve)	12.9	63/6
Right ventricle (mid-portion)	12.5	
Right auricle (near tricuspid valve)	13.0	6
Right auricle (upper portion)	11.9	
Systemic artery	16.7 (97 per cent)	125/65

[1] This investigation was aided in part by a grant from the John and Mary R. Markle Foundation, and from the Proctor Fund of the Harvard Medical School.

Body surface area	1.50 sq. m.
Arteriovenous oxygen difference	32 ml. per l.
Cardiac output	7.6 l. per min.
Cardiac index	5.1

Discussion: Calculation of the volume of flow through the ductus was made first by Eppinger, Burwell, and Gross (3) on the basis of blood samples obtained from the pulmonary artery at the time of operation. Blood samples withdrawn through the intracardiac catheter have the great advantage of being obtained with the patient in a relatively basal state. An oxygen content of blood in the pulmonary artery significantly higher than that in the right ventricle has been found regularly by venous catheterization in patients with patent ductus arteriosus.

In a previous study with the catheter in a control series of patients (2), it was observed that the greatest variation between the highest oxygen content of blood in the right ventricle and that in the pulmonary artery was 0.5 volume per cent. On this basis, it is believed that flows through the ductus of less than 0.5 l. per min., and possibly as high as 1.0 l. per min., are probably not detectable by the venous catheter method unless the tip of the catheter can be placed in the stream of arterial blood flowing into the pulmonary artery through the ductus, in which case smaller defects may be detectable.

Some patients with patent ductus have shown an elevation of pressure in the pulmonary artery and right ventricle, as in the example cited. In the majority of patients, however, the pressures have been normal.

The diagnosis of patent ductus arteriosus has been confirmed by venous catheterization in 7 patients to date and has been proved subsequently at the time of operation in each.

Tetralogy of Fallot

The tetralogy of Fallot consists of pulmonary stenosis, interventricular septal defect, dextroposition of the aorta, and right ventricular hypertrophy. There is a diminished blood flow to the lung. A shunting of blood from the right ventricle into the aorta produces cyanosis.

Case 2. P. B. was 22 years old and had been a "blue baby." All his life he had been subject to periodic attacks of intense cyanosis and syncope, and his activities had always been restricted. On physical examination, he was tall and well-developed with moderate cyanosis of lips and nails and pronounced clubbing of fingers and toes. The blood pressure was 103/84 mm. Hg. There was a harsh systolic murmur in the second left intercostal space transmitted widely over the precordium without thrill or diastolic component. There were no signs of congestive heart failure. X-ray of the heart (Figure 3) showed enlargement to the left. The apex appeared to be lifted above the diaphragm. An electrocardiogram showed right axis deviation. The red cell count was 8.2 million, the hemoglobin was 27.4 grams, and the hematocrit was 75.

The results of *venous catheterization* are shown in Figure 3 and Table III. It will be noted that 8 samples of blood from the right auricle, right ventricle, and pulmonary artery checked well as to oxygen content. The high systolic pressure in the right ventricle with a low pressure and narrow pulse pressure in the pulmonary artery indicated pulmonic stenosis (see Figure 4). Simultaneous pressures were not obtained from right ventricle and femoral artery, and hence the identity of these systolic pressures could not be tested. The systolic arterial blood showed a moderate degree of unsaturation. It was concluded that the patient had pulmonary stenosis and ventricular septal defect.

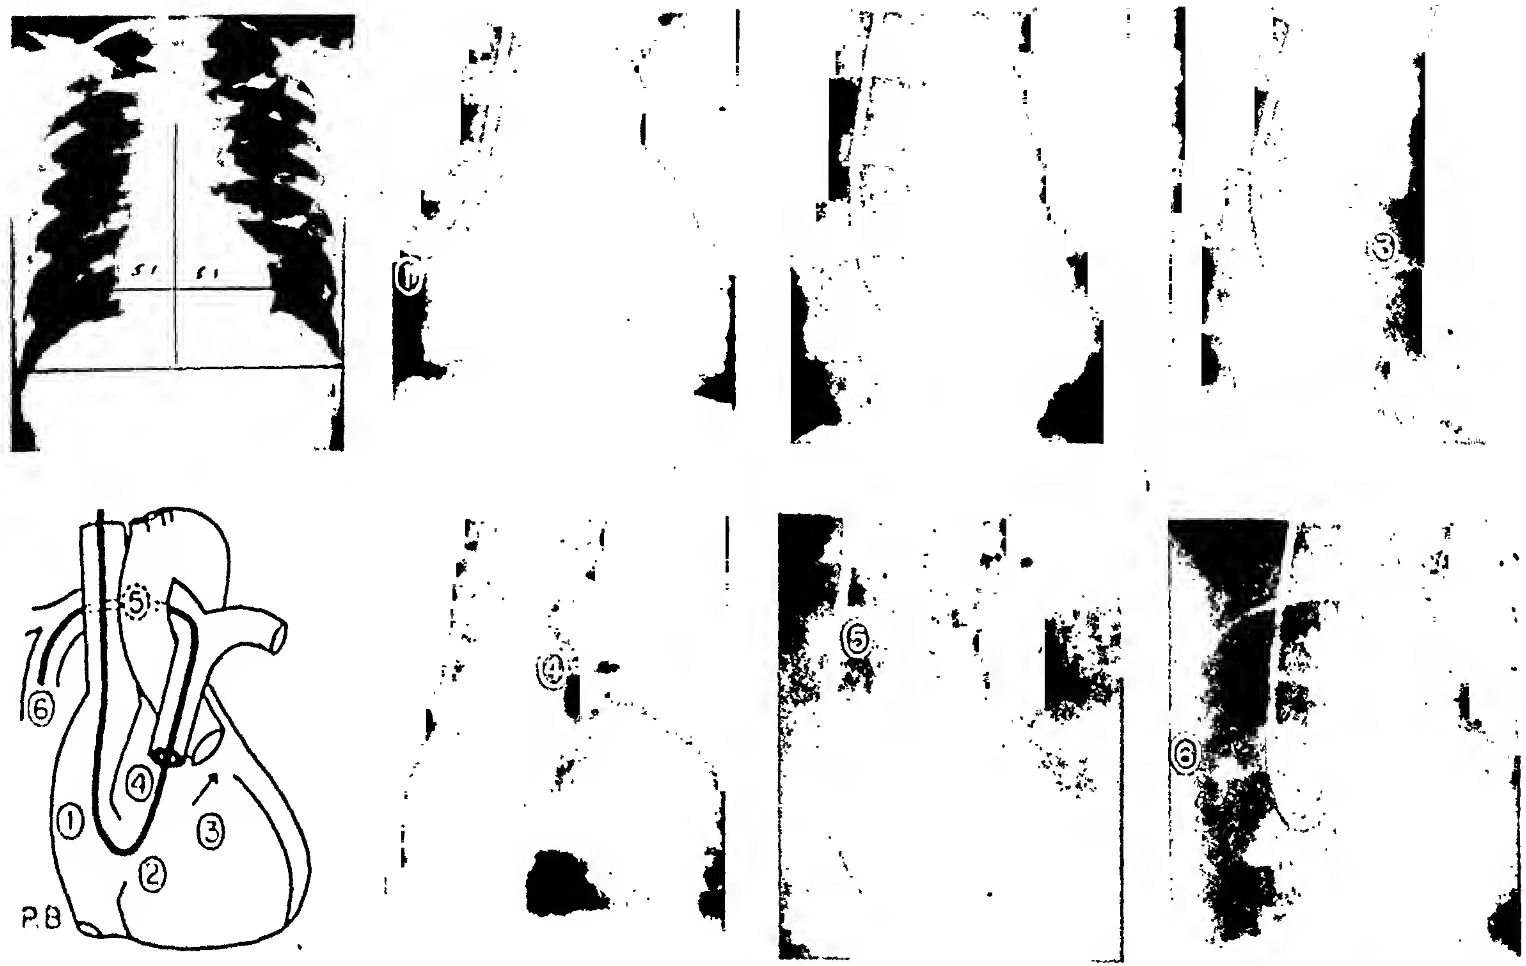

Fig. 3. Tetralogy of Fallot (Case 2)

[illegible] the catheter are identifiable by the corresponding numbers in the schema. Note that the catheter entered the pulmonary artery through [illegible] valve.

TABLE III

P. B. Age 22. Tetralogy of Fallot

Sample	Oxygen content	Pressure
	ml. per l.	*mm. Hg*
Right pulmonary artery	242	8/4
Right pulmonary artery	243	
Right ventricle (near pulmonary valve)	248	98/0

Right auricle (mid-portion)	253	
Right auricle (upper portion)	250	
Systemic artery	295 (85 per cent)	103/80*

A–P diameter of chest	19.0 cm.
Oxygen consumption	220 ml. per min.
Body surface area	1.71 sq. m.
Pulmonary arteriovenous oxygen difference (assuming 95 per cent saturation for pulmonary venous blood)	89 ml. per l.
Peripheral arteriovenous oxygen difference	43 ml. per l.
Pulmonary artery blood flow	2.5 l. per min.
Peripheral blood flow	5.1 l. per min.
Flow through defect	
Right to left	2.6 l. per min.
Left to right	none

* Not recorded simultaneously with that of right ventricle.

Flow calculations indicated only a moderate reduction of pulmonary blood flow. Bing (4) has studied cases of tetralogy of Fallot in considerable detail by means of the venous catheter and by exercise and respiratory tests, and has evidence, both physiological and morphological, that these individuals frequently develop a collateral circulation from systemic arteries to pulmonary artery which is not revealed by application of the direct Fick principle with the venous catheter. In view of his findings, it is probably more accurate to define our flow calculations as pulmonary artery flow rather than pulmonary blood flow since we are in agreement with Bing that the method as described in this report will not reveal the collateral circulation to the lung.

Following a subsequent operation, the patient expired. *Post-mortem examination* revealed that the orifice of the pulmonary valve was only 0.5 cm. in diameter (Figure 5). A 1.5 cm. defect was present in the upper part of the interventricular septum. The right ventricular wall measured 15 mm. in thickness, and that of the left ventricle, 12 mm. There was dextroposition of the aorta.

Case 3. H. S. was a 10-year-old boy who at the age of 6 weeks was found to have a heart murmur. He had never been as active as his playmates and had had a constant cyanotic tinge to his nails and lips. He had always had dyspnea on climbing one flight of stairs, but this had not been progressive. On physical examination, he was well-developed and well-nourished. The lips and nail beds were slightly bluish. No clubbing was present. The heart was enlarged to percussion. The only murmur heard was a loud machinery murmur, maximal in the aortic region but audible over the entire precordium. There was no thrill. The blood pressure was 110/70 mm. Hg. There were no signs of cardiac failure. The hemoglobin was 17.3 grams, and the hematocrit was 49. Circulation time with magnesium sulfate was 8 seconds. An electrocardiogram showed right axis deviation. X-ray (Figure 6) and fluoroscopy of the heart showed it to be enlarged to the left with dilated engorged hilar vessels. The aortic knob projected to the right.

On *venous catheterization* the catheter passed into the right ventricle and thence into the aortic arch and the descending aorta (Figure 6). This demonstrated the existence of an over-riding aorta or a ventricular septal defect and also of a right-arched aorta. Oxygen and pressure data are

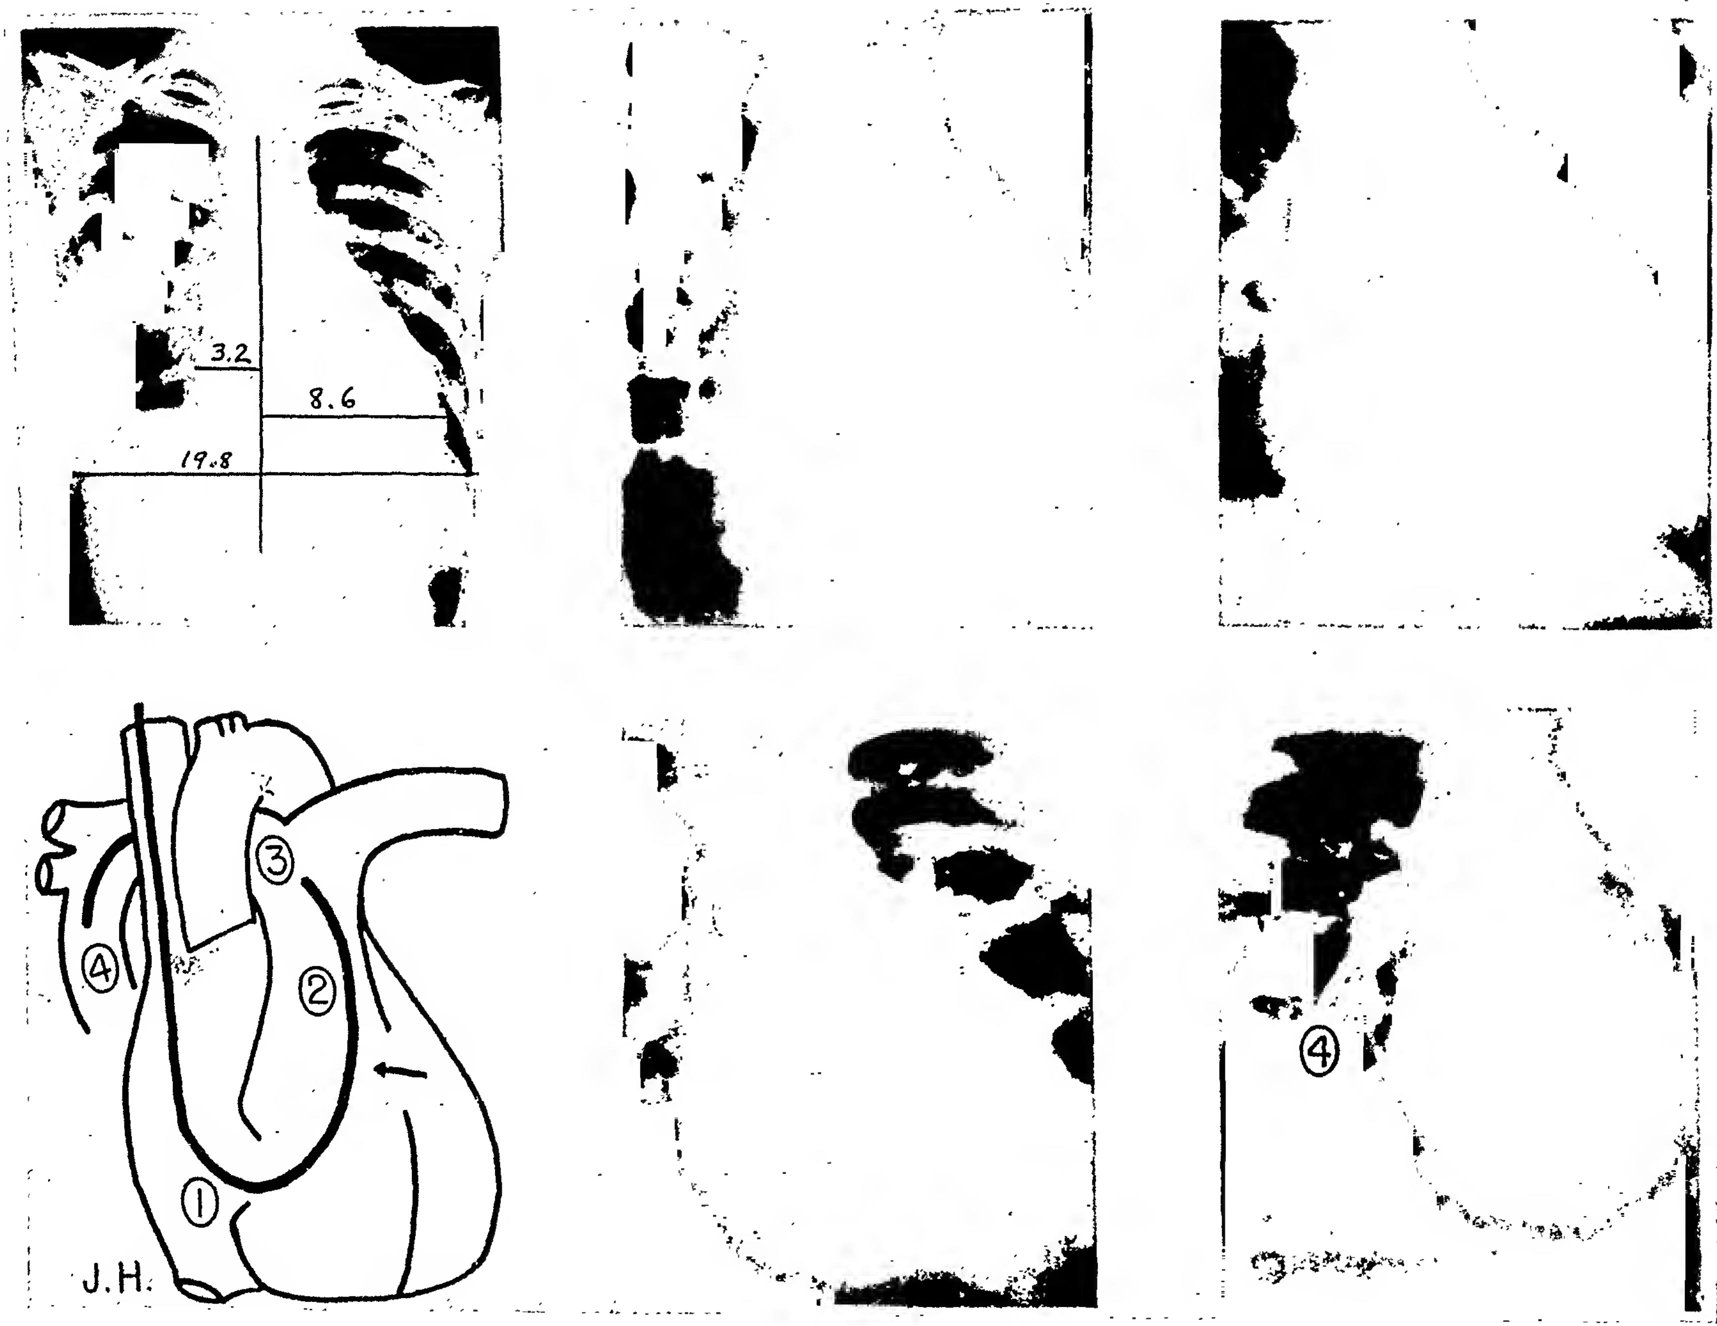

Fig. 8. Interventricular Septal Defect (Case 4)
The positions of the catheter are identifiable by the corresponding numbers in the schema.

In no case as yet has the catheter been introduced into both the aorta and the pulmonary artery in the same patient.

Interventricular septal defect (Roger's disease)

Defects in the ventricular septum vary in size and are most commonly located at the base of the heart just below the aortic valve. Since the pressure in the left ventricle is higher than that in the right ventricle, the shunt is from the left to the right side of the heart except under certain special conditions.

Case 4. J. H. was a 6-year-old boy who had had a known murmur since the age of 11 months but had never had any limitation of activity. Physical examination revealed a healthy-looking active boy of normal development. There was no cyanosis or clubbing. Cardiac findings included a blood pressure of 105/45 mm. Hg, a heart enlarged to left and right, and an extremely loud and harsh systolic murmur heard maximally at the third left intercostal space and transmitted over the entire precordium. This murmur was accompanied by a thrill. A soft early diastolic murmur was heard along the left border of the sternum. X-ray (Figure 8) and fluoroscopy of the heart showed marked enlargement, especially in the region of the left ventricle, a dilated left auricle posteriorly, and enlargement of the pulmonary artery. Hilar vessels were engorged but could not be demonstrated to pulsate. An electrocardiogram was normal.

Venous catheterization was performed as shown in Figure 8, and the results are tabulated in Table V. It is apparent that a considerable amount of arterial blood entered the right ventricle, suggesting the presence of a defect in the ventricular septum. The recorded pressures were normal. Catheterization did not explain the low diastolic pressure or the diastolic murmur. There was no evidence of a concomitant patent ductus arteriosus with pulmonary insufficiency. It was believed that this patient probably had an aortic insufficiency in addition to an interventricular septal defect.

Discussion: The recognition of interventricular septal defect by venous catheterization should depend upon finding a significant increase in the amount of oxygen in the right ventricle as compared with that from the right auricle. Two such cases have been described by Baldwin, Moore, and Noble (5). A significantly elevated oxygen content of blood in the right ventricle may reflect the presence of an interventricular septal defect or, theoretically, of a patent ductus arteriosus with an associated pulmonic insufficiency. Three instances of the latter have been suspected, in one of whom division of the ductus eradicated all murmurs and subsequent venous catheterization failed to reveal any significant variations of oxygen in the right auricle, right ventricle, or pulmonary artery. It is believed, therefore, that a diagnosis of interventricular septal defect in the presence of a patent ductus arteriosus should be made with caution.

TABLE V

J. H. Age 6. Ventricular septal defect, aortic insufficiency

Sample	Oxygen content	Pressure
	ml. per l.	*mm. Hg*
Right pulmonary artery (mid-portion)	160	29/12
Pulmonary artery (at bifurcation)	154	
Right ventricle (near pulmonary valve)	158	29/4
Right ventricle (mid-portion)	155	
Right ventricle (near tricuspid valve)	156	
Right auricle (near tricuspid valve)	126	4
Right auricle (upper portion)	121	
Superior vena cava	128	
Systemic artery	177 (100 per cent)	

A–P diameter of chest	14.5 cm.
Oxygen consumption	158 ml. per min.
Body surface area	0.82 sq. m.
Pulmonary arteriovenous oxygen difference	20 ml. per l.
Peripheral arteriovenous oxygen difference	52 ml. per l.
Pulmonary blood flow	7.9 l. per min.
Peripheral blood flow	3.4 l. per min.
Flow through shunt	4.5 l. per min.

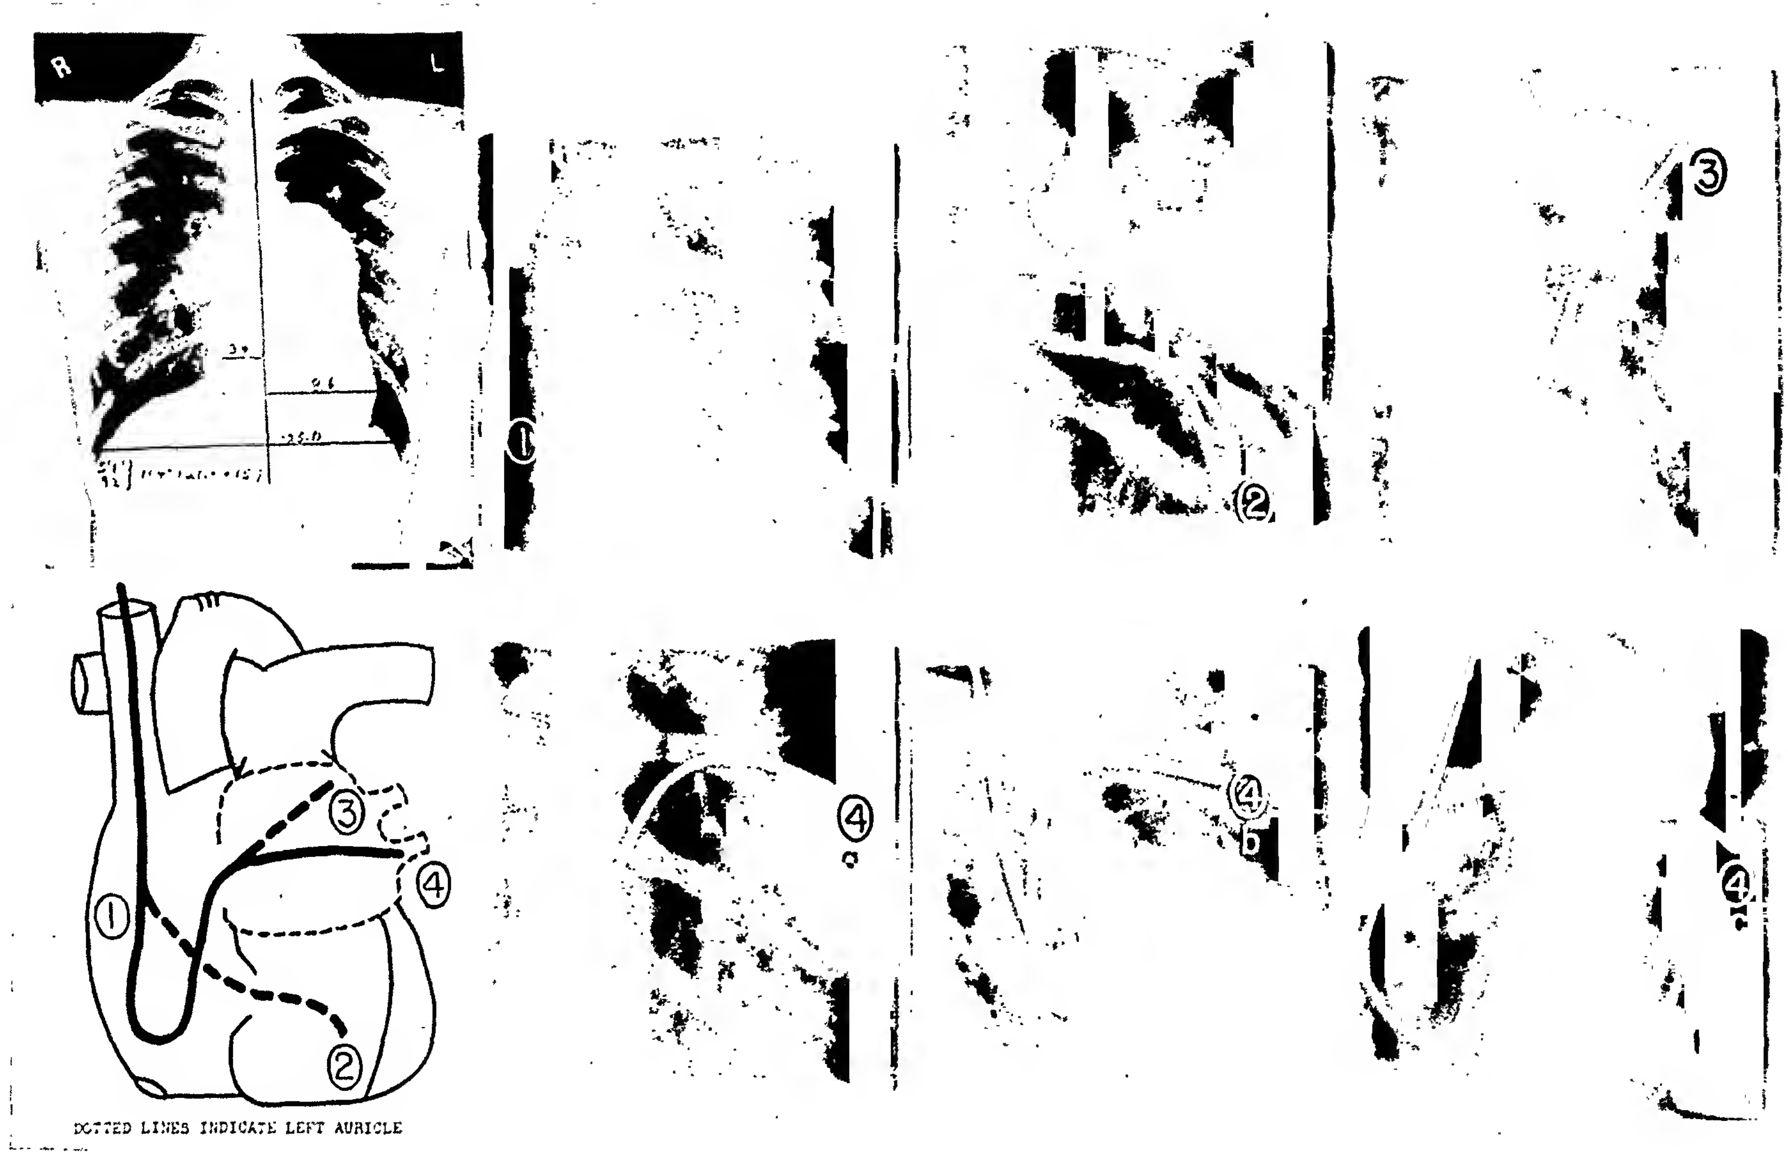

FIG. 9. AURICULAR SEPTAL DEFECT (CASE 5)

The positions of the catheter are identifiable by the corresponding numbers in the schema. Note that the catheter assumes an acutely oblique upward course in the right auricle and that the tip lies outside the cardiac shadow. The right anterior oblique view is shown in Figure 4-B, and the left anterior oblique view in Figure 4-C.

ure, the right ventricular pressure has been normal in all of our cases to date.

Interauricular septal defect

Defects in the interauricular septum vary considerably in size. The flow of blood is predominantly from the left auricle to the right auricle (6). If the defect is large or if pressure in the right auricle becomes elevated, a right-to-left shunt may likewise be present (7).

Two patients will be described to illustrate 2 different ways in which venous catheterization may aid in the recognition of auricular septal defects.

Introduction of catheter through the defect: Case 5. E. M. was a 25-year-old woman who had been found to have a heart murmur in grade school. She had always experienced fatigue rather than dyspnea on exertion. For 5 years she had had cyanosis on exposure to cold and on exertion. She was slender and there was no clubbing, but the fingers and lips were perceptibly cyanotic. The heart was overactive, and there was a harsh diastolic murmur without thrill at the fourth intercostal space. The blood pressure was 108/76 mm. Hg. X-ray (Figure 9) and fluoroscopy of the heart revealed it to be markedly enlarged with a huge pulmonary artery. An electrocardiogram showed right axis deviation.

Venous catheterization was incomplete in this patient. The catheter entered the right auricle (Figure 9), and followed a course acutely upwards and to the left so that the tip lay outside the cardiac shadow. Blood obtained from this point was 97 per cent saturated with oxygen (see Table VI). It was concluded that the catheter had passed through an auricular septal defect into the left auricle and into one of the pulmonary veins. Attempts to introduce the catheter into the pulmonary artery were unsuccessful.

Left-to-right shunt: Case 6. H. C. was a 56-year-old man who denied ever having had any symptoms referable to the heart. On admission to the hospital for carcinoma of the bladder, it was noted that his heart was enlarged to left and right, that the rate was rapid, and that there was a harsh systolic murmur without a thrill maximal at the third left intercostal space and widely transmitted over the precordium and back. No diastolic murmurs were heard. The pulmonic second sound was accentuated. Cyanosis and clubbing were absent. There were no signs of congestive failure. The [illegible] and [illegible] were normal. X-ray (Figure 10) and fluoroscopy of the heart showed it to be considerably enlarged, especially to the left, with [illegible] enlargement. An electrocardiogram [illegible].

TABLE VI

E. M. Age 25. Auricular septal defect

Sample	Oxygen content	Oxygen saturation	Pressure
	ml. per l.	*per cent*	*mm. Hg*
Superior vena cava	130	60	—
Inferior vena cava	156	72	—
Right auricle (along right wall)	142	66	6
Left auricle	196	91	10
Pulmonary vein	212	97	14
Systemic artery	187	89	108/76

Venous catheterization (Figure 10 and Table VII) revealed a large increase of oxygenated blood in the right auricle as compared with that in the superior vena cava, as well as a value in one of the samples from the right auricle practically identical with that found in the femoral artery. On the basis of these findings, the diagnosis of an auricular septal defect seemed justified. There was no evidence of other cardiac defects.

TABLE VII

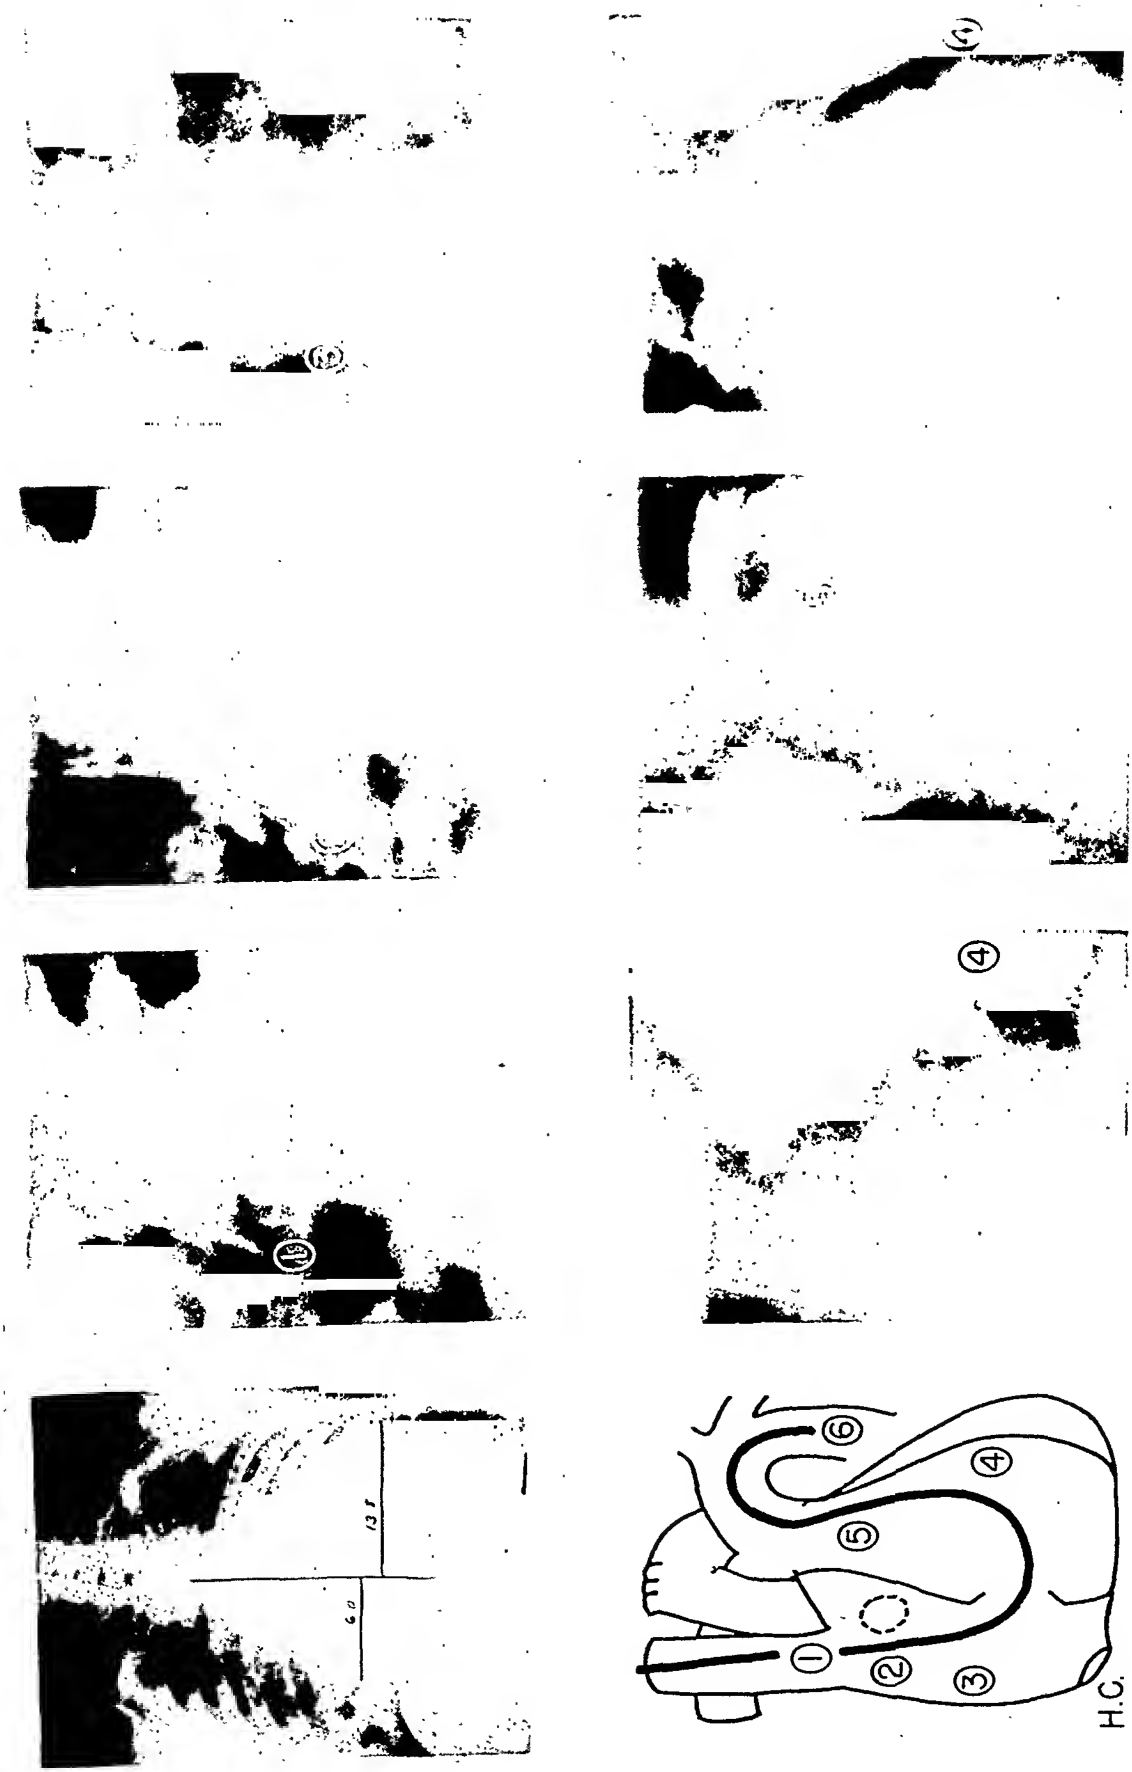

Fig. 10. Auricular Septal Defect (Case 6)
The positions of the catheter are identifiable by the corresponding numbers in the schema.

Discussion: Two methods, as described by Brannon, Weens, and Warren (9), can be utilized with the venous catheter to assist in the diagnosis of auricular septal defect: (*a*) Introducing the catheter through the defect (Patient 5), and (*b*) finding a significant increase in the oxygen content of blood in the right auricle (left-to-right shunt) (Patient 6).

Attempts to introduce the venous catheter through a defect in the auricular septum have been unsuccessful in the majority of cases. Anatomically, there appears to be no reason that, with experience, it could not be done with fair regularity.

A significant increase of oxygen content of blood in the right auricle may be present as the result of an interauricular septal defect with a left-to-right shunt, of an anomalous pulmonary vein emptying into the right auricle (7, 10), or of tricuspid insufficiency associated with interventricular septal defect. Baldwin, Moore, and Noble (5) have observed an instance of the latter and recognized tricuspid insufficiency by analysis of the auricular and ventricular pressure tracings as described by Cournand and associates (11). The recognition of a pulmonary vein emptying into the right auricle is practically impossible with our present knowledge. Statistically, auricular septal defect is much commoner than anomalous pulmonary veins emptying into the right auricle or tricuspid insufficiency associated with a ventricular septal defect. In control patients, the oxygen content of the right auricle has been observed to be as much as 1.9 volumes per cent higher than that of the superior vena cava (2). It is apparent that sizable auricular septal defects can be easily overlooked unless the catheter can be placed in the stream of arterial blood flowing from left auricle to right auricle.

DISCUSSION

Venous catheterization has opened new possibilities for the recognition of many congenital defects, for elucidating the hemodynamic changes, and for assisting in rendering a prognosis by defining the nature and physiological magnitude of the defects. As with other methods, it has its limitations and these we have tried to point out. The tetralogy of Fallot may be recognized with a high degree of accuracy if the assumptions on which the interpretations of pulmonary stenosis and ventricular septal defect were made are accepted. Patent ductus arteriosus can be detected in most instances where the defect is of sufficient size to produce symptoms or signs. Defects in the auricular and ventricular septa offer greater difficulties in diagnosis than the other 2 lesions. The diagnostic accuracy of the method in septal defects depends upon the success with which the tip of the catheter can be placed in the stream of arterial blood flowing into the right side of the heart from the left.

The necessity of obtaining multiple samples from each chamber is apparent, and a prerequisite of successful venous catheterization in patients with congenital cardiac defects is the gathering of as much information as possible by history, physical examination, x-ray, and fluoroscopy before catheterization is performed. Although we have not as yet used the method of Robb and Steinberg (12) of visualization of the cardiac chambers and great vessels with diodrast, information derived from this procedure should serve as a valuable adjunct to venous catheterization.

Finally, the increase of knowledge of hemodynamics acquired by techniques such as this will lead to increasing ease of diagnosis by simpler methods. Since certain varieties of congenital heart disease can be relieved or cured by surgery, precise diagnosis is of such importance that all doubtful cases should be studied with all available diagnostic techniques.

SUMMARY

1. Venous catheterization has been applied as a diagnostic measure and as a method of studying the hemodynamics of various types of congenital heart disease.

2. In patent ductus arteriosus, blood in the pulmonary artery is more highly oxygenated than that in the right ventricle.

3. In interventricular septal defect, blood in the right ventricle is more highly oxygenated than that in the right auricle.

4. In the tetralogy of Fallot, pulmonary stenosis is identified by finding a higher systolic pressure in the right ventricle than in the pulmonary artery. In some instances, the catheter may be introduced through the ventricular septal defect into the aorta. Other aspects of the diagnosis are discussed.

5. Auricular septal defect may be recognized by introducing the catheter through the defect into the left auricle, or by finding arterial blood in the right auricle in cases with a left-to-right shunt.

6. The limitations and potentialities of the method are discussed.

The authors are indebted to Dr. Samuel A. Levine for his help and encouragement in this study. Patients 1, 3, and 4 were referred by him for evaluation by venous catheterization, and Dr. Paul D. White sent us patient 5.

The authors wish to express their appreciation to Miss Barbara Jacobs for her technical assistance.

A BACTERIOLOGIC STUDY OF THE FACTORS AFFECTING THE EFFICACY OF STREPTOMYCIN THERAPY OF URINARY TRACT INFECTIONS [1, 2]

By GEORGE T. HARRELL, E. GARLAND HERNDON, Jr., CHARLES M. GILLIKIN, and JERRY K. AIKAWA

(From the Department of Internal Medicine, Bowman Gray School of Medicine of Wake Forest College and the North Carolina Baptist Hospital, Winston-Salem, North Carolina)

(Received for publication December 9, 1946)

Streptomycin appears to be the most useful antibiotic available at present for the treatment of infections due to gram-negative bacilli. The absorption, distribution, and excretion of the drug following various modes of administration have been studied (1). The results of clinical trials of the drug in various types of infections have been reported (2). Treatment schedules and the influence of various factors in determining the optimum dosage of streptomycin have been investigated clinically, and the results are being reported elsewhere (3). The observation that the most common cause of therapeutic failure was the development of bacterial resistance or fastness [3] to streptomycin focused attention on the necessity for further bacteriologic studies in relation to concentrations of streptomycin. The cases of urinary tract infection afforded an opportunity for further investigation of the effect of streptomycin on bacteria.

MATERIALS AND METHODS

Bacteriologic methods

In each case an attempt was made to detect all the flora involved. Urine was collected by catheterization in all females and in many of the males; in the remainder of the males voided specimens were collected after thorough cleansing of the glans and meatus with a 1:1,000 solution of mercuric chloride. After a small amount of urine had been voided to wash out the urethra, the stream was interrupted with a sterile test tube for the collection of the specimen.

The urine was centrifuged and smears were made and stained by the Gram method. Cultures were made routinely on beef extract broth, blood agar slants or plates adjusted to a pH of 7.5., and desoxycholate plates. Individual colonies were transplanted to differential sugars for further identification. When the presence of organisms which required special bacteriologic methods was suspected, the necessary conditions of partial or complete anaerobiosis or increased carbon dioxide tension were achieved.

Therapy was usually started as soon as gram-negative bacilli were detected on a smear or culture, without awaiting complete identification. During therapy, cultures were usually made daily. One or more additional cultures were done at least 24 hours after the completion of therapy, before the patient was discharged from the hospital, and a culture was made on each follow-up visit.

In vitro *sensitivity* (*susceptibility* [4]) tests

In all cases the susceptibility of the etiologic agents to streptomycin, penicillin, and sulfadiazine was determined *in vitro* when the organisms were initially isolated. A test tube method was adopted because of its simplicity and convenience. Three milliliters of beef extract broth was placed in each tube, and the tubes were sterilized in an autoclave. Sterile aqueous stock solutions were prepared which contained respectively 2.5 mgm. of sulfadiazine, 250 units of penicillin, and 1,000 micrograms (0.001 gram) of streptomycin per ml. Three series of tubes were arranged in a rack, one series for each of the drugs. One ml. of the stock solution of the chemotherapeutic agent was mixed with the broth in the first tube of the series, and 1 ml. of this mixture was transferred to the second tube; 1 ml. of the mixture from the second tube was then transferred to the third, and so forth. In order to keep the volume constant, 1 ml. was removed from the last tube of the series and discarded. In this fashion were prepared a series of 4 tubes containing graded concentrations

[1] The streptomycin used in this study was furnished by the Committee on Chemotherapeutics and Other Agents of the National Research Council.

[2] These studies were aided by a grant from Miss Edith Pipkin and Mrs. J. B. Pipkin.

[3] Although the term resistance has been used to denote a lack of response by the organism to the drug, the possibility of confusion with resistance (immunity) of the host would suggest that another term such as insensitivity, refractoriness, fastness, or non-susceptibility should be used when referring to the bacteria. Refractoriness or fastness would imply the development of insensitivity in a previously susceptible organism. At present this is known to develop only after exposure to the drug.

[4] The term sensitivity, when applied to the response of organisms to chemotherapeutic agents, may lead to confusion with sensitivity (allergic) of the host. Perhaps susceptibility or inhibitory level is a better term.

of sulfadiazine ranging from 64 to 1 mgm. per 100 ml., another series of 4 tubes containing 64 to 1 units of penicillin per ml., and a third series of 6 tubes containing 250 to 0.3 μg. of streptomycin per ml. A control tube of broth containing no drug was added to each series.

All tubes were inoculated with approximately the same amount of the test organism; colonies were picked from solid media, or a loop of pure broth culture was transferred. The tubes were incubated for 24 hours, and then examined for bacterial growth as evidenced by turbidity. The result was usually obvious on inspection of the tubes. The lowest concentration of the drug which inhibited growth was taken as an index to the susceptibility of the organism.

The predominating organism in each case was tested; in cases of mixed infections most of the other organisms were also tested, either singly or in combination with the predominant organism. Studies were repeated at intervals during the course of therapy. The organism originally isolated was subcultured for comparison with those recovered at various intervals after the initiation of therapy. Therapy with streptomycin was not withheld pending the demonstration of sensitivity of the organism, since one object of the study was the evaluation of the *in vitro* technique as a means of predicting the efficacy of therapy. In the early stages of the study the concentrations of streptomycin in the media were occasionally varied, so that some results for concentrations of 10 and 100 μg. per ml., as well as for the standard dilutions, are reported in the tables.

Determinations of streptomycin concentrations in blood and urine

The method of Price, Nielsen, and Welch was used without modification to determine the concentration of streptomycin in serum and urine (4). Blood samples were drawn at random during the course of therapy; the blood was centrifuged and the serum used undiluted. Single voided specimens of urine, as well as 12 and 24-hour total collections, were assayed. All urine specimens were passed through a Seitz filter prior to the determination; preliminary experiments had indicated that no appreciable loss of streptomycin occurred by adsorption on the filter. Urine which was thought to contain a high concentration of streptomycin was tested in a dilution of 1:50.

The fluid to be tested was serially diluted in test tubes with a special broth adjusted to pH 7.8. In a second series of tubes the fluid of unknown streptomycin content was replaced by a solution of streptomycin containing 10 μg. per ml. To each tube in both series 1.5 ml. of a 1:100 dilution of a 12-hour growth of *Bacillus circulans* in broth was added. The tubes were incubated overnight at 37° C.; the last tube in which no growth occurred was considered the end point. The concentration of streptomycin in the test fluid was determined by comparing the end point of the first series of tubes with that of the second.

Patients

Forty-five patients received 52 courses of streptomycin for urinary tract infections due to gram-negative bacilli. Seven patients each received 2 courses of the drug. All patients were admitted to the wards of the North Carolina Baptist Hospital [5] and were treated between March and October, 1946. The youngest patient was 4 years, and the oldest, 74 years of age. In 12 instances the infection had been present 4 weeks or less; in the remaining 40, symptoms had been present for periods ranging from 1 month to 22 years. As many patients as possible were seen in the Outpatient Department at monthly intervals after discharge; the average duration of follow-up was 2½ months, and the maximum period was 6 months.

Methods and treatment

The total daily dose varied from 0.15 to 2.0 gram; the individual doses ranged from 25,000 to 333,000 μg. each and were contained in 1 to 2 ml. of sterile physiological saline [6] or water. The daily dose was divided into 6 equal doses given intramuscularly every 4 hours day and night; the usual course of therapy was 5 days, though some patients were treated for as few as 2 days and some as many as 13 days. When the patient's condition permitted, the concentration of streptomycin in the urine was raised by restricting the fluid intake in an attempt to limit the urinary output to approximately 1 liter a day.

Early in the course of the investigation no attempt was made to regulate the pH of the urine. The importance of adequate alkalinization of urine was soon demonstrated, however, by preliminary *in vitro* experiments which indicated that the effectiveness of the same concentration of streptomycin was increased 16-fold by raising the pH from 5.5 to 8.0. Thereafter, an attempt was made in all cases to increase the pH of the urine to at least 7.4. The pH of random voided samples of urine was determined with indicator paper prepared by saturating filter paper in a 0.05 per cent solution of phenol red in 70 per cent methyl alcohol; this method was found to be reasonably accurate within 0.2 of a pH unit.

RESULTS

Susceptibility of organisms

Fifty-nine strains of 8 species of organisms were isolated. A single organism was demonstrated in 44 cases; in the remaining 8 cases, the infections were mixed and were due to 2 organisms. Those organisms which were inhibited by 16 μg. or less of streptomycin per ml.—a level which can be attained in the blood—were arbitrarily considered susceptible.

---

[5] We are greatly indebted to Dr. Fred. K. Garvey, of the Department of Urology, for supervising the complete urologic study of these patients.

[6] Some evidence has been presented that saline inactivates solutions of streptomycin; water is a better diluent.

Streptococcus, non-hemolytic	1							1					
Total	59	14	12	9	5	12	1	3	1	2	20	3	17

* These concentrations were used in early experiments only. In some succeeding tables these data are grouped with those for the next higher concentration.

The concentrations of streptomycin required to inhibit the organisms originally isolated are shown in Table I. The susceptibility of different species of gram-negative bacilli and of various strains within the same species varied greatly, but most gram-negative bacilli were susceptible initially to concentrations of streptomycin which can be readily attained *in vivo*. Of the organisms most frequently isolated, strains of *Aerobacter aerogenes* were slightly more sensitive than those of *Pseudomonas aeruginosa;* strains of *Escherichia coli* were intermediate in susceptibility. In view of the levels of streptomycin which can be attained in blood or urine, the variations in susceptibility to concentrations of streptomycin below 16 μg. per ml. are of doubtful clinical importance.

The most striking bacteriologic finding in the study was the development of fastness to streptomycin in organisms previously sensitive to the drug. The results of sensitivity tests using strains of organisms obtained after the completion of streptomycin therapy are also shown in Table I. All the organisms were recovered from patients in whom treatment with streptomycin had failed, and the levels recorded represent the maximum degree of resistance observed. Further testing several months later of the available strains of organisms which had been found insensitive to more than 250 μg. of streptomycin per ml. revealed the following levels of susceptibility:

Concentration of streptomycin in μg. per ml.	2,500	10,000	>10,000
Number of strains	4	2	3

The relation of bacterial fastness to the dose or concentration of streptomycin, the duration of therapy, and other factors will be discussed further below.

Susceptibility to streptomycin of the organisms originally isolated is compared with their sensitivity to sulfadiazine and penicillin in Table II. No correlation was found; organisms resistant to sulfadiazine and penicillin were susceptible to streptomycin. A comparison of the susceptibility of the organisms to sulfadiazine and penicillin was made. Most of the organisms which were refractory to sulfadiazine were found also to be resistant to penicillin, but it should be stated that all of the patients had had an unsuccessful clinical trial with at least one of these drugs before streptomycin was administered.

Comparison of the dose of streptomycin with the concentration in blood and urine

In Figure 1 the total daily dose of streptomycin is compared with the maximum level attained in the blood. The blood levels varied widely, but in general the blood concentration was found to be proportional to the size of the dose. When the data are plotted in relation to the body weight, a much closer correlation is observed.

TABLE II

Susceptibility of organisms to streptomycin compared with that to penicillin and sulfadiazine

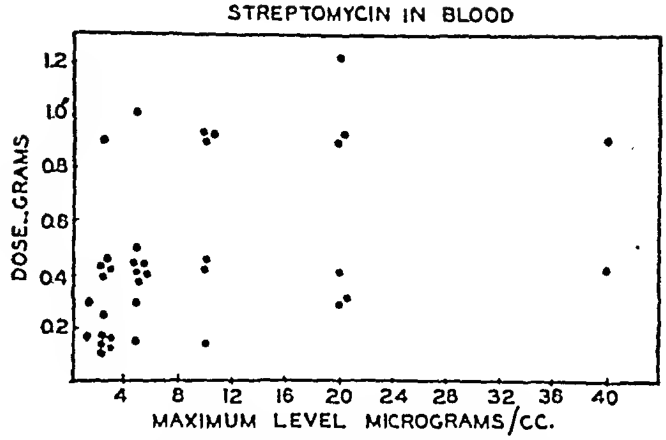

FIG. 1. COMPARISON OF THE MAXIMUM LEVEL OF STREPTOMYCIN IN THE BLOOD WITH THE TOTAL DAILY DOSE INJECTED INTRAMUSCULARLY

The maximum levels of streptomycin in the urine vary widely in relation to the total daily dose as is shown in Figure 2. The concentration in the urine was usually several times greater than that in the blood. When the maximum urinary level observed is compared with the daily dose calculated in relation to body weight, the correlation is slightly better.

Since only one of the patients exhibited marked impairment of renal function, the effect of renal

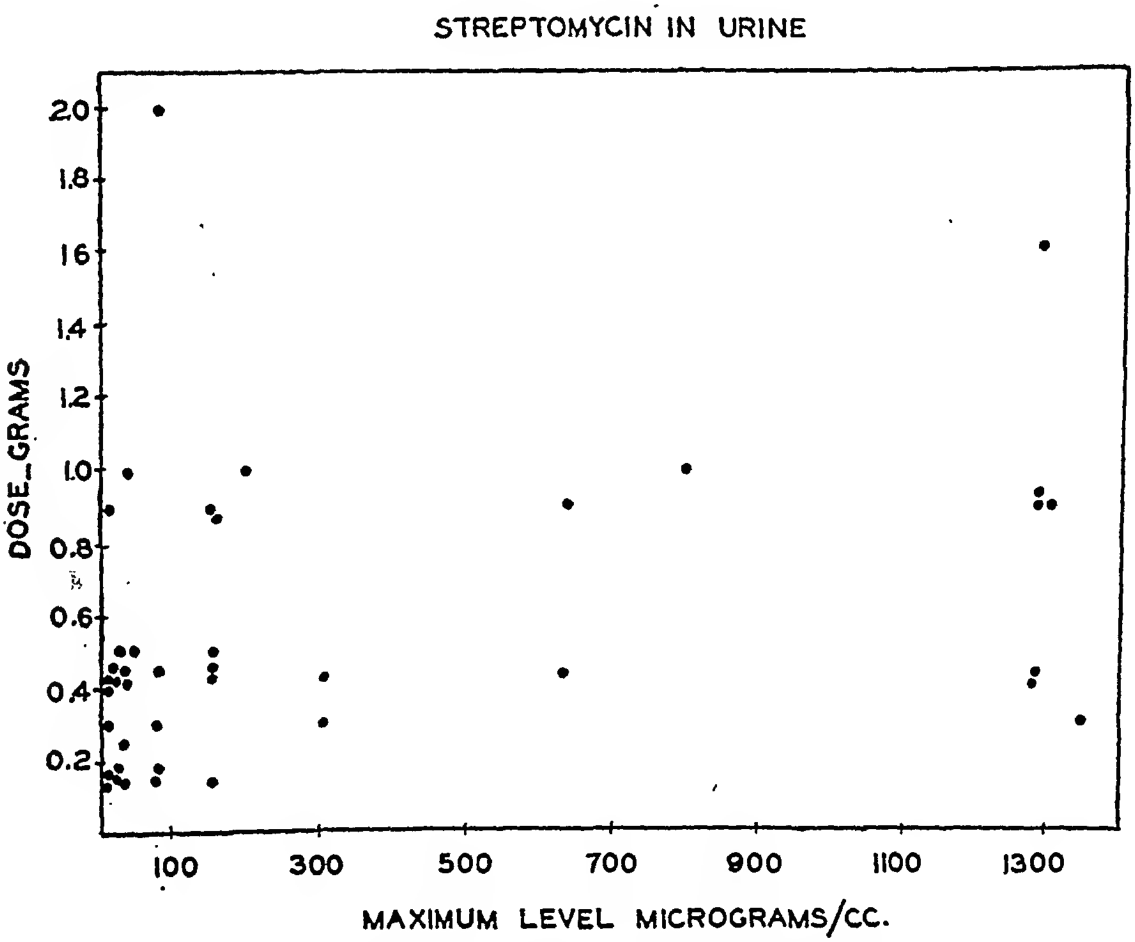

FIG. 2. COMPARISON OF THE MAXIMUM LEVEL OF STREPTOMYCIN IN THE URINE WITH THE TOTAL DAILY DOSE INJECTED INTRAMUSCULARLY

function on the concentration of streptomycin in the urine could not be determined. Alteration of the pH of the urine did not appear to increase or decrease the rate of streptomycin excretion in the few patients in whom the urinary concentration of the drug was redetermined after the administration of alkali. The greatest factor affecting the urinary concentration of the drug appeared to be the urine volume. In most cases the amount of streptomycin excreted within 24 hours in the urine fell close to the reported average of 65 per cent of the total injected daily dose (1, 5).

It appears that a minimum daily dose of 0.6 gram of streptomycin is necessary to assure a blood level of 10 µg. per ml., and that a dose of 1.5 to 2.0 grams is necessary to raise the blood level above 16 µg. per ml. With the minimum dose used (0.15 gram daily) it was possible to attain a urinary level 5 times that which inhibited susceptible organisms *in vitro*. The minimum daily dose of streptomycin required to maintain a urinary concentration above 100 µg. per ml. appeared to be 0.6 gram.

Effectiveness of therapy[7]

In 29 of the 52 infections (56 per cent), the urine became sterile before the completion of therapy.

Relation of susceptibility and streptomycin concentration to the therapeutic results. A comparison of the *initial level of susceptibility* of the organism with the maximum blood level of the drug attained indicates no correlation between these factors either in the arrested cases (Figure 3) or in the therapeutic failures (Figure 3A). In some patients infected with apparently non-susceptible organisms the urine was rendered sterile with low blood levels of streptomycin, whereas therapy failed in other cases when the maximum blood concentration exceeded many times the *in vitro* level of susceptibility of the organism.

A comparison of the initial level of sensitivity of the organism and the *maximum urinary level* of streptomycin attained reveals no correlation between these factors for either the arrested cases (Figure 4) or those in which therapy failed (Fig-

[7] Unless it is otherwise stated, the results given are based on the cultures made at discharge. The difficulty in differentiating between late relapses and reinfections is thus avoided.

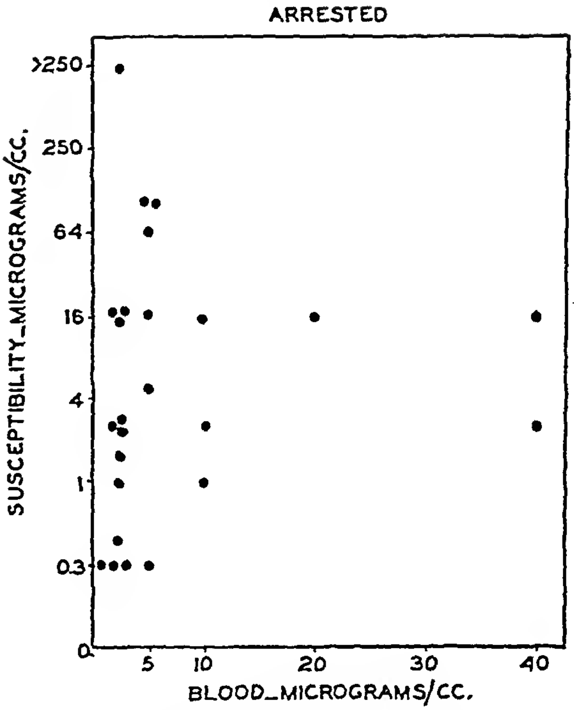

Fig. 3. Comparison of the Degree of Susceptibility to Streptomycin with the Maximum Blood Level of the Drug in the Arrested Cases

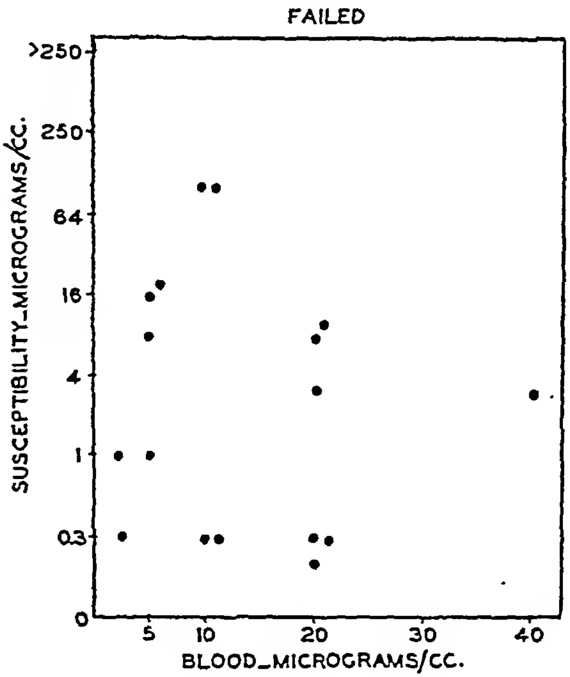

Fig. 3A. Comparison of the Degree of Susceptibility to Streptomycin with Maximum Blood Level of the Drug in the Cases Where Therapy Failed

Results of therapy in relation to duration of treatment

	Days												Total
	2	3	4	5	6	7	8	9	10	11	12	13	
Number cases	4	2	3	17	7	10		3	2		2	2	52
Arrested	4	1	2	10	5	6			1				29
Failed		1	1	7	2	4		3	1		2	2	23

ure 4A). Instances of favorable response to therapy were observed when the maximum urinary concentration did not exceed the *in vitro* level of susceptibility of the organism. On the other hand, failures were observed when the urinary concentration exceeded the *in vitro* level of sensitivity a hundred times. The greatest number of bacteriologic arrests occurred with a urinary concentration of 100 μg. per ml.; almost all the immediate cures occurred with a concentration of 200 μg. per ml. of urine.

Other factors affecting the therapeutic results. The *total daily dose of streptomycin* did not appear to affect the result of therapy as is shown in Table III. The results of therapy at discharge are compared with the *total duration of treatment* in Table IV. The effectiveness of streptomycin did not seem to be dependent upon the *duration of the infection* before the institution of therapy. Four chronic infections, 2 of which were mixed.

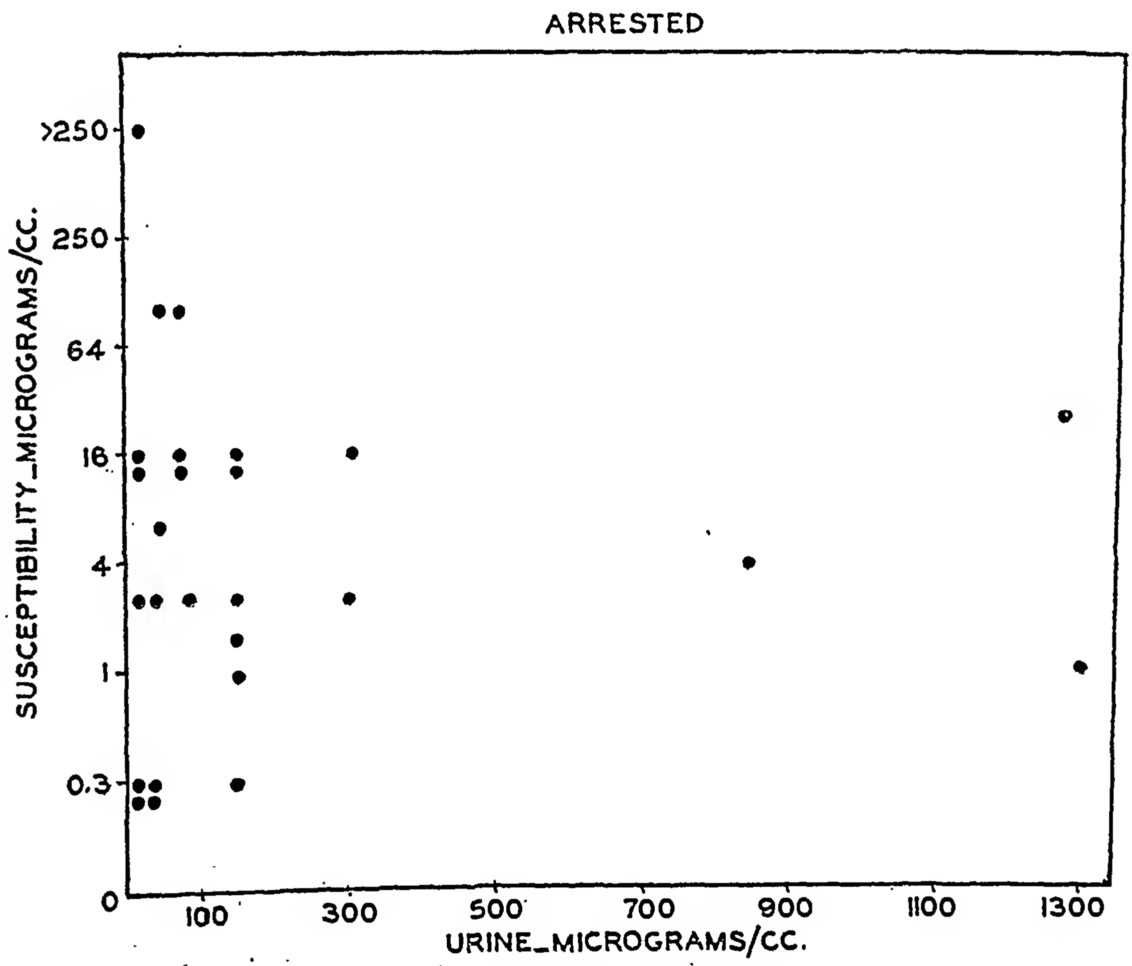

Fig. 4. Comparison of the Degree of Susceptibility to Streptomycin with the Maximum Urine Level of the Drug in Arrested Cases

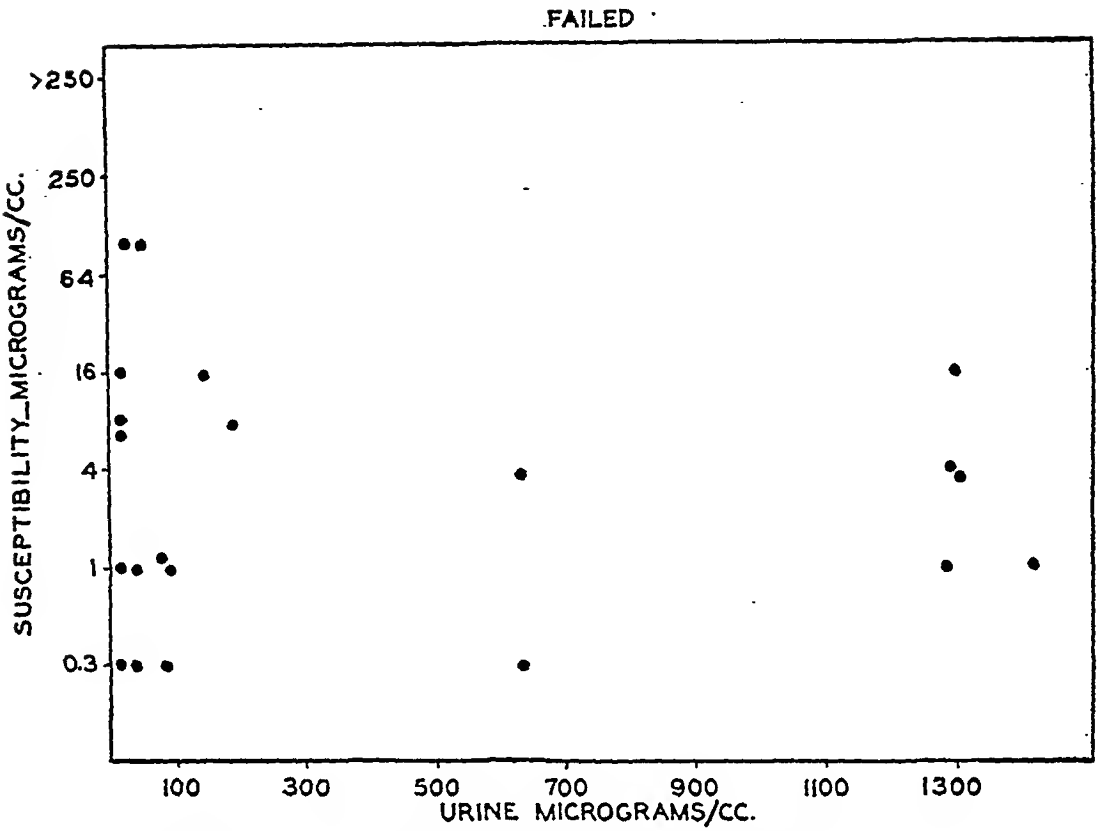

FIG. 4A. COMPARISON OF THE DEGREE OF SUSCEPTIBILITY TO STREPTOMYCIN WITH THE MAXIMUM URINE LEVEL OF THE DRUG IN CASES WHERE THERAPY FAILED

were treated for 48 hours only; the urine became sterile within 36 hours, and was sterile at discharge.

When the cases are divided into infections of the upper urinary tract (above the bladder) and those of the lower urinary tract (in and below the bladder), the *location of the infection* is seen to be of little consequence (Table V).

The effectiveness of streptomycin in sterilizing the urine did not seem to be dependent upon the *species of the etiologic agent* or its *original susceptibility* (Table VI). Of the two most commo single etiologic agents, therapy failed in 42 pe cent of the infections with *A. aerogenes* and in 5 per cent of those with *Ps. aeruginosa; A. aero genes* was slightly more susceptible in the *in vitr* test than *Ps. aeruginosa.* Because of the smal number of cases involved, the difference in re sponse is not thought to be significant. Mixed in

* Failure was due to mismanagement of therapy.

fections, including the 3 with streptococci, cleared as well as did those due to a single organism.

The effectiveness of therapy was greatly decreased by the *presence of a complication,* such as a foreign body (cystostomy tube, urethral catheter, or calculus), obstruction to the urinary flow (hydronephrosis, neurogenic bladder paralysis, or benign prostatic hypertrophy), a source of constant reinfection (prostatitis or external ureterostomy), or impaired renal function. Failures were extremely common in the presence of such complications (Table VII), and with 1 exception were accompanied by the development of drug-fastness, which is discussed further below.

Further analysis of the 23 cases in which therapy was unsuccessful revealed that in 4 cases the poor results could be at least partially attributed to *failure to alkalinize the urine;* complications were present in 2 of these cases. One patient in whom no complication was present was thought to have received an inadequate dose too intermittently, and to represent an instance of *mismanagement of therapy.* In 1 uncomplicated case the organism isolated before the institution of therapy was not susceptible *in vitro.*

Factors affecting the rapidity of bacteriologic arrest. In 28 of the 29 arrested cases the urine was sterile by the end of the third day. The rapidity with which sterilization occurred did not seem to be dependent upon the *species of bacteria.* When the data are plotted on a scatter diagram, it would appear that in general the *susceptibility* of the organism to streptomycin before therapy is inversely proportionate to the time required for

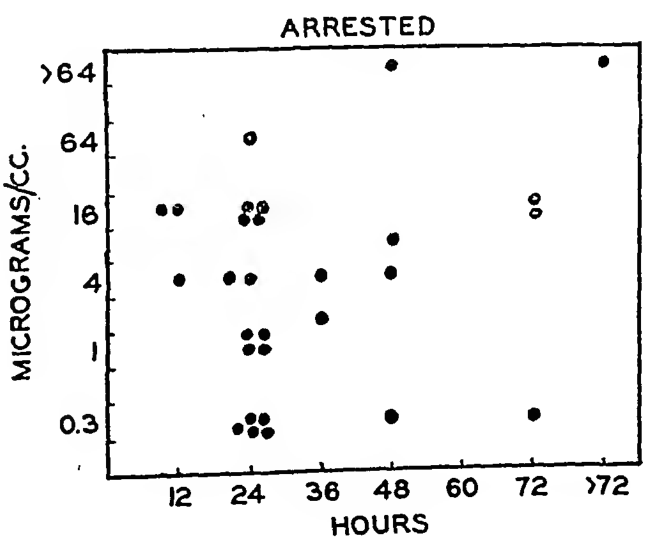

Fig. 5. Comparison of the Degree of Susceptibilty to Streptomycin with the Time Required to Sterilize the Urine in the Arrested Cases

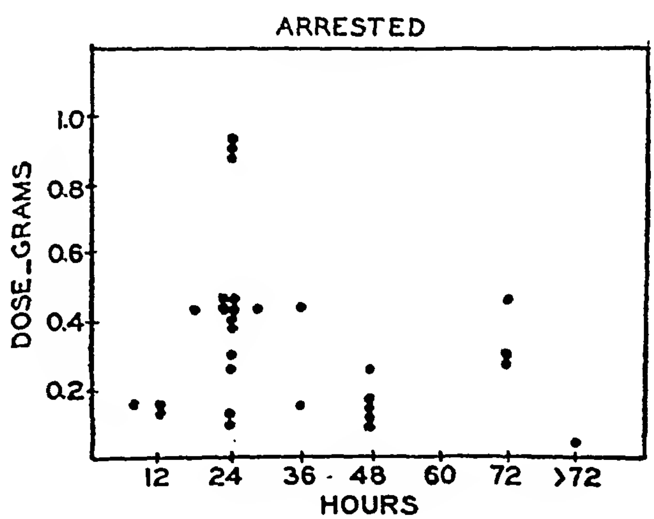

Fig. 6. Comparison of the Total Daily Dose of Streptomycin with the Time Required to Sterilize the Urine in the Arrested Cases

the urine to become sterile (Figure 5). When the *total daily dose of streptomycin* is compared with the time required to sterilize the urine, the data appear to indicate that the larger doses cleared the urine more quickly. When the data are plotted in a scatter diagram, however, the correlation between the dosage and the time at which cultures became sterile is less striking (Figure 6).

Accuracy of in vitro *test in predicting results of therapy.* The results of therapy are compared with the *in vitro* susceptibility of the organism in Table VII. The results indicate that the *in vitro* test predicted a favorable response in 24 of the 29 uncomplicated cases, and that this prediction proved to be correct in every case but one. A favorable response which would not have been anticipated occurred in 3 cases out of 5 in which the organisms were classified as non-susceptible. The 2 failures in patients without complications were attributed to mismanagement of therapy—inadequate and intermittent doses—or treatment of non-susceptible organisms. Only 2 of the patients with complications obtained a favorable response. In the remainder, with 1 exception, the organisms developed drug-fastness. The *in vitro* test would therefore appear to be useful only in cases without complications.

Follow-up studies. The majority of the patients were followed at least 1 month; the average duration of follow-up was 2½ months. Of the 29 patients whose infection was arrested at the time of discharge, 15 remained free of infection at the last follow-up examination, and 5 were found to be infected; 9 were not traced. Thus approximately ⅔ of those whose urine became sterile during therapy had sterile cultures and no pyuria when they were reexamined. In the patient with the longest history of infection (22 years), the urine was still sterile 6 months after discharge. In 3 of the 5 patients who were found to be reinfected, a different organism was cultured from the urine 3 to 8 weeks after the original infection was cleared up. Two patients whose urine became sterile under therapy were found, 5 and 8 weeks later, again to have infections with the same species of organism, which had the same susceptibility to streptomycin as the original strain; it is not known whether these cases represent reinfections or late relapses.

Fastness

The development of fastness in the organism was the most common cause of therapeutic failure observed. In 23 instances, bacilluria persisted following completion of a course of streptomycin. The prolongation of therapy did not alter the clinical results, and second courses of therapy after the organism had become fast invariably failed.

The development of fastness to streptomycin did not alter the susceptibility of the organism to other types of therapy, however. Infections with resistant organisms have cleared on subsequent therapy with mandelic acid, for instance, and have cleared without additional chemotherapy when a complicating factor—such as neurogenic bladder paralysis due to poliomyelitis—was removed.

Once an organism became fast, it remained fast. The development of refractoriness only rarely altered the cultural characteristics of the organism.

Factors affecting the development of fastness. Fastness developed much more frequently in the presence of a *complicating factor.* The fact that the organism became resistant in 3 out of 4 cases of bacteriologic failure in which the urine was not alkalinized suggested the possibility that the *pH of the urine* might have some effect on the development of fastness. Another possible explanation for failure also was present in each case, however.

The development of fastness apparently bore no relation to the *initial susceptibility of the organism* (Table VIII). Resistance developed in roughly

TABLE VIII

Initial susceptibility of organisms in relation to development of drug-fastness

	Streptomycin ($\mu g.$ *per ml.*) 0.3	1	4	16	Total
Number of organisms	14	11	10	17	52
Number developed fastness	4	5	4	5	18
Per cent developed fastness	29	46	40	30	35

30 to 45 per cent of the organisms cultured regardless of the original degree of sensitivity. In 21 of the 23 cases in which the original course of therapy was ineffective, *in vitro* tests to determine the sensitivity of the causative organism were repeated. In 1 case the organism retained its original susceptibility. In 17, it was found to be resistant to streptomycin in a concentration of at

least 250 µg. per ml. (Table I). In 3 instances the sensitivity decreased by only 1 tube in the *in vitro* test. A maximum urinary concentration of streptomycin at least 5 times as great as the original *in vitro* level of sensitivity had been obtained in all patients infected with susceptible organisms.

When the duration of therapy before the development of fastness is plotted against the initial susceptibility, it is seen that, in general, organisms which were inhibited by streptomycin in a concentration of 16 µg. per ml. became refractory earlier than organisms which were originally not inhibited by this concentration. In the majority of the cases a period of 24 to 72 hours elapsed before the organisms became fast, though, in 1 case, resistance developed in 8 hours. In several instances cultures made 10 to 24 hours after initiation of therapy were sterile, while subsequent cultures revealed resistant organisms. In only 2 instances did susceptible organisms become fast after 72 hours (Figure 7); obstruction was present in both cases, and both patients received small doses of the drug.

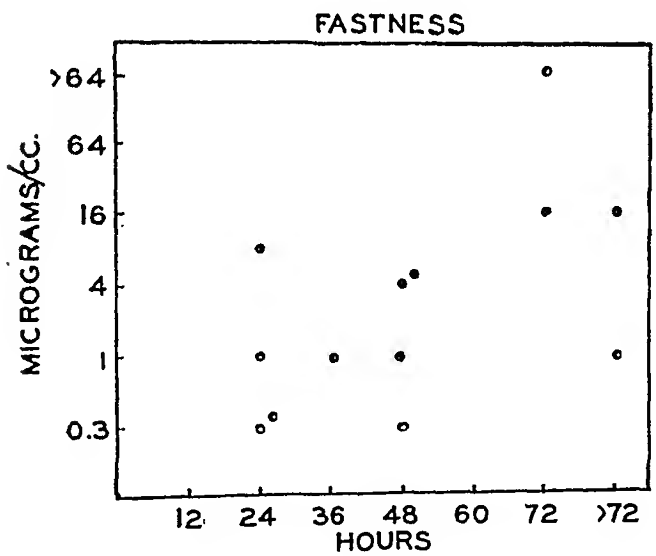

Fig. 7. Comparison of the Initial Degree of Susceptibility to Streptomycin with the Duration of Therapy before the Development of Fastness

When the duration of therapy before the development of fastness is plotted against the *total daily dose of streptomycin*, it is seen that some organisms developed resistance in 48 hours in spite of relatively large doses. On the other hand, in the patients receiving the smallest doses, fastness occasionally developed in 72 hours; one such patient was infected with a susceptible organism but also had a complication, while another was infected with an organism which was originally resistant to 16 µg. of streptomycin per ml. Small doses had been administered for 4 and 5 days to the 2 patients in whom fastness developed after the third day (Figure 8); both organisms were originally susceptible, but both patients had complications.

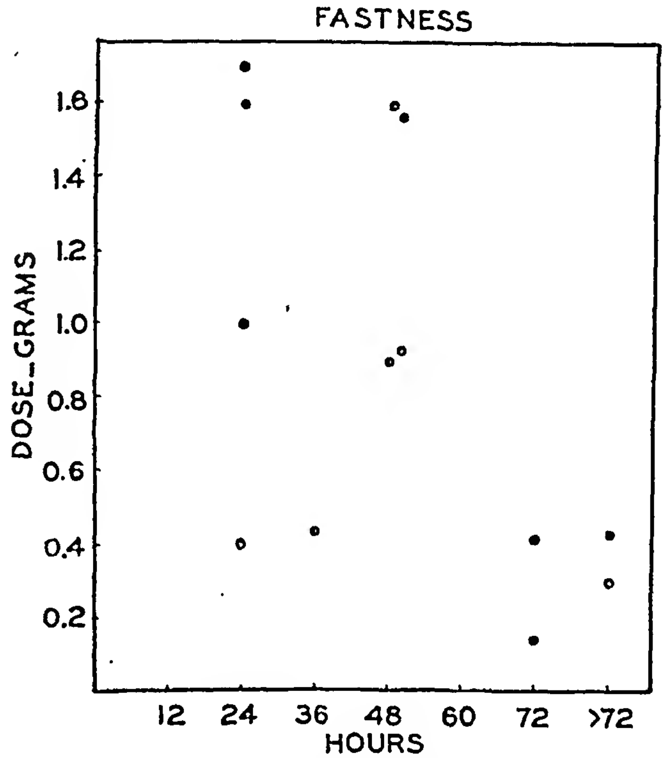

Fig. 8. Comparison of the Total Daily Dose of Streptomycin with the Duration of Therapy before the Development of Fastness

DISCUSSION

Bacteriologic methods

Most gram-negative bacilli, when isolated prior to therapy, are susceptible to streptomycin *in vitro*. The arbitrary classification of organisms into susceptible and non-susceptible strains upon the basis of the *in vitro* response to streptomycin in concentrations of 16 µg. or less per ml. is useful; this concentration can be attained in blood or urine with average doses of the drug. The fact that insensitive strains of organisms were occasionally found within the various species of organisms which are usually considered susceptible would justify preliminary *in vitro* tests in each individual case before administration of the drug.

The *in vitro* sensitivity test predicted the suc-

cess of therapy in a sufficient number of uncomplicated urinary tract infections to justify its routine use. The test was not dependable in the presence of complications, however.

Routine *in vitro* tests before therapy may conveniently be done with only 3 tubes—2 containing dilutions of streptomycin in the range of 16 μg. per ml., and another containing no drug. The organisms to be tested are introduced into one of the tubes containing streptomycin and into the tube containing no drug, which serves as a negative control; the other streptomycin-containing tube is inoculated with a susceptible organism such as *B. circulans* and serves as a positive control.

Since it is likely that increasing numbers of resistant strains of organisms will be developed, as streptomycin becomes more widely available, a dependable *in vitro* test for the detection of streptomycin-fast strains before the initiation of therapy will become an important part of the testing and identification of the organism. All organisms recovered from positive cultures after the third day of therapy should be retested for the development of fastness; if a single concentration of streptomycin is used for this purpose, it should probably be either 250 or 1,000 μg. per ml.

The finding that the sensitivity of gram-negative bacilli to streptomycin bore no relationship to their susceptibility to sulfadiazine and penicillin suggests that these drugs work through different enzyme systems of bacteria. There is a possibility that therapy with streptomycin combined with another chemotherapeutic agent might improve clinical results; further study of this question is justified.

At present there is no substance which can be added to culture media routinely to inhibit the action of streptomycin present in the body fluids of patients under therapy. The development of such a substance [8] would greatly improve the accuracy of bacteriologic methods for evaluating the effectiveness of therapy, especially in determining the time at which organisms disappear, and might aid in the earlier detection of strains developing fastness. Cultures made after therapy is begun should be incubated at least 7 days, since organisms may grow more slowly then.

[8] Hydroxylamine hydrochloride is the most promising substance in use at present.

We have no explanation for the fact that relatively few strains of Proteus were recovered from the patients in this series.

The fastness of organisms to streptomycin

Whether the development of streptomycin-fastness is due to a mutation of organisms of a single strain or to the removal of a susceptible strain inhibiting a non-susceptible strain present simultaneously cannot be stated from our data. It is known that the tolerance of cells to a toxic agent increases when they are repeatedly exposed to it. Further study from the bacteriologic point of view with the idea of potentiating the action of streptomycin in its blockage of bacterial enzyme systems, is urgently needed.

Clinically, the development of fastness in organisms is of the greatest importance. The widespread development of streptomycin-fast strains of organisms would reduce the clinical usefulness of the drug. Whether the virulence of the infecting organism is altered by the development of fastness has not been determined definitely. The early detection of resistance will prevent delay in altering therapy, thus conserving the yet small supplies of the drug, and preventing waste of money. The data suggest that the development of resistance may be avoided in some measure by the use of very vigorous therapy, from the beginning, with doses greater than the minimum ones used in this study. Infections should be hit hard when therapy is started, regardless of the duration of the infection.

Since refractoriness to streptomycin is very likely to develop in the presence of complications, and since it is a permanent characteristic of the organism once it is acquired, it might be advisable, if a complication correctable by surgical measures is present, to use other chemotherapeutic agents preoperatively and to reserve streptomycin for postoperative use. An exception should be made when the use of streptomycin might permit the performance of surgery that otherwise would not be possible.

Because of the evidence suggesting that fastness may develop in organisms highly susceptible to streptomycin if they are exposed to low concentrations for 3 to 5 days, the use of small doses of the drug to prevent reinfection in arrested cases would not seem justified and may be harmful. Reinfec-

tion is dependent on the underlying pathologic process, which is not changed by chemotherapy; late relapses or reinfections with new strains are not due to failure of the drug. Streptomycin has worked as effectively in reinfections and relapses due to susceptible organisms as in the initial infections treated; this fact leads us to suspect that the host plays no part in the development of refractoriness of the organism.

Clinical use of streptomycin

In the light of these studies it would seem justifiable at present to begin streptomycin therapy in cases of urinary tract infection as soon as gram-negative bacilli are demonstrated in smears or cultures, without awaiting complete identification of the organisms and determination of their susceptibility. As streptomycin-fast strains become more widely distributed, however, it would be wise to initiate therapy only after the determination of *in vitro* sensitivity, especially while the drug is so expensive.

From these studies it is impossible to say whether the concentration of streptomycin in the blood or that in the urine is more important. The arrest of cases of pyelonephritis would suggest that the low concentration which must be present in the glomerular filtrate and which probably is in the range of that of the blood is effective. The greater concentration of the drug in the urine below the kidney tubule is important, however; for the reduction in the number of organisms free in the urine will decrease the opportunity for reinfection of the epithelial surface of the urinary tract. It is probable that the concentration of the drug which is of the greatest importance is that in the capillaries of the kidney and the mucous membrane of the urinary tract, where immune bodies are also found.

The determination of levels of streptomycin in the blood or urine is probably not sufficiently useful to justify its use routinely. Blood and urine levels of the drug should be determined in cases which are not responding to therapy as anticipated.

The smallest daily dose used in this study (0.15 gram) was sufficient to maintain blood and urine concentrations which were found effective. Since 0.8 gram of streptomycin was required to maintain with some consistency blood and urine levels of 10 and 100 μg. per ml. respectively, this dose is suggested as the safe minimum for routine use. In view of the frequent development of fastness, however, we believe that 1.5 grams daily would be a better dose, especially in cases with complications. Therapy should be continued for 3 days. If cultures are still positive, the organism is probably fast. In a few cases cultures became negative after the third day, but this occurrence was not common. If the urine has not become sterile by the third, or certainly the fifth day, the continuation of therapy or the administration of a second course at a later time is not likely to be effective. If the culture is positive after the third day, it is probably wise to change to some other chemotherapeutic agent.

Some factor or factors other than the type of bacteria involved, the susceptibility of the organism to streptomycin, the dose of the drug administered, and the levels attained in the blood and urine are concerned in recovery; one of these factors is undoubtedly the immunity of the host. Several patients with chronic urinary tract infections were found to be hypersensitive to an intradermal test with autogenous vaccine prepared from the strain of bacteria isolated before therapy was begun.

The explanation for the decrease in pyuria and the symptomatic improvement which sometimes occurs in the presence of persistent bacilluria remains obscure. We have not been able to demonstrate decrease in motility or lysis of white blood cells in smears made on slides prepared with dried films of streptomycin in concentrations up to 1,000 μg. per ml.

SUMMARY

1. Streptomycin is the most effective antibiotic available at present for the treatment of urinary tract infections due to gram-negative bacilli.

2. The susceptibility to streptomycin of different species of gram-negative bacilli and of various strains within the same species varies greatly. *In vitro* testing for susceptibility is useful before therapy is begun and in cases where cultures remain positive after the third day.

3. Streptomycin therapy should be continued at least 3 days; if the patient has not improved after 5 days, the organism has probably become refrac-

tory and further therapy is not likely to be effective.

4. The occurrence of bacteriologic failures in this series of 52 cases could not be correlated with the susceptibility of the organism *in vitro*, the daily dose of drug, or the levels of streptomycin in blood and urine.

5. Bacteriologic failures were usually due to the presence of a complication in the urinary tract; in the presence of a complicating factor. the organism rapidly became streptomycin-fast.

6. Fastness to streptomycin develops very rapidly and to a high degree; once acquired, it is a permanent characteristic of the organism.

7. The minimum recommended dose in cases without complications is 0.8 gram daily, given in 6 equally divided intramuscular injections every 4 hours day and night; fewer failures will probably be encountered with a daily dose of 1.5 grams.

INTRODUCTION

The value of blood, as contrasted with that of plasma or of plasma products, lies chiefly in the ability of its erythrocytes to perform their oxygen-carrying function in the circulation of the recipient, the rôle of the other formed elements being considered relatively unimportant. Studies on the storage of whole blood therefore are primarily concerned with the problem of optimal preservation of erythrocytes. Improvements of preservative technique are dependent upon reliable and practical testing procedures of the post-transfusion survival of erythrocytes. While the ability of erythrocytes to survive in the circulation of the recipient, as determined by direct measurement, remains the final criterion of the value of any method of preservation, the laboriousness of the methods available created the need for preliminary testing procedures which could be applied for screening of new preservative solutions before these are submitted to definitive testing in a direct manner. Repeated attempts have been made to use physical, osmotic, and chemical properties of stored blood *in vitro* as a guide in the appraisal of preservative methods. A short review of the existing information is indicated.

Review of the literature

The occurrence of hemolysis in stored blood was noted by the earliest observers and has become the most widely used *in vitro* test of preservation of blood. The retarding effect of glucose on the appearance of hemolysis was reported by Rous and Turner (1) and has been confirmed repeatedly. High concentrations of sucrose and dextrin (2 to 4), and decrease in blood pH (2, 4 to 6), have been shown to have similar effects. Some authors have used spontaneous hemolysis as a decisive criterion of the preservation of stored blood (7 to 9), while others have stressed the variability of this criterion and have emphasized the fallaciousness of conclusions based on its use (4, 5, 10). Particularly misleading results have been obtained with bloods preserved in electrolyte-poor carbohydrate-rich media, where the observed hemolysis after prolonged storage was incongruently slight when compared with the state of the cells determined by their survival *in vivo*. Some observers have stressed the "negative" value of the test as means of excluding rather than selecting preservative solutions (4, 11).
